When the bed is reproduced with sand (Fig. 2 and Fig. 4) the scour assumes a conformation with a lesser degree of symmetry than in case of gravel (caused, for the smaller flow rate, by a greater possibility for the stream to meander through the stilling basin), characterised by two deep lateral scours. For the higher flow rate, these two lateral scours are of elliptical shape and they are however located symmetrically and downstream of the lateral edges of the stilling basin. This deep scours are practically double size of the scouring produced near the axis. The measure of the scour in the axial area is, moreover, very close to the size of the maximum scour obtained with sand and the same flow rate. In the case of experiments conducted with sand the ratio, between the longitudinal and transverse dimensions of the level curves measured experimentally, is also higher than 1 and in the area of greatest depth, for the higher flow rate, it

assumes a value equal to about 2.50. Moreover, for the tests with sand, also the ratio between maximum scour and flow rate assumes a value higher than 1 (more than 2.25). Therefore, when the size d of the granular material in the model is changed and when there are flow phenomena with highly three-dimensional characteristics, the above mentioned experimental measurements point out a remarkable lack of geometrical similarity. In actual fact, for the deep scours measured in the experiments, the stream flow was characterised by marked eddies that are thought to be associated to upward forces relative to velocity gradients and turbulent velocity components directed along the normal to the grain lying plane. Clearly, in this hydrodynamic pattern the sand can be set in motion by these actions, due to the nonuniform distribution of the velocities, before being transported downstream where it is deposited when the velocities fall below the critical value. In the model, the described sand transport mechanism seems to supply the depositing of granular material both in the most lateral area of the reproduced bed and the axial area which seems to be eroded in a lesser degree than it was expected. The experimental measurements point out that the dragging action, transmitted from the stream flow by means of eddies, creates an effect and hence a final geometric conformation of the scour that is not independent of the size d of the grains making up the mobile bed. In other words, as the diameter varies, not only the maximum depth but also the geometry of the scour is modified. This affects and determines the distribution of the field of velocity vectors and the bed equilibrium profile for the corresponding supply conditions. In fact it is possible that, for bed shear stress values τ_o close to (but lower than) the critical value τ_c of incipient motion for grains, particular conformations

of the river bed may give rise to particular orientations

of the grain layers such as to favour local grain motion

conditions and, hence, favour scour (Ghetti, 1979).

The complexity of the observed phenomenon is cer

tainly deserving of further investigation, both experi

mental and theoretical.

Indeed, considerable interest seems to lie in the

determination of the parameters regulating the scour

phenomenon in the presence of eddies such as that observed experimentally, both to understand the the ory of the phenomenon and to propose an analytical model that could be used to evaluate the entity of the scour phenomenon.

One possible initial simplified approach, taking into account the gradual diffusion of the stream flow which causes eddies (the eddies are not actually caused by an obstacle), is to consider the phenomenon linked to the ratio τ o /τ c between the bed shear stress and the critical shear stress as previously defined.

This approach would lead to the possible definition of a relationship like the one proposed in other cases by Laursen (1952):

in which the maximum scour e max divided by water depth h is a function both of the ratio b/h and of the above mentioned ratio τ o /τ c , where b is equal to the distance between the stream flow axis (where the maximum velocity is found) and the eddies.

This approach encounters an objective difficulty in determining the local values of τ , in the presence of eddies and in the presence of a mobile river bed (Carravetta et al., 1999, 2000).

Moreover, the influence of the time variable on the determination of the considered quantities should not

be forgotten.

Remember that, in the case of a fixed river bed

and for eddies caused by a narrowing represented by a

flat vertical plate laid transversally to the flow, Adami

(1970) (Adami & Da Deppo, 1974) determined the

distribution of the shear stresses on the bed.

In particular these experimental measurements

pointed to shear stress values in the eddy area that

are up to four times greater than the shear stress when

the obstacle constituted by plate is absent.

This interesting result confirms the need for a

systematic investigation of the experimental determi

nation of local stresses τ in the presence of a mobile

river bed in order to evaluate scour.

4 CONCLUSIONS

The study reported in the present paper supports the

view that localized scour phenomena such as the

type examined here, i.e. depending both on three dimensional and asymmetrical hydrodynamic patterns and also on the time variable, cannot be easily solved using numerical models, and normally have to be studied through specific physical models. The experimental measurements have confirmed the necessity, if we are to obtain a closer to prototype, albeit qualitative, geometrical conformation of the scouring phenomenon, to carry out different batteries of tests with different values for the diameter d of the granular material reproducing the mobile bed studied. This methodology must be in particular followed, in the modelling practice, if a model of simple Froude similarity is adopted in the experiments. Moreover, this procedure may mitigate the uncertainty of scour evaluation resulting from the difficulty encountered in adequately

modelling the grain size and the consistency of the material making up the actual mobile bed. Because of the experiment's three-dimensional nature, the experimental measurements point out a lack of geometrical similarity in the scour when, with all other conditions remaining the same, the size of the diameter d of the granular material making up the mobile bed in the model is changed (in particular when passing from diameters of d< 5 mm to diameters of d> 5 mm). This result cannot be derived by hydrodynamic patterns simpler than the one considered in the present paper. Moreover, as the diameter d varies, not only the maximum scour depth but also its geometry is modified. Consequently, there is a further possibility to modify the field of the velocity vectors, the bed shear stress and the bed equilibrium profile, for the corresponding supply conditions. The particular geometrical conformation of the scour measured in the experimental installation seems to be related to the formation of eddies appearing in the flow in the areas of maximum scour. Note that these eddies practically form in such a way that it can be defined as free formation (i.e. without an obstacle) as a result of the expansion of the stream flow which is characterised transversally by differences in water depth. The interesting observed phenomenon suggests the need for theoretical and experimental investigations in order to gain a more complete definition of the phenomenon and to obtain an analytical model that could be used for evaluating the size of scour. The working hypothesis to be followed calls for the main parameter to be the ratio τ o /τ c between the bed shear stress and the critical shear stress of incipient flow of the material making up the mobile bed. Finally, the complexity of the phenomenon suggested exploring an experimental working hypothesis

based on the overlapping of effects induced by eddies

and longitudinal transport.

An experimental installation is thus being prepared

so as to analyse the action of a fixed eddy on a mobile

bed, reproduced using different grain sizes, as a prelim

inary step to the following studying of more complex

installations with longitudinal transport.

Interaction between particles and water in near-wall region of particle-laden open-channel flows

I. Nezu

R. Azuma

Ph.D. Student, Dept. of Civil & Global Environmental Eng., Kyoto University, Japan

ABSTRACT: The present study focuses on the interaction between solid-particles and fluid in particle-laden open-channel flows. Turbulence measurements of both particles and fluid (water) were conducted by means of a discriminator particle-tracking velocimetry (PTV). The titanium compound polystyrene (specific density= 1.16 to 1.29, diameter= 0.39 to 1.18 mm) was used for solid-particles. In these experiments, the ratio between the particle scale and turbulence-length one was changed systematically. As the results, it was found that the particle velocity is larger than the fluid velocity in the near-wall region of $y^+ \leq 15$, whereas the former is smaller than the latter in the region of $y^+ > 15$. This relative velocity between the particles and fluid increases with an increase of the particle diameter and specific density. The sweeps of particles near the wall become much larger than the ejections of particles as the diameter and specific density are larger. These facts suggest strongly that the particle motions may inrush towards the wall and transport high momentum to fluid.

1 INTRODUCTION

Particle-laden flows have been paid attention by many researchers because it changes the flow resistance law and plays an essential role in sediment transport. The earlier studies of sediment transport have been explained empirically by changes of fluid velocity profiles and an expression of the sediment concen tration was derived from diffusion theory, e.g. see Yalin (1972). However, the simultaneous velocity of solid-particles and fluid is needed to estimate the effects of interaction between solid-particles and fluid quantitatively.

Recently, simultaneous measurements of particles and fluid in particle-laden flow have been conducted for the background mentioned above. The changes of velocity profiles were examined when the particle laden flow was compared with clear-water flow, and consequently the relative velocity between particles and fluid was revealed by some researchers, e.g., Kaftori et al. (1995), Best et al. (1997) and Muste & Patel (1997). Experiments on particle-laden flows can be classified into two groups, the inner-layer ($y/h \leq 0.2$) and outer-layer ($y/h \leq 0.2$) experiments. As for the experiment on outer-layer flow, Itakura & Kishi (1980) pointed out that the wake-strength param eter # in the log-wake law was changed by the existence of

particles. Cellino & Graf (1999) observed that the value of# increased with the particle concentration. On the contrary, Valiani (1991) reported that # decreased and a significant change was observed in the inner layer where the particle concentration is high. It has not yet reached agreement about the value of #, but the changes of this outer-layer property are considered to be influenced from the innerlayer one. On the other hand, as for on the inner-layer experiment, Kulick et al. (1994) have measured the velocities of fluid and copper particles in a vertical wind duct by a laser Doppler anemometer (LDA). They have discriminated the fluid and powder data by the difference of the amplitude of LDA burst signals in the measurement volume. Kaftori et al. (1995) have measured turbulence characteristics in an open-channel flow including polystyrene particles over the smooth bed. They tried to discriminate the particle signals from the fluid-flow signals by making use of the voltage of burst signals. Best et al. (1997) have conducted simultaneous measurements of glass beads and fluid by means of phase Doppler anemometer (PDA) in an open-channel flow, in which the same glass particles were attached on the channel bed. Muste & Patel (1997) have measured the velocities of sand-particles and fluid in open-channel flow over the movable-sand bed using

a discriminator LDV that combines LDV (or LDA)

with a unit for particle-size discrimination.

Kulick et al. (1994) and Kaftori et al. (1995)

observed no meaningful differences of velocity pro

files between the clear-water flow and particle-laden

flow. On the contrary, Best et al. (1997) and Muste &

Patel (1997) observed a downward shift of fluid

velocity profiles in particle-laden flow. The factors

of this downward shift in velocities may be due to

the bed roughness and the effect of particles. They

pointed out that the factor is only the bed roughness,

but an interaction between particles and fluid will

probably influence fluid-velocity profiles. It is because

this interaction has a close relation to the momen
tum exchange. In this mechanism, particle motions are
explained by the bursting motions of fluid in the near
wall region, e.g., Sumer & Deigaard (1981), Rashidi
et al. (1990) and Nino & Garcia (1996). However,
experimental data and knowledge about the interaction
between turbulence of the near-wall fluid and the par
ticle motions are not yet sufficient to understand and
develop the two-way models in particle-laden flows.
In this study, some experiments were conducted
in smooth bed, which was covered by no rough
ness elements. Particularly, the near-wall region was
highlighted, in which the interaction between par
ticles and fluid is most significant. The titanium
compound polystyrene (specific density= 1.16 to
1.29, diameter= 0.39 to 1.18 mm) was used for solid
particles, and the ratio between the particle scale and
the turbulence-length one was changed systematically
in keeping the latter fixed. Simultaneous measure
ments of water and these particles have been con
ducted by means of a discriminator particle-tracking
velocimetry (PTV). The particle-data and fluid-data
were separated by the discriminator of occupied-area
sizes of the particle images. The hydro-dynamic char
acteristics of both the near-wall and outer layer were

investigated intensively.

2 EXPERIMENTAL SETUP AND HYDRAULIC CONDITIONS

2.1 Experimental equipment

The experiments were conducted in a 4 m long and 5 cm wide tilting flume, as shown in Figure 1. x, y and z are the streamwise, vertical and spanwise coordinates, respectively. The present PTV/PIV system was the same as used by Nezu & Onitsuka (2001). The instantaneous velocity components and $\tilde{u}(t) \equiv U + u(t)$ and $\tilde{v}(t) \equiv V + v(t)$ were measured by PTV with a discriminator, as mentioned later. In which, the capital letter and the small letter denote the time-averaged value and turbulent fluctuations, respectively. Particles recirculated with water through the flume and the measurements were conducted one hour later from the begin of water circulation, at which the flow and particles motions attained an equilibrium state. A 2W Argon-ion laser beam was guided through an optical fiber cable and illuminated vertically from the channel bottom as a 2 mm thickness laser light sheet (LLS), see Figure 1. LLS can be adjusted by the computer controlAOM, in which the emission interval and duration were adjusted as 3–6 ms and 0.5–0.9 ms, respectively, as schematized in Figure 2. Pair of images of particles were taken by a high sensitive CCD camera (SONY), which was placed near the sidewall. Its resolution was 512× 480 pixels. The original image consists of the odd and even scanning lines and the time interval is 1/30 s (30 Hz). The images were recorded by a digital laser-disc recorder (SONY).

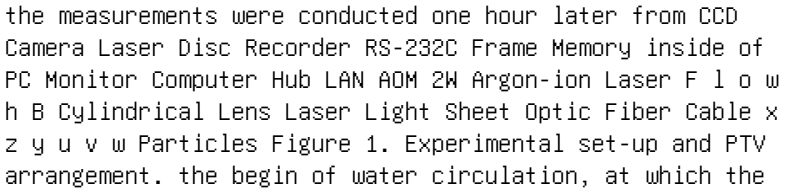

Figure 1. Experimental set-up and PTV arrangement.

2.2 Experimental conditions

The

hydraulic conditions are summarized in Table 1. In which, d p (≡d) is the median diameter of particle, ρ p is the specific density of particle, U m is the mean bulk velocity, U ∗ is the friction velocity (its evaluation method will be discussed later in section 4.3), h is the water depth, R ∗ ≡U ∗ h/ν is the Reynolds number based on U ∗ , Re≡U m h/ν is the Reynolds number based on U m , Fr≡U m / √ gh is the Froude number and C is the particle volumetric concentration averaged in the whole flow depth. The case name of PM denotes PMMA/PS (poly-methyl methacrylate/polystyrene), T denotes the titanium compound polystyrene and the figures denote the compound ratio and particlediameter. The diameter d p and specific density ρ p of particles were systematically changed, i.e., dp= 0.39 to 1.18 mm and ρ p = 1.15 to 1.29. The case of CW4 is clear-water flow. In this study, two kinds of experiments were conducted in each case, (A) and (B). For one group (A), a size of the measurement region is the whole flow depth, and for the other group (B) the near-wall region from the channel bed up to 20 mm (the close-up pictures). corresponded to 0.153 mm for A and 0.0303 mm for

B, respectively.

The water discharge Q and the flow depth h were

set almost constant throughout all of experiments.

Consequently, h= 50 mm and U m =Q/A= 42.0 to

43.3 cm/s were obtained. Thus, the turbulence scale, l,

of water fluid was the almost same in all experiments,

and in contrast the particle scale, d p , was changed in

a wide range. The effect of particle size on particle–

fluid interaction will be revealed because the value of

d p /l is a significant factor in turbulence modulation

mechanism, as pointed out by Gore & Growe (1989).

In the (B) group, the mutual interaction between parti

cles and fluid was investigated in detail as a parameter

of the wall unit, i.e., ν/U ∗ , in which superscript symbol

“+” is used here. In contrast, the diameter and density of seeding particles (Nylon 12) for water fluid are 0.1 mm and 1.02, respectively; we call the fluid tracer. The test section was located 3 m downstream of the channel entrance.

The measuring time of PTV was 60 s (1800 frames). These methods are the almost same as used by Nezu & Onitsuka (2001). 3 CALCULATION METHOD OF FLUID AND PARTICLES VELOCITY 3.1 Discrimination of fluid and particle data Any discrimination between particle and fluid on a snapshot image of CCD camera has firstly to be

developed for simultaneous measurements. There are

some methods, for example, (1) particle-color dis

crimination (discriminated by color of particles) and

(2) particle-area discrimination (discriminated by the

occupied area of particles).

Figure 2 shows an example of the raw image and

processing images of solid-particles and fluid tracer.

The raw image consists of the odd and even scanning

lines. First of all, the brightness of raw image was

adjusted most suitably, and separated into the odd and

even fields. The separated images were binarized then

and discriminated by using a threshold value of the

occupied area of particles.

For this occupied-area discrimination, it is impor

tant to set a resolution of CCD camera reasonably. In

this study, the length of 1 pixel in the CCD image cor

responded to 0.102 mm for (A) group and 0.040 mm

for (B) group. The occupied area of the minimum dia

meter 0.39 mm (case T1004) was larger than 15 pixels,

while that of fluid tracer was 1 pixel. Therefore, it was

easy to discriminate automatically the solid-particles

and fluid. This occupied-area discrimination method

was applied reasonably to all cases of the present experiments.

3.2 Calculation algorithm

Nezu et al. (1999) have conducted PTV measurements of sand particles over a gravel bed by making use of the 4-fields-image algorithm, which is one of the most popular methods in PTV. However, it was very diffi cult to track sand-particle motions near the bed by the earlier PTV algorithm using four consecutive images, because these motions were quite complicated, i.e., the dropping sand particles are sometimes reflected on the channel and lifted upward again. In contrast, Okamoto et al. (1995) have developed a 2-fields-image algo rithm, based on the pattern matching of the particle cluster between two consecutive images using invisible elastic springs; they called the “spring model”.

The spring model PTV is very powerful for flow fields including even the appearing and disappearing particles in images. Nezu et al. (2001) have tried to apply the spring model PTV to a sediment-laden open channel flow and concluded that this model is very reliable even in such an open-channel flow. Therefore, this algorithm was also adopted in this study.

4 RESULTS AND DISCUSSIONS

4.1 Clear water flow

Figure 3 shows the mean velocity profiles of clear

water flow (CW4), which is almost same hydraulic

condition as particle-laden flows (Table 1). The sym

bols (PTV) and (LDA) in Figure 3 indicate the results

by PTV and LDA, respectively. The PTV data are 0 5 10 15 20 25 30 1 10 10 2 10 3 U ∗ U f CW4(PTV) CW4(LDA) U f + y + van Driest curve AU f + ln(y +)+ 1 y ≡ yU ∗ ν Figure 3. Streamwise velocity profiles of clear-water. shifted 5 units in the vertical axis to avoid confusions. Three theoretical curves are included in Figure 3. in which, U + ≡U/U ∗ and y + ≡ yU ∗ /v are the inner parameters normalized by the inner variables of the friction velocity, U ∗ , and the kinetic viscosity, v. Equation (1) is the theoretical formula in the viscous sublayer of y + ≤ 5, whereas (3) is the log-law that is satisfied in the region of y + ≥ 30, in which κ is the von Karman constant and A is the integration constant. No analytical solution is available in the buffer layer of 5< y + < 30, but a numerical curve is obtained from (2) by using the van Driest damping function; we call the “van Driest curve”. in which, + is the normalized mixing length and R ∗ ≡ hU ∗ /v is the Reynolds number based on the friction velocity. Nezu & Nakagawa (1993) have reviewed that the von Karman constant, κ, is really a universal one of κ= 0.41 over smooth and rough beds in open-channel flows of clear water. The maximum velocity is observed at y/h= 0.6 and such a velocity-dip occurs due to secondary currents, because the aspect ratio, B/h, is as small as 1 in this experiment, as pointed out by Nezu & Nakagawa (1993). These secondary currents would cause a

downward flow at the center of channel. The reason

why such a small aspect ratio of channel was adopted

here is the optical limitation in PTV measurements

of comparatively dense particle concentration flow, in

spite of occurrence of secondary currents. However

fortunately, both of LDA and PTV data are in a good

agreement with the theoretical curves of (1)-(3) from

the viscous sublayer to the log-law layer of y/h≤ 0.2.

The friction velocity, U ∗ , was evaluated from the theo

retical formula of (1), and then the Karman constant, κ,

was calculated from (3). Consequently, κ= 0.41 was

obtained and this result coincides perfectly with that

of Nezu & Rodi (1986).

Figure 4 shows the Reynolds stress,- uv/U 2 ∗ , mea

sured with the present PTV and LDA. The theoretical

curves of (5) and (6) are included in Figure 4.

The measured values of-uv deviate significantly from

(6) in the outer layer of y/h> 0.2 and indicate negative

values near the free surface.This deviation is caused by

secondary currents, as discussed by Nezu & Nakagawa

(1993). However, both of LDA and PTV data are in a

good agreement with the theoretical curve of (5) in

the inner layer of y/h< 0.2. Therefore, it is considered

that the inner layer does not affected by secondary

currents and we can highlight this near-wall region in

the present study. It should also be noticed the friction

velocity, U ∗ , evaluated from (1) in the viscous sublayer

coincides well with that evaluated from the Reynolds

stress distribution of (6).

4.2 Classification of multiphase flows

Elgobashi (1994) has classified multiphase flows on

the basis of Stokes number St and the volumetric parti

cle concentration, C. The Stokes number is defined as

St≡ t p /t e , in which t p ≡ ρ p d 2 p /(18ρ f ν) is the particle

relaxation time, t e ≡ l/u ′ is the eddy turnover time of

fluid and u ′ is its turbulence intensity. The eddy char

acteristic length-scale l was approximately identified

as a mixing length and evaluated from (4).

Figure 5 shows the vertical profiles of the volumet

ric particle concentration, C. The Rouse formula of (7)

is indicated in Figure 5.

in which, w s is the settling velocity of particles, h p is the

thickness of suspended layer and C a is the particle con

centration at y= 0.05h p . The value of β was chosen in

order that the curve of (7) coincides with the measured

present data of C. In all cases, the vertical profiles of C 0 0.5 1.5 0.0 0.2 0.4 0.6 1.0 CW4(PTV) CW4(LDA) U ∗ 2 -u f v f h y U ∗ 2 -u f v f =11.0 h y 1.0 Outer layer inner layer dy + dU + h y U ∗ 2 -u f v f 1= □ □ □ □ Figure 4. Vertical profiles of particle concentration. were expressed satisfactorily by the Rouse formula of (7). However, the value of β was much larger than 1.0. Therefore, the particle motions may show the bed-load rather than the suspended ones, because the particle layer, h p , did not reach the water surface. According to Elgobashi (1994), a diagram of St vs. C is shown in Figure 6. The turbulence in the region of St > 1 is enhanced by solid particles, whereas it is depressed by particles in the region of St < 1. The Stokes number St in particle-laden open-channel flow increases with an increase of the particle concentration C and it is larger than the unity near the bed, i.e., t p > t e . This fact suggests strongly that the turbulence

generated by particles is larger than that of clear water flow very near the wall. On the contrary, the turbulence will be depressed due to the existence of particles in the outer layer. 10 -3 10 -1 10 10 3 10 -6 10 -4 10 -2 1 C

laden open-channel flows.

4.3 Evaluation of friction velocity

It is difficult to evaluate the friction velocity, U_*, from

the log-law of (3) in particle-laden open-channel flows,

because the von Karman constant, κ, in such flows

is not perfectly established even now. Guo & Julien

(2001) have reviewed previous data of velocity pro

files in sediment-laden open-channel flows that were

obtained by intrusive (conventional) velocity measure

ments such as Pitot tubes. They suggested that the von

Karman constant κ, decreased with an increase of the

sediment concentration, especially in dense suspended

sediment-laden flows. In contrast, Muste (2002)

has recently reviewed the sources of bias errors in

sediment-laden flow data and pointed out that the von

Karman constant remains a universal one of κ= 0.41

even in dilute sediment-laden flows on the basis of

non-intrusive measurements such as LDA and PDA. 0 10 20 15 25 1 10 10 2 10 3 0 5 U ∗ U f U f + =y + T1012 T2009 T1005 T1004 LDA (CW4,Clear-water) CW4 1.18 T2009 T1004 Case 0.39 T1005 ρ p d (mm) T1012 0.46 0.85 1.16 1.16 1.16 1.29 : Best et al.(1997) d=0.22mm ρ p =2.60 : Kaftoriet al.(1995) clear water : Present data yU ∗ U ∗ U f 1 ln κ v + A = y + yU ∗ v ≡ Figure 8. Mean velocity profiles of fluid in two-phase particle-laden open-channel flows. Figure 7 shows the measured values of Reynolds stress of fluid, − u f v f , in particle-laden open-channel flows. These values coincide well with the theoretical curve of (5) in the inner layer of y/h< 0.2. Therefore, in this study, the friction velocity, U ∗ , was determined by an extrapolation of the measured Reynolds stress, − u f v f , to y= 0, i.e., using (6). This evaluation method was also used by Lyn (1991), Kaftori et al. (1995), Muste & Patel (1997) and Best et al. (1997). The values of U ∗ evaluated from −u f v f distributions are indicated in Table 1, together with the values of κ evaluated then from (3) using these values of U ∗ . The friction velocity increases in the existence of particles and increases with particle diameter and specific density. It is also observed that the von Karman constant decreases slightly with particle diameter, d p , specific density, ρ p , and mean concentration, C. 4.4 Mean velocity profiles of fluid and particles Figure 8 shows the mean velocity profiles of fluid, U f , in two-phase open channel flows. Each case is shifted by 5 units in the vertical direction. Our LDA data of clear water, LDA data of Kaftori et al. (1995) and PDA data of Best et al. (1997) are also shown in Figure 8. These profiles of U + f =U f /U ∗ agreed well with clear-water LDA data except for the buffer layer of y + < 30. Best et al. (1997) and Muste & Patel (1997) pointed out that the velocity profiles of fluid, U + f , in sediment-laden flows showed a downward shift as compared

with the clear water flow. However, this downward shift was not observed in this study, because the present flow condition was no roughness elements covered on the bed, as mentioned in Figure 2. Of particular significance is that the velocity of U^+_f in the

region of $y^+ \leq 10$ for particle-laden flow is larger and

flatter than that for clear-water flow.

Figure 9 shows the mean velocity profiles of parti

cles, U_p . The particle velocity, U_p , is slightly smaller

than the fluid velocity, U_f , and parallel to the log-law

line of fluid in the region of $y^+ > 30$ in all cases. The

same results were obtained by Rashidi et al. (1990),

Kaftori et al. (1995) and Nino & Garcia (1996). In

contrast, the particle velocity near the wall is larger

than the clear-water one, which was also observed

by Kaftori et al. (1995). These particles will trans

port the high-momentum to the surrounding fluid and

make it high velocity. As a result, the fluid velocity

is larger than the clear-water one, and thus the flatter

distribution was observed these in this study.

4.5 Relative velocity

Differences between fluid and particle velocities are

not so clearly recognized in the plots of Figures 8 and

9.Therefore, the relative velocity between the particles

and fluid phases, $U_r \equiv U_f - U_p$, is examined in the

following ways.

4.5.1 Effect of particle density

Figure 10 shows the relative velocity, U r ≡U f − U p ,

together with the results of Kaftori et al. (1995)

and Best et al. (1997). In this figure, the particle

scale (particle diameter, d ≡ p) keeps almost constant

(d = 0.8 and 0.85 mm), and the particle density, ρ p ,

was changed from 1.05 to 1.29. The relative velocity,

U r , is positive farther from the wall (y + > 15), i.e., the

fluid velocity, U f , is larger than the particle velocity,

U p . In the outer layer of y + ≤ 200, the values of U r

are small and constant in all cases. They also coincide

open-channel flows. well with the data of Best et al. (1997) who used the glass particles of ρ p = 2.6 and measured the U r in the region of y + > 150. Therefore, the effect of particle density, ρ p , on the relative velocity is not recognized significantly in the outer layer. This is because that the particle relaxation time t p is much smaller than the eddy turnover time t e (St << 1) and thus

the particles can follow the fluid sensitively. In contrast, the relative velocity is negative in the near-wall region of y + ≤ 15, that is, U p >U f , which coincide well with the data of Kaftori et al. (1995). In a comparison of case T2009 (ρ p = 1.29) and PS08 (ρ p = 1.05), the relative velocity increases slightly with an increase of the particle density, ρ p . The particles moving toward the wall have a grain inertia and high momentum when they inrush into the near-wall region. In contrast, the fluid velocity is depressed by the viscous effect. Consequently, the particle velocity, U p , is larger than the fluid one, U f , and the particles will transport some momentum to fluid in the near-wall region.This momentum transfer to fluid increases with the particle density and induces the flatter distributions of fluid velocity, U f , near the wall. 4.5.2 Effect of particle diameter Figure 11 shows the relative velocity, U r , in which the particle density, ρ p , keeps constant (ρ p = 1.16) and the particle diameter, d p , change from 0.39 mm to 1.18 mm. The particle velocity, U p , is smaller than the fluid velocity, U f , in the region of y + ≥ 15, whereas the former is larger than the latter in the near-wall region (y + < 15). It should be noted that the effect of particle diameter on the relative velocity, U r , is recognized clearly. That is to say, the value of U r increases with an increase of particle diameter, d p . This is because the particle relaxation time, t p ∝ d 2 p , becomes much larger as d p increases. 4.6 Quadrant Reynolds stress and bursting motions

4.6.1 Quadrant theory

In the previous section, the particle velocity, U p ,

becomes larger than the fluid velocity, U f , very near

the wall due to both the high momentum of particles

and the viscous effect of fluid. Momentum transfer

of turbulence in smooth-wall boundary layer is iden

tified as bursting motions of fluid. These motions

are analyzed successfully by a quadrant theory of the

instantaneous Reynolds stress -u(t)v(t), as pointed

out by Nakagawa & Nezu (1977). The 1st quad

rant motion is the outward interaction (u> 0, v> 0),

whereas the 3rd quadrant is the inward interaction

(u< 0, v< 0). The 2nd quadrant (u< 0, v> 0) motion

transports the low momentum (ρu< 0) to the upward

region (v> 0) that is called the “ejection”, whereas the

4th quadrant (u> 0, v< 0) transports the high momen

tum (ρ u > 0) to the downward region (v< 0) that is

called the “sweep”. It is well known that the ejections

and sweeps are significantly contributory to burst

ing motions. The contributions of ejections RS2 and

sweeps RS4 of fluid motions are defined as follows:

in which, the function S(t) is given by 0.5 1.0 1.5 1 10 10 2 10 3 0.5 1.0 1.5 2.0 Particle-phase Fluid-phase :Clear-water (CW4) d (mm) Case p p T1009 T1509 T2009 PM08 1.16 1.23 1.29 1.15 1.05 0.85 0.80 0.85 0.85 0.80 PS08 y + yU ∗ v ≡ y + =15 (RS) p (RS4) p (RS2) f (RS4) f Figure 12. Relation between ejections and sweeps of fluid and particle motions (Effect of particle specific density, p p). The threshold value H is usually set as H = 1 in order to distinguish the bursting events from non-coherent ejection-like and sweep-like turbulence in clear-water flows. So, this study also chosen H = 1. In the same manner, this quadrant theory is now applied to the particle motions in two-phase flow. The contributions of ejections and sweeps of particle motions are defined as (RS2) p and (RS4) p , respectively. 4.6.2 Effect of particle density Figure 12 shows the ratio of sweeps to ejections, RS4/RS2, for fluid and particle motions, in which only the particle density, p p , was changed. In the case of clear-water, CW4, the value of RS4/RS2 is almost constant of 0.8–0.9 in the inner layer of 15< y + < 200, and these ratios of fluid phase in particle-laden flow are similar to that of clear-water flow. In the region of y + < 10, the contribution of sweeps is larger than that of ejection, (RS4) f > (RS2) f , and these ratios of fluid in particle-laden flow were smaller than that of clear-water flow. It may be supposed that the bursting motions of fluid is restrained by an existence of particles. On the other hand, as for the particle phase in particle-laden flow, the profiles are similar to those of fluid phase and thus the particle motions are controlled by motions of surrounding fluid. In the near-wall region of y + < 50, (RS4) p /(RS2) p is larger than the unity irrespective of particle density. It should be noted that the ratio of sweeps to ejections of particles becomes larger than that of fluid in the region of 10< y + < 100, in which bursting motions occur most violently, e.g., see Nezu & Nakagawa (1993). Figure 13 shows the distributions of (RS4) p /(RS4) f and (RS2) p /(RS2) f . In the region of 15< y + < 200, 0.5 1.0 1.5 2.0 1 10 10 2 10 3 1.0 1.5 2.0 (RS4) f

(RS4) p

(RS2) f

(RS2) p RS4(sweep) RS2(ejection) 2.5 d (mm) Case p p T1009 T1509 T2009 PM08 1.16 1.23 1.29 1.15 1.05 0.85 0.80 0.85 0.85 0.80 PS08 y + yU ∗ v ≡ y + =15

Figure 13. Relation between contributions of particles and

fluid (Effect of particle specific density, ρ p).

the ratio (RS2) p /(RS2) f of ejections is smaller than the unity and thus the ejection contribution of fluid is larger than that of particles. In contrast, the ratio (RS4) p /(RS4) f of sweeps is larger than the unity in all regions, namely the sweep contribution of parti cles is larger than that of fluid. The difference between the particle and fluid motions are much remarkable in the region of y + < 15 and especially the sweeps of particle motions is much larger than those of the surrounding fluid. The particles having high momen tum rush into the near-wall region and some of these particles may rebound from the wall like ejections. The sweeps of particles become larger as the particle density increases.This is due to the grain inertia effect.

4.6.3 Effect of particle diameter

Figure 14 shows the ratio RS4/RS2 of fluid and par ticles, in which only the particle diameter, d p , was changed widely.The distributions of (RS4) f /(RS2) f are in a good agreement with Figure 12, which implies that the fluid motions are not so significantly affected by particle sizes. In contrast, the distributions of (RS4) p /(RS2) p changes systematically with the diam eter, d p . The ratio (RS4) p /(RS2) p of particles increases

with an increase of the particle diameter, i.e., the grain inertia effect. Particles are lifted up by the ejections of fluid and accelerated in the upper region of high velocity. These particles having high-momentum fall down due to gravity into the near-wall region and con sequently the contribution of particle sweep motions is most predominant with the particle diameter.

Figure 15 shows the ratio between the contributions of particles and fluid, in which only the particle diam eter was changed. The contribution of particle sweeps 0.5 1.0 1.5 1 10 10 2 10 3 0.5 1.0 1.5 2.0 Particle-phase Fluid-phase :Clear-water (CW4) Case ρ p T1004 1.16 T1005 T1006 T1007 T1009 T1012 1.16 1.16 1.16 1.16 1.16 0.39 0.46 0.85 0.55 0.65 1.18 d (mm) y + yU ∗ v ≡ y + =15 (RS) p (RS4) p (RS2) f (RS4) f Figure 14. Relation between contributions of particles and fluid (Effect of particle diameter, d p). is larger than that of fluid, and this property becomes more significant with an increase of particle diameter. 5 CONCLUSIONS Simultaneous measurements of both particles and fluid (water) were conducted in particle-laden openchannel flows by means of PTV. Particles and fluid were discriminated by the occupied area size of particle images on CCD camera. The mean velocity and the bursting motions of particles and fluid were examined by changing the particle diameter and specific-density systematically. The main findings obtained in this study are as follow:

(1) Above the near-wall region of y + > 15, the particle mean velocity, U p , is smaller than the fluid mean

velocity, U_f, and this relative velocity increases with the particle diameter and specific density. This is because the inertia force increases with the particle diameter and specific density.

(2) In the near-wall region of $y^+ \leq 15$, the particle mean velocity, U_p, is larger than the fluid mean velocity, U_f. This may be because the fluid velocity is decelerated by viscous effect near the wall, while the particles inrush toward the wall with high-momentum.

(3) Interactions between particles and fluid were examined by the quadrant analysis. The difference between particles and fluid interactions was observed in the near-wall region where the contribution of sweeps is larger than that of ejections. This contribution of particles increases with the particle diameter and specific density. The sweeps of particles are much larger than those of fluid, and in turn the particles contribute to a uniformity of velocity gradient near the wall.

The existence of particles has a significant influence on flow field of the near-wall region as well as that of the outer layer. The near-wall region is very important to consider the interaction mechanism between turbulence and particles and this study

will offer a meaningful perspective of particle-laden open-channel flows.

Development of a new Marker-in-Cell hydraulic and sediment transport

model for braided river flow

ABSTRACT: This paper presents a new Marker-in-Cell hydraulic and sediment transport model. This model

simulates fluid flow and sediment transport in the horizontal plane and depth, logarithmic velocity profile and

deposits in the vertical plane. Non-uniform total-load sediment transport by size class is simulated by using

a non-equilibrium approach, taking into account hiding and exposure effects among different size classes. To

represent historical erosion and deposition, the bed is divided into a surface or active layer and a subsurface layer.

The model is being applied to a reach of the braided South Saskatchewan River, Saskatchewan, Canada to

examine small-scale spatial and temporal processes. This reach has been affected by the 1967 closure of Gardiner

Dam 30 km upstream, which causes the river to be significantly below sediment transport capacity for much of

the time. However, analyses suggest minimal channel adjustments downstream of around 13 km of the dam. Bed

adjustment must therefore be simulated utilizing a non-equilibrium approach.

1 INTRODUCTION

1.1 Modeling braided rivers

Combining the definitions of Lane (1957) and Leopold

& Wolman (1957), a braided river is one that “flows

in two or more anastomosing channels around allu

vial islands” (Leopold & Wolman 1957), forming a

pattern resembling “the intertwining effect of a braid

when viewed from above” (Lane 1957). On observa

tion, braided rivers appear to exhibit chaotic hydraulic

and sedimentologic interactions (but see the work of

Foufoula-Georgiou & Sapozhnikov 2001), linked to complex patterns of flow convergence and divergence related to the form-process feedback associated with bar formation and migration. Classically, braiding has been associated with a combination of factors such as high slope, abundant bedload, coarse grain size, and flashy discharge (e.g. Leopold & Wolman 1957, Schumm & Khan 1972, Fredsoe 1978, Schumm et al. 1987). In contrast to these findings, Paola (2001) stated that “Braiding is the fundamental instability of streams flowing in noncohesive material”. Channels formed in material of little or no cohesion or vegetative stabil

ity (to restrict channel widening) tend to braid. Those with cohesive banks and/or vegetation become progressively more sinuous or anastomosed (Smith & Smith 1980, Nanson & Knighton 1996), especially if there is some base-level control. Within sandy flume channels, meandering is merely a dynamic phase of channel adjustment. Once the thalweg becomes mildly sinuous, the flow cuts across emergent point bars forming incomplete chute cutoffs (e.g. Friedkin 1945, Schumm & Khan 1972, Schumm et al. 1987). The task of successfully modeling the behavior of braided rivers is therefore a difficult one. Many previous authors have addressed the issue by applying a range of modeling solutions, the dimensionality of which has been controlled largely by the scale at which the model was to be applied. Contingent upon limitations imposed by computing power (Nicholas 2003) and a lack of integrated field and laboratory datasets at a suitable resolution (Lane & Richards 2001), approaches range in complexity in relation to the spatial and temporal scales to which they are applied. For example, at the scale of individual braid bars or confluence units, two-dimensional depth-averaged and fully three-dimensional hydraulic models have been used to simulate flow patterns (e.g. Lane & Richards 1998, Bradbrook et al. 1999, Lane et al. 1999, Nicholas

& Sambrook Smith 1999). At the braidplain scale, one-dimensional models of section-averaged flow and bedload transport (e.g. Paola 1996, Nicholas 2000), simplified two-dimensional cellular automata models (e.g. Murray & Paola 1994, Thomas & Nicholas 2002) and, recently, two-dimensional models have been applied (e.g. McArdell & Faeh 2001, Nicholas 2003). However, despite recent advances, numerical modeling has contributed surprisingly little to our understanding of the hydraulics and sedimentology of braided rivers.

1.2 The Marker-in-Cell method

Given the apparent dichotomy between the need for three-dimensional models and the associated computational and data limitations, one novel solution to the problem is the Marker (or Particle)-in-Cell method (Tetzlaff & Harbaugh 1989). This method was originally developed at the Los Alamos laboratory for use in particle physics (e.g. Harlow 1964), but was adapted to fluvial hydraulics during the 1980s by John Harbaugh and his graduate students at Stanford University (e.g. Tetzlaff & Harbaugh 1989). The Marker-in-Cell method can be considered to combine the best aspects of classical Lagrangian and Eulerian methods (Tetzlaff & Harbaugh 1989). Lagrangian units that

characterize the properties of the fluid (e.g. velocity and sediment load) are tracked through an Eulerian mesh that characterizes the field variables (e.g. depth and bed elevation). As units accelerate and decelerate due to interactions with each other and topography, erosion and deposition are induced. Table 1 reviews the advantages and disadvantages of the approach.

The Marker-in-Cell method has been utilized in the SEDSIM family of models (e.g. Tetzlaff & Harbaugh 1989, Koltermann & Gorelick 1992, Wendebourg 1994, Chin 1997, Tuttle & Wendebourg 1999, Tetzlaff & Priddy 2001, Griffiths et al. 2001). However,

Table 1. Advantages and disadvantages of the Marker-in-Cell approach as compared to traditional Eulerian and Lagrangian approaches.

Advantages	Disadvantages
Handles flow-field distortion	Computationally demanding
Fluid elements help resolve sub-grid scale features	Within a large region of flow there must be no small region for which detailed resolution is required
Relatively simple to deal with 2+ dimensions (fluid flow in 2-D, plus depth, velocity profile and deposits)	It must be not be necessary to know in detail the fluid logarithmic variables at Eulerian grid boundaries at any given instant of time
Handles material interfaces	the applicability of early versions of SEDSIM was largely limited by flow and sediment

continuity problems. Flow was discretized in time and space using fluid elements of finite mass and volume. The average velocity and flow depth in each grid cell was determined by updating these quantities in accord with fluid elements that traveled through the cell during each time step (Chin 1997). Therefore, at low bed slopes, flow continuity may not have been maintained in an individual grid cell if the cell did not receive new fluid elements before fluid elements previously present in the cell left it, resulting in a discontinuous water surface (Chin 1997). Alternatively, if flow decelerated, fluid elements tended to congest and create a ‘water mountain’, so that fluid elements moving towards a water mountain were blocked and shunted sideways (Chin 1997). Both these possibilities caused flow directions and sediment transport to become erratic and unpredictable, and the bed topography to change rapidly as sediment was eroded and deposited irregularly. 1.2.1 Overcoming continuity problems As recognized by Chin (1997), continuity problems can be overcome by utilizing a mixed LagrangianEulerian flow representation. Instead of fluid elements, flow is represented by momentum tracers that have neither mass nor volume. For each tracer, the momentum equation is solved in its Lagrangian form to reduce numerical dispersion, while the continuity equation is solved in its Eulerian form to achieve improved mass conservation. The accuracy of flow representation is directly related to the number of tracers, with flow velocities averaged within grid cells, yielding velocity components for the downstream and cross-stream directions. In addition, the Lagrangian momentum equations which were initially simplified assuming a uniform vertical velocity, have been modified to utilize the von Kàrmàn-Prandtl logarithmic velocity profile (e.g. van Niekerk et al. 1992) exhibited in natural rivers. It is believed that the use of momentum tracers in this way may permit the simulation of some of the more stochastic features noted in braided rivers (e.g. Paola 1996, Nicholas 2000). 2 EQUATION DERIVATION The model presented here can be readily separated into a hydraulic sub-model and a sediment transport sub-model. 2.1 Hydraulic sub-model It is possible to obtain two key equation sets for a single fluid unit from Newton’s laws of motion: (i) the law of conservation of mass for an incompressible fluid in Eulerian form and (ii) the Navier-Stokes momentum equations for an incompressible fluid (Lane 1998).

2.1.1 Mass conservation

In two dimensions, and assuming that the fluid is

homogeneous, incompressible and at constant temper

ature, the continuity or mass conservation equation can

be expressed as:

where h= fluid depth; t= time; and Q= depthand

time-averaged horizontal velocity ($u^{-}i + v^{-}j$).

2.1.2 2-D Navier-Stokes momentum equations

Derivation of the two-dimensional Navier-Stokes

momentum equations requires the integration of the

full three-dimensional momentum equations in the x

and y directions with respect to z. During this pro

cess, we assume a hydrostatic pressure distribution

with constant density over the fluid depth, and neglect

the Coriolis force and water surface wind stress terms

(Lane 1998). In this paper, a constant velocity profile,

r, is applied in the vertical dimension, where r is the

function that satisfies

where q xy = horizontal velocity (ui + vj); z= an eleva

tion within the flow; z b = bed elevation; and h= flow

depth.

Setting s= (z – z b)/h and $\int_0^1 r(s)ds = 1$, we obtain

(Tetzlaff & Harbaugh 1989):

where μ=molecular viscosity; ρ= fluid density;

c f =Darcy-Weisbach friction coefficient; and 2.1.3
Vertical velocity profile Figure 1 illustrates two
potential velocity profiles. The first, from Toffaleti
(1969 in Vanoni 1975) expresses the horizontal point
velocity as the product of the depthand time-averaged
velocity and s raised to a power related to temperature

(Vanoni 1975). The second sets r so that within the boundary layer (0.2≥ s), the profile obeys the law-of-the-wall and above this level, the velocity is constant (e.g.Tetzlaff & Harbaugh 1989). Despite the obvious differences between the profiles, the coefficients, α through γ , can be approximated for both profile shapes as: α≈ 0, β≈ 1, χ≈ 0, ε≈−0.5, φ≈−z b /h, and γ ≈−κ (e.g. Tetzlaff & Harbaugh 1989), where κ is the von Kàrmàn constant which has a value of ≈ 0.33 in suspended sediment-laden flows (Bennett et al. 1998). Equation 3 therefore reduces to (in Lagrangian form): Equations 1 and 4 provide a complete mathematical description of flow for an isotropic Newtonian fluid (Tetzlaff & Harbaugh 1989). The system of equations is solved using the Lax differencing method and the second-order Runge-Kutta method, which maintain second-order accuracy in both space and time (Press et al. 1992). 2.2 Sediment transport sub-model For the determination of sediment transport in a nonuniform sediment mixture, it is convenient to divide 0 0 1 1 R e l a t i v e e l e v a t i o n ((z z b) / h) Tetzlaff & Harbaugh 1989 Toffaleti 1969 in Vanoni 1975 0.8 0.8 0.6 0.6 0.4 0.4 0.2 0.2 1.2 Relative velocity Figure 1. Potential vertical velocity profiles. Relative velocity is such that unit area is bounded by the curves.

the mixture into several size classes. For each size

class k , the three-dimensional convection-diffusion

equation of sediment transport is:

where c= concentration; t= time; u, v and w= velocity

components in the x-, yand zdirections, respec

tively; ω= particle fall velocity; ε s = ν/σ s = eddy

diffusivity of sediment (ν= eddy viscosity and

σ s = turbulent Prandtl-Schmidt number); q s = rate of

sediment inflow from surrounding cells and other

sources; and the subscript k denotes the kth size class.

The sediment transport sub-model presented here

operates in two dimensions, namely, in the direction

of the horizontal Lagrangian velocity and vertically

through the flow. Therefore, we assume that the mass behavior of the number of tracers present in the flow will represent any cross-stream variations in sedi ment transport. We can therefore derive the following convection-diffusion equation of total load sediment transport (van Niekerk et al. 1992, Wu et al. 2000a): where C tk = total load sediment concentration of the kth size class, defined as C tk = c k + q bk /(Qh); Q= the Lagrangian velocity; ij= the horizontal plane in the direction of Q; E b = entrainment rate of particles from the bed; and D b is deposition rate of particles onto the bed.

2.2.1 Non-equilibrium total load transport model

Many early sediment transport models assumed that local equilibrium conditions applied when simulat ing bedload transport. This sets the actual bedload transport rate to be equal to the sediment transport capacity under equilibrium conditions. However, this may lead to unrealistic predictions of bed deforma tion, especially in cases where flows are above (e.g. after urbanization, forest exploitation, channelization; Simon 1992, Stott et al. 2001, Trimble 1997) or below (e.g. downstream of a reservoir; Sherrard & Erskine 1991) capacity for much of the time, so that non equilibrium transport effects should be taken into

account.

As the problem of total load sediment transport has

been approached utilizing a method that incorporates suspended load fluxes, the bed change relation by size fraction due to bed-material load can be formulated as: whereλ= bed porosity; Z = bed deformation;α= nonequilibrium adaptation coefficient; and C t∗ = the total load transport capacity, defined as C t∗ = c ∗ + q b∗ /(Qh). 2.2.1.1 Non-equilibrium adaptation length The non-equilibrium adaptation length can be considered as a time scale representing the adjustment rate of the sediment mass C t to C t∗ , the equilibrium sediment mass, which is a function of local, instantaneous flow conditions. Various formulations of α exist in the literature. For particles transported in suspension, Armanini & Di Silvio (1988) suggest: where a= thickness of the surface or active layer; and u ∗ = shear velocity. Among others, Phillips & Sutherland (1989) and Wu et al. (2000b) have proposed relations for sediment particles transported as bed load. However, although it was not derived for sediment particles transported as bed load, the formulation of Armanini & Di Silvio (1988) is adopted, because for coarse particles it correctly tends to C t =C t∗ as α□x/Q, where □x is the distance step. 2.2.1.2 Sediment transport capacity Sediment transport capacity is the transported sediment load under equilibrium conditions (i.e. uniform flow and no net erosion or deposition). Sediment transport capacity is determined utilizing a modified version of the SEDTRA module (Garbrecht et al. 1996, Langendoen 2000), which determines the fractional transport capacities of bed load and suspended load, and takes into account hiding and exposure effects among different size classes. The modified version of SEDTRA calculates the total sediment transport by size fraction for fourteen predefined particle size classes (0.004 mm< d < 64 mm) with a suitable transport equation for each size fraction: - transport as wash load without deposition for sediment particles smaller than 8µm, - Laursen (1958) for silts and fine sands (0.008- 0.063 mm), - Yang (1973) for sands (0.063-2.0 mm), and - Meyer-Peter and Muller (1948) for gravels (2.0- 64 mm).

The total sediment transport capacity, C t∗ , is then

defined as:

where p k = fraction of sediment in the kth size class

available for transport; and C *k = sediment transport capacity of the kth size class. The fraction p k depends on the fractional content by volume of size class k in the surface layer and the fraction of sediment in the kth size class entering the reach from upstream and the streambanks.

2.2.1.3 Accounting for hiding and exposure

For sediments with a widely graded size distribution, the differences in the critical flow strength tend to be significantly reduced (e.g. Wilcock 1993). Widely graded sediment beds tend to increase the critical flow strength for initiation of the sizes finer than the mean size and decrease the critical flow strength of the sizes coarser than the mean size (e.g. Kuhnle 1993). To account for the hiding and exposure effect of non uniform sediment mixtures, the sediment size used to calculate the critical flow strength for each size class is adjusted by considering the effect of the mixture on the critical flow strength of individual size fractions. SED TRA defines the critical diameter for initiation of each of the fourteen size fractions as (Wilcock 1993, Kuhnle 1993, Garbrecht et al. 1995, Kuhnle et al. 1996):

where $\bar{d}$ =mean size of the bed material; and x= a hiding coefficient that ranges from 0 to 1. For x= 1, the mean size of the sediment is the critical diameter

for all size fractions and all fractions tend to move at the same flow strength. For x= 0, each size fraction behaves independently of the others and the d k for each size fraction is used to calculate flow strength at which motion begins (Kuhnle et al. 1996).

Extensive testing of SEDTRA found it to be applicable to channels with widely graded sediment distributions and to channel networks with variable sediment characteristics (Garbrecht et al. 1996). Gar brecht et al. (1996) tested SEDTRA against Brownlie's (1981) data set. Garbrecht et al. (1996) concluded that for laboratory data, about 80% of the computed sedi ment transport rates were within a factor of two of the measured values and about 90% were within a factor of three. For field data, about 55% of the computed sediment transport rates were within a factor of three and about 70% were within a factor of 5.

2.2.1.4 Fall velocity

The equations of Laursen (1958), Yang (1973) and Armanini & Di Silvio (1988) all require the fall velocity w to be determined. This is attained by one of two methods. For well-rounded natural sediment particles, the fall velocities provided by the U.S. Interagency Committee on Water Resources, Subcommittee on Sedimentation (USICWR 1957) are utilised. For particles of irregular shapes, sizes and densities, or when temperature data is lacking, the method of Dietrich (1982) is applied. Dietrich (1982) found good agreement between his predictive equations and data from a number of other researchers. For further details, see Dietrich (1982). 2.2.1.5 Mixing layer algorithm To represent historical erosion and deposition,

the bed can be divided into a surface or active layer and a subsurface layer. These layers constitute the mixing layer (e.g. Hirano 1971). Sediment particles are continuously exchanged between the water column and the surface layer. In contrast, sediment particles only exchange between surface layer and substrate when the bed scours or fills (Fig. 2). Variation in the bed material composition in the surface layer is determined ((Figure 2. Bed-material sorting within the mixing layer: (a) entrainment of sediment particles from the surface layer displaces the layer downward, causing sediment from the surface layer to mix with substrate layers 1 and 2; and (b) deposition of sediment particles leads to an upward displacement of the surface layer and causes part of the surface layer to become new substrate layer 1 (from Langendoen 2000).

from mass conservation:

where β s k = bed material composition in the surface

layer; a= thickness of the surface layer, which is

related to flow and sediment transport conditions as

well as bed deformation; ∂z b /∂t= total bed deforma

tion rate;β ∗ k =β s k when ∂a/∂t−∂z b /∂t= 0; andβ ∗ k = the

bed material composition in the subsurface layer when

∂a/∂t−∂z b /∂t= 0.

The thickness of the surface or active layer is related

to the time scale under consideration (van Niekerk

et al. 1992, Langendoen 2000). For very small time

scales, the surface layer can be considered as a thin

layer containing particles susceptible to entrainment

into the flow due to a momentary increase in the bed

shear stress. If the time scale is of the order of the time

it takes for a bed form to traverse its own wavelength,

the thickness of the surface layer is approximately the

height of the bed form. For very long time scales dur
ing which considerable changes in bed level elevation
may occur, the surface layer thickness is related to the
thickness of the layer of material eroded or deposited.
In this paper, we follow van Niekerk et al. (1992)
and Takebayashi et al. (2003), who consider the sur
face layer thickness to be a function of shear stress.
The method of Takebayashi et al. (2003) is utilized.
The surface layer thickness is expressed as:
where ϕ= angle of repose; θ= local bed slope; and
τ_* = non-dimensional shear stress of the mean bed
material diameter.

3 MODEL APPLICATION

The model is at present being applied to the South
Saskatchewan River, Saskatchewan, Canada. At the
time of writing, simulations were not complete and so
results will not be presented at this stage. Definitive
results will be presented at the meeting.

3.1 Field location description.

The South Saskatchewan River (Fig. 3) is formed
in Southern Alberta by the junction of the Bow and
Oldman Rivers, from where it flows eastwards until
its confluence with the North Saskatchewan River in
central Saskatchewan. Postglacial incision into highly
erodible glacial deposits and Cretaceous sediments

has acted to localize sediment sources to the lower, steepened sections and immediate sides of the valley (Ashmore 1993). The sediments that make up the valley sides permit mass movements, extensive gullying and the development of badlands (Ashmore & Day 1988a, Ashmore 1992). Indeed, microscale erosion studies of badlands developed in Cretaceous shales of the Red Deer River valley, Alberta, indicate that annual erosion from this small portion of the basin is equivalent to the annual load of the river (Ashmore 1993). Similar localized erosion occurs along other rivers in southern Alberta and Saskatchewan, including the South Saskatchewan, Bow and Oldman rivers (Ashmore 1993). 3.1.1 Previous studies and implications A number of studies have documented sediment loads and concentrations for a reach of the South Saskatchewan River around Outlook, Saskatchewan (e.g. Cant & Walker 1978, Rasid 1979, Ashmore & Day 1988a, Ashmore 1992), as well as bar and channel geometries (e.g. Cant & Walker 1978, Rasid 1979). In this reach, the river flows in a valley about 0.6 km wide, with an average slope of 0.0003. Bar-full discharge (equivalent to the elevation of the ‘sand flats’ described by Cant & Walker (1978)) is 280 m 3 s −1 , while bank-full discharge (required to inundate islands and floodplains) is around 1240 m 3 s −1 . The total drainage area is approximately 158,600 km 2 , although the contributing area is only around 85,700 km 2 , since the rolling and hummocky topography of the glacially sculpted Prairies cause large areas to be internally drained (Ashmore & Day 1988a). The hydrological and sedimentological regime of the river has been greatly altered by human activity in the past 100 years. For example, in the South Saskatchewan system upstream of the AlbertaSaskatchewan border, it has been estimated that consumptive water use has reduced natural flows by 15–25% (Prairie Provinces Water Board 1982 in Ashmore & Day 1988b). Of greater significance is the construction and closure in 1967 of Gardiner Dam 30 km upstream of Outlook, which stands 64 m high and 4.8 km wide, impounding about 9.4× 10 9 m 3 of water to form Lake Diefenbaker (Rasid 1979). In terms of the hydrological regime, the closure and operation of Gardiner dam resulted in a decrease in the magnitude of high flows, an increase in the magnitude of low flows, and a re-distribution of high flows from the spring and early summer, representing snowmelt runoff, to the winter months (Fig. 4). In addition, consumptive uses of water from Lake Diefenbaker, such as irrigation, municipal and industrial water supply account for about 5% of annual flows and in an average year, evaporation losses from Lake Diefenbaker’s surface account for an additional

5% of annual flows. N 5 0 0 m 0 F i g u r e 3 . Post-dam (1967-2002)

Figure 4. Average annual hydrographs constructed for the Water Survey of Canada gauge 05HG001 South Saskatchewan River at Saskatoon. Dashed lines represent 10th and 90th percentiles, respectively. Note the vast change in the annual flow regime.

In terms of the sedimentological regime, because of its length (225 km) and storage volume, Lake Diefenbaker can be considered to have a 100% sediment trapping efficiency (Yuzyk 1983). Suspended sediment concentrations have hence been substantially reduced (Rasid 1979), with mean concentrations falling from 350 to 30 mg l −1 and bankfull concentrations falling from 1400 to 650 mg l −1 .

Perhaps surprisingly, however, early post-dam research (Rasid 1979) noted bed lowering over the study reach of only 0.2 m, a figure Cant & Walker (1978) found to be “much less than local fluctuations due to channel shifting” (p. 627). In addition, Cant & Walker (1978) noted that a comparison of aerial photographs obtained before and after the emplacement of the dam shows that the planform of the river, in terms of its braid-bar scale, type and activity, is unchanged. Indeed, more recent research (Phillips 2003) suggests that there has been minimal impact on the mean bed

elevation from around 13 km downstream of the dam. The lack of change in the characteristics of the channel and sediments of the South Saskatchewan River is perhaps surprising, given the significant changes in both the hydrological and sedimentological regimes. This causes the river to be significantly below sediment transport capacity for much of the time. Galay et al. (1985) used the HEC-6 flow-sediment model developed by US Army Corps of Engineers to predict future degradation on the South Saskatchewan River. Results predicted degradation of 4.2 m within 1.6 km of the dam by the year 2000. However, Phillips' (2003) analysis indicates average bed degradation of 0.54 m and thalweg degradation of 2.06 m. Clearly, the model employed by Galay et al. (1985) significantly overestimated degradation. This finding reinforces the desirability of non-equilibrium treatments of sediment transport. 4 CONCLUSIONS Exploration of the Marker-in-Cell method (Tetzlaff & Harbaugh 1989) was recently advocated by Paola (2001). This paper has presented a new Marker-inCell hydraulic and sediment transport model. This model simulates fluid flow and sediment transport in the horizontal plane and depth, logarithmic velocity profile and deposits in the vertical plane. Nonuniform total-load sediment transport is simulated by using a non-equilibrium approach. Sediment transport capacity is determined utilizing a modified version of the SEDTRA module (Garbrecht et al. 1996, Langendoen 2000), which determines the fractional transport capacities of bed load and suspended load, and takes into account hiding and exposure effects among different size classes. To represent historical erosion and deposition, the bed is divided into

a surface or active layer and a subsurface layer. Sediment particles are continuously exchanged between the water column and the surface layer. In addition, when the bed scours or fills, sediment particles exchange between surface and subsurface layers. The model is presently being applied to a reach of the South Saskatchewan River, Saskatchewan, Canada to explicate small-scale spatial and temporal processes. This reach has been affected by the closure of Gardiner Dam 30 km upstream, in 1967. However, comparison of aerial photographs obtained before and after the emplacement of the dam indicates that braidbar scale, type and activity is relatively unchanged, while cross-section analyses suggest minimal degradation downstream of around 13 km of the dam. This is despite significant changes to both the hydrological and sedimentological regimes, which cause the river to be significantly below sediment transport capacity for much of the time. Modeling of the study reach with an equilibrium total load sediment transport model by Galay et al. (1985) significantly overestimated the amount of degradation observed in the South Saskatchewan River. This over-estimation reinforces the desirability of non-equilibrium treatments of sediment transport. It is hoped that this model will contribute to improving process representation in simulating feedbacks between morphology, flow and sediment transport (Bates & Lane 2000), and hence improving our understanding of braided rivers.

A finite volume model of flow and sediment transport in the lagoon of Grado-Marano

S. Bosa & M. Petti

Dipartimento di Georisorse e Territorio, University of Udine, Italy

ABSTRACT: The Grado-Marano Lagoon in the Northeast of Italy has many problems related to the silting of its navigable channels and hence a study of sediment

transport inside the basin is becoming necessary. A finite volume numerical model for simulating solid transport in lagoons is proposed. Of all the different techniques to evaluate the numerical fluxes in the integration scheme, one technique was adopted, that solves a local Riemann problem at each intercell. To choose the most appropriate solver for this kind of problem, a test was developed to simulate the tidal run-up and run-down on a beach. Some results are shown in the paper. The sediment transport was evaluated through the Van Rijn total load formula. Finally the model was used to simulate the oscillations of consecutive tides in the Grado-Marano lagoon and the results are discussed.

1 INTRODUCTION

The Grado-Marano Lagoon is a large basin on the Adriatic coast in the Northeast of Italy and represents one of the most important Italian lagoon systems. It extends about 32 km from east to west and 5 km from north to south (Figs 1, 2).

In the last years a growing deterioration of the environment has occurred on this site causing silting of the navigable channels with sediments. This process happens both in natural and artificial channels and it is becoming a serious problem for the local population, navigation being one of its main sources of income (fishing, tourism, etc).

Nowadays, there is no plan for regulating environmental operations like dredging of navigation channels

or construction of lagoon structures to limit the silting of the channels. There are two main reasons: the sediments are polluted and up to the present time no reliable hydraulic model has been used to study sediment transport phenomena inside the lagoon. The presence of polluted sediments requires technical solutions, whose validity can be tested only with a model. The lack of a reliable model for testing possible technical solutions has inspired the present work.

The study of sediment transport in lagoon basins is a complex three-dimensional phenomenon and is controlled by turbulent diffusion, tidal currents and wind, the geometry of the bed. Erosion and sedimentation processes of non-cohesive sediments are mainly controlled by vertical turbulence, while circulation of sediments is due essentially to convective tidal and wind currents; horizontal turbulent diffusion is less important in this process. Hydrodynamic characteristics and particle properties of sediments in the lagoon show that both suspension and bed load transport mechanisms are important. In the present work a finite volume numerical model for simulating both suspended and bed load sediment transport is proposed. The field of motion of the flow is described by vertically integrated 2-D coupled equations (the classical shallow water equations). For calculating the sediment transport, both Van Rijn (1984a, b) and Ackers & White (1973) formulations are considered. In the model we use an explicit time-dependent discretization based on a split finite volume method. The classical Godunov approach is used, with the Harten, Lax and van Leer (HLL) Riemann solver (Toro 1999, 2001). The resulting scheme is second-order accurate in space and time and satisfies the Total Variation Diminishing (TVD) condition. The model implemented is able to represent steep water fronts and fronts with concentration of sediment, and it can be used to determine bed changes near lagoon structures and dredged

navigation channels for moderate irregularity of the bottom. Some hydrodynamic tests used to choose the solver are presented here. Finally some numerical simulations on the Grado-Marano lagoon are presented and it is shown how tidal currents control sediment circulation inside the basin.

arrows show the cross section depicted in paragraph 4.

2 MORPHODYNAMIC MODEL

The model proposed can be subdivided into two main

phases: the first one solves the hydrodynamic problem

and the second one calculates the new bed elevation

through the Exner equation.

2.1 Hydrodynamic model

The equations used to describe the motion are the well

known shallow water equations. The shallow water

hypothesis is very close to reality, because water depth

is very small compared with the planimetric dimen

sion of the motion field. The equation system (Liggett

1994) is:

with:

where h is the water depth, U and V are the veloc

ities on the horizontal plane x-y, g is the gravity

acceleration, z f is the bed elevation, K s is the Gauckler

Strickler coefficient and ν t is the turbulent viscosity

(assumed isotropic on the horizontal plane). U is the

variables vector, F and G are the fluxes vectors in x

and y directions, S f is the source vector due to the bed

slope and flow resistance and S t is the source term due

to turbulence; in the following the sum of S f and S t is

referred to simply as source term.

The differential system has been discretized using

temporal splitting, which is second order accurate

(Toro 2001) and that can be summarized by: where U n and U n+1 are the solution vectors at time t and t+Δt,A and S are the convective and the source operators. To evaluate S t , it is necessary to quantify the turbulent viscosity coefficient υ t . A scale analysis shows that υ t can be expressed as the product of a velocity scale that accounts for turbulent oscillations and a length scale to account for vortex dimensions; in this work the former is assumed to be the friction velocity u ∗ and the latter the water depth: where § is an dimensionless coefficient. The most appropriate values for § in literature are extremely variable (between 0.1 and 100), so that often § becomes an instrument to calibrate numerical models (Garcia & Kahawita 1986, Maa 1990 and Pedlosky 1987). Some tests on the Grado-Marano lagoon showed that the change of § does not substantially modify the results. In this work a value of 10 is assumed for § in the following tests. The most difficult step in Equation 3 is the convective one: where U con is the solution of the homogeneous pure convective problem. Equation 5 can be written explicitly as: To solve the homogeneous problem in Equation 6, the new variable H is introduced: after which it is possible to integrate the differential equation on a generic control volume in the horizontal plane: where n is the outward unit normal vector to the control volume boundary. Using a finite difference method, with time accuracy of first order, we get: H i3 n H i1 n H i4 n H i2 n Δs i i Ω i

Figure 3. i-th control volume and the fluxes associated to

its boundary.

where the meaning of the terms in the summary is depicted in Figure 3.

The evaluation of the fluxes H n ik is the most important step in the solution of Equation 9. One way to evaluate them is to solve a local Riemann problem between two neighbouring cells. The different techniques that take inspiration from this method are called ‘Riemann solvers’.There are exact solvers and approximate solvers. The most used approximate solvers can be subdivided into two classes. In the first class, one computes an approximate solution and then the numerical flux is obtained by evaluating the exact physical flux vector at this approximate state. In the second class one directly obtains an approximation of the flux. To choose an appropriate solver some preliminary tests were evaluated. Included in these were tests of wave run-up on a beach, these were key to the description of the run-up of the tide on the banks near the sea at the boundary of the lagoon and the phenomenon of periodical emersion and immersion of the sand banks inside the lagoon. In the following the results of these tests are shown.

Some solvers proposed by Toro (1999) (FORCE, centered Godunov and HLL) were tested and the HLL solver gave the best results. For this reason the

approximate solver HLL was chosen and is now briefly

presented.

The approximate solver family first computes an

approximate solution W ik (x/t) (where W ik is the vec

tor of the variables h, U and V associated with the k-th

side of the i-th cell) to the Riemann problem; then an

approximate numerical flux is obtained by evaluating

the physical flux

The HLL solver assumes a constant solution U HLL in

the region between characteristic straight lines (S L and

S R) representing the left and right perturbation (waves)

of a hyperbolic problem. Also the corresponding flux

F HLL is constant. U HLL can be found by integrating (5)

on the control volume [(x L − x R)× (0−Δt)] shown in

Figure 4. In this figure the subscript L and R identify 0 x L x R x t TS L TS R Δt S R S L h L U L V L h R U R V R h HLL U HLL V HLL F L F R Figure 4. x-t plane used to solve the Riemann problem. two regions, called left and right region, where the left and right wave have not arrived yet; for example h L , U L ,V L , F L , are respectively the water depth, the velocities in x and y directions and the fluxes vector in x direction of the left region. The left and right waves move with wave speed S L and S R . In this way U HLL is obtained: where F L and F R are the physical fluxes obtained from U L and U R . To evaluate the flux F HLL one can integrate (6), as done to obtain U HLL , but on the control volume [(x L − 0)× (0−Δt)]. In this way one obtains: Hence the numerical flux on the intercell is: The final model is made second order accurate also in space, through the use of ‘minmod’ limiters, that assume a linear distribution of the variables inside each cell (Hirsch, 1984). To increase the accuracy of the solution it is also necessary to improve the evaluation of the source term; hence we introduced a technique to calculate the bed slope, consisting in associating to each cell in x and y direction

the bed slope of the plane made by the two neighbouring cells in the two different directions, as shown in Figure 5.

x y z

Figure 5. Structure of the bed slope evaluation with a

second order accuracy.

2.2 Solid transport model

Assuming slowly varied motion and the absence of

lateral mass entering the control volume, the bidimen

sional sediment mass conservation can be written as:

where q si is the total sediment volumetric rate in i

direction, and p is the porosity. Equation 14 is known

as the Exner equation.

Integrating Equation 14 on a generic control vol

ume and discretizing it with an explicit second order

accurate finite volume scheme, one obtains:

where q n+1/2 sik is a value between q n+1 sik and q n sik (the

subscripts i and k mean that q s is associated with the

k-th side of the i-th cell.

2.3 Solid transport evaluation

In the Grado-Marano lagoon the hydrodynamic field

and the sediment diameters do not allow us to neglect

either the bed load or the suspended load transport.

In the development of the present model we used the

Van Rijn (1984) and Ackers & White (1973) formulae

to evaluate the sediment transport.

The Van Rijn formulation evaluates the bed load

and the suspended load separately and their sum gives

the total load in x and y directions q sx and q sy . For the

volumetric rate of the bed load in x and y directions q bx

and q by , he proposed an expression valid for particles

in the range 200–2000μm (Van Rijn, 1984a): where g is the gravity acceleration, S g is the specific gravity, d 50 is the particle diameter, T i is the transport stage parameter in i direction and D* is the dimensionless particle parameter. To evaluate the suspended solid volumetric rate in x and y directions q ssx and q ssy he proposed (Van Rijn 1984b): where a is the reference level where the reference concentration in i direction c ai is evaluated, h is the water depth, U is the mean water velocity and Z ′ i is the modified suspension number in i direction. To evaluate the parameters used in Equation 16, one has to calculate first the Shield's parameter in x and y directions θ x and θ y : then the critical Shield's parameter is needed and here the formulation proposed by Brownlie (1981) is used to evaluate θ cr0 , independent from the bed slope: the dimensionless particle parameter is: where υ is water kinematic viscosity coefficient. To consider the bed slope Chiew & Parker (1994) proposed modifying θ cr0 , obtaining: where α x and α y are the bed slopes in x and y directions and ϕ is the angle of repose of the sediment.

After that one can easily calculate the transport stage

parameter as:

To evaluate the suspended load, it is necessary to calcu

late first the critical Shield's parameter for suspended

sediments by following Van Rijn's works:

The suspended transport stage parameter in i direction

T si is then:

Assuming a= 0.015h, the reference concentration can

be evaluated as:

Calculating the modified suspension numbers as pro

posed by Van Rijn (1984b), one can finally obtain the

suspended solid volumetric rate from Equation 17.

The Ackers White formulation (1973) directly

obtains the total load in x and y directions q sx and (a)
(b)

Figure 6. Mining trench test. In (a) Van Rijn’s formula is used, while in (b) Ackers & White’s formula is used. q sy as: where G gri is the general transport parameter in i direction, d is the grain diameter, h the water depth, U and V , u ∗ and v ∗ the mean and shear velocities in x and y directions and n is a parameter depending on the dimensionless particle size. The general transport parameter may be calculated as: where C, A and m are parameters depending on the dimensionless particle size and F gri is: It is easy to see that while in Van Rijn’s formulation the coefficient responsible for the beginning of grain motion depends both on particle dimension and bed slope, in the Ackers & White one it depends only on sediment dimension. To choose one of these two formulations a mining trench test was simulated: a trench situated

transversely on a chute with slope 0.3% was modeled.

The bottom of the trench was inerodible. The results

of the simulations are shown in Figures 6a (using Van

Rijn’s formulation) and b (using Ackers & White’s

formulation).

Figure 9. Tidal test: the results with centered Godunov solver. From the left to the right the first ascending phase of the

sinusoid, the descending one and the second ascending one. The results obtained using Van Rijn's formulation agree with a realistic evolution of the bed elevation (convective and diffusive phase) described by Armanini & Di Silvio (1988), Lee et al. (1993) and Gill (1994). On the other hand the result using the Ackers & White formulation is worse, perhaps because of the omission of the bed slope in calculating the beginning of sediment motion. On the basis of these considerations in the next simulation only the Van Rijn formula was used. 3 VALIDATION TESTS In this section the hydrodynamic tests are related, to show the reason why the HLL solver was chosen. To verify that a solver is able to represent the runup and run-down of tides on isles and sand banks, a test was carried out to simulate a sinusoidal wave on a sloping beach in a channel. The mesh parameters are summarized in Table 1; the initial conditions were zero velocity and constant water level H 0 (Fig. 7); the sinusoidal wave amplitude was 0.5 m and the period was equal to 560 s (in the following we call this test 'tidal test'). In the test flow resistance was omitted and a Courant number 0.7 used. Different simulations were carried out with different solvers: FORCE, centered Godunov and HLL. The results are shown in Figures 8–10. All

solvers are able to describe the wave run-up and run

down on the sloping beach, showing that they can

all describe the effects of the tide on the isles and

sand banks. Nevertheless both FORCE and centered

Godunov solvers show some oscillations and for this

reason the HLL solver was chosen.

The next attempt to get a better solution was to

use the Nujic's technique (Nujic 1995), who proposed moving the pressure term 0.5 gh 2 from the flux vectors F and G to the source term; Nujic's idea was to work with the water level gradient instead of bed slope to avoid instability arising from the irregularity of the bottom, very evident in stationary flow conditions. Applying this method to the previous test, an improvement of the solution in static conditions is observed, but, dynamic tests show worse results (Figs 11–13) than that obtained with the technique illustrated before.

4 APPLICATION ON GRADO-MARANO LAGOON

The present model was applied to the Grado-Marano Lagoon to study erosion and silting of some of its channels in order to check its applicability in planning channel dredging interventions. The usual tide with amplitude of about 0.5 m is not considered to be

Figure 10. Tidal test: the results with HLL solver. From the left to the right the first ascending phase of the sinusoid, the descending one and the second ascending one.

Figure 11. Tidal test: the results with Nujic's technique and FORCE solver. From the left to the right the first ascending phase of the sinusoid, the descending one and the second ascending one. of great influence from a sediment transport point of view. The most consistent transport phenomena are in correspondence with high tidal oscillations that take place only a few times a year. The model was applied to

this kind of event. To this purpose, we built a grid, made by about 31,000 quadrangular elements with the support of Italian numerical cartography. Figure 12. Tidal test: the results with Nujic's technique and centered Godunov solver. Even in the first ascending phase of the sinusoid the solver becomes unstable.

The model works with almost any kind of quadran

gular cells, even if irregular; this allows the modeling

of the most critical regions (i.e. the channels) and

hence to find more realistic values for the flow char

acteristics (water depth and velocities). The result is

a very coarse grid where the bed elevation is quite

regular and a very fine one near the channels.

Initial conditions are quasi-dynamic, that is, at the

beginning of the simulations the water depth and

velocities of the lagoon are those found after some

tidal oscillation. Wall and beach conditions have been

imposed on all the lagoon boundary except for the

lagoon mouths. The water flow contribution of the

lagoon rivers is negligible compared to the water mass

that goes in and out from the lagoon mouths.

At the lagoon mouths a tidal oscillation was

assigned, which was characterized by wave height of

1.5 m and period of 12 hours. The duration of each

simulation was 60 hours.

Only one Manning resistance coefficient was used

all over the lagoon. To evaluate it, a calibration was 0.5

Concerning the solid transport, the van Rijn formula was used with a characteristic sediment diameter equal to 0.2× 10 -3 m (Brambati 1970). To simulate silting and erosion of the channels, 5 channels were studied (Figs 1-2). Figures 14-18 show the development of the bed of one cross section of each channel. It can be observed that in many channels deposition occurred. The shape of the cross sections analyzed, is quite similar to the convective phase of a mining trench. One explanation for this could be that the oscillatory sediment movements caused by tides are not completely reversible, because of the hydrodynamic field and lagoon morphology.Thus a preferential flow direction is created, causing the moving and the silting of channels.

allow the application of this model on such a large domain with a simulation lasting some years; neverthe less the results obtained could be considered indicative of channel silting phenomena, because associated with medium to high tidal events.

5 CONCLUSIONS

A horizontal bidimensional finite volume numerical model to study sediment transport in lagoon systems is proposed. To evaluate the numerical fluxes on the intercells in the hydrodynamic model a local Riemann problem was solved, using the HLL solver. The choice

Field investigation on macro-roughness characterization in mountain rivers

F. Canovaro & M. Catella

Department of Civil Engineering, University of Firenze, Italy

ABSTRACT: The macro-roughness characteristics obtained by field measurements are herein analyzed for

mountain rivers. In this conditions flow resistance is deeply affected by geometrical and spatial characteristics

of macro-roughness elements. The roughness geometry complexity makes difficult the evaluation of a repre

sentative roughness height. In the present paper a criterion for macro-roughness characterization based on bed

surface surveys and photographs is proposed. Experimental

data collected during field activities were satisfactory compared to data from laboratory investigations.

1 INTRODUCTION

The flow resistance in mountain rivers is deeply affected by the large-scale roughness mainly related to spatial density, arrangement and size of the sedi ment particles in the channel (Sayre &Albertson 1963, Barnes 1978, Bathurst et al. 1981).

The empirical relations taking into account only particle-size to estimate flow resistance in gravel or boulder bed channels give normally unreliable results (Bray 1985, Nikora 1998, Baiamonte 2001).

To determine the flow resistance in steep channels the macro-roughness geometry has to be characterized in terms of the cumulative effects of arrangement and spatial density of the coarser sediments protrusions above the stream bed.

The primary objective of this study is to character ize the macro-roughness elements in natural mountain streams.

The effective roughness height, representative of the protrusion distribution, has been defined using the location and the elevation of the highest point and the contact points between all particles exposed along a series of cross sections. In particular the methodology

proposed by Gomez (1993) for a laboratory flume has been extended to field conditions.

The field data collected throughout a three months survey has been compared with results obtained by Gomez on a stable armored surface in a laboratory flume showing good agreement.

2 SITES OF FIELD INVESTIGATION

Primarily the detection of suitable stream reaches for the investigation has been conducted. In order to avoid additional effects on flow resistance, the main properties of the studied channel should be: straight reach without sinuosity, spread presence of macroroughness, absence of macro scale bed morphologies such as bars or step-pool. The three sites of Navale, Picignana and Resco Creeks located in the mountain region of Tuscany (Italy) have been considered. The general morphology of the streams under investigation are very much alike. They run in carved channels within the deep straits of the valley with no alluvial plain. They show a plan-form sinuosity values ranging round the unity both in the case of low and high flows. Bed slopes are around 2-3% and sediments feeding is strong, quite sorted and coarse (essentially gravel, cobbles and boulders). In particular, the Picignana Creek bed surface is randomly spread by isolated boulders without showing any transversal or longitudinal structure (Fig. 1), thus recognizable as a cascade stream morphology (Montgomery & Buffington 1997). The Navale and Resco Creeks bed surfaces are composed by irregular sequences of small and big boulders transversely placed along the entire cross section (transverse rib morphology). This morphology differs from the step-pool in terms of absence of pools and sediment deposition in the upstream side, minor height of the step and a more regular streambed profile (Lenzi et al. 2000). The main characteristics of channel reaches geometry and bed surface are listed in Table 1. 3 MACRO-ROUGHNESS MEASUREMENTS 3.1 Bed topography measurement In order to characterize bed surface variations, the stream bottom elevation has been recorded with

Figure 1. Cascade stream bed morphology in the Picignana

Creek.

determined by fitting lines using linear least squares
regression. An example of a single cross section bed
surface profile is reported in Figure 5. Bed measurements
has been repeated for all the cross sections in which the
study reaches have been subdivided.

Figure 6. Vertical photographs of bed surface (Resco

Creek).

Figure 7. Characterization of bed surface topography (Resco Creek – transect 1). Effective roughness height of the sediment particle h= h 1 – (h 2 + h 3)/2.

In particular in the Navale and Picignana Creeks 9 transects have been identified in two 45 meters long reaches, while in the Resco Creek 10 transects in a 30 meters long reach have been defined.

Following Gomez (1993), the location and the ele vation of the highest point and the contact points between the sediment particles has been detected along a cross section (Fig. 7). The sediment arrangement on the bed surface has been reconstructed by means of a series of vertical photographs (Fig. 6) taken across each stream transect along the telescopic rod.

The photographs have been taken by a digital cam era positioned on the top of a vertical 5-m-long rod, able to reproduce a stream portion 5-m-long and 4-m-wide.

3.2 Macro-roughness characterization

In order to characterize the macro-roughness geom etry two main aspects need to be considered. First, a criterion to determine the roughness height of each protrusion has to be defined. Second, a roughness Table 2. Effective roughness heights, for h≥ h 95 , of single particle on the bed surface. The b-axis corresponds to the median particle size (intermediate axis). NA PC RS b-axis h b-axis h b-axis h (mm) (mm) (mm) (mm) (mm) (mm) 430 365 670 415 600 405 580 440 690 406 640 611 730 445 910 615 660 360

1170 655 1610 740 920 740 height representative of the cumulative effects of protrusion distribution has to be determined. In the present paper the Gomez methodology has been extended to define the bed surface roughness height of a single particle in field condition. The effective roughness height h of a single particle has been defined as the difference in elevation between the highest point on the particle itself and the average elevation of the two contact points of the adjacent particles respectively on the right and left side (Fig. 7). This definition takes the entire bed surface variation into account for the macro-roughness assessment. The representative roughness height k of the sediment elements constituting the bulk has been determined as the average value of the effective roughness heights for h≥ h 95 (the height for which 95% of the effective roughness height are smaller). The h 95 value has been chosen since the sediments with h≥ h 95 are the most responsible to the macroroughness, assuming that few large particles dominate the flow resistance (Robertson & Wright 1973, Burkham & Dawdy 1976). The single particle effective roughness heights for h≥ h 95 for the three reaches under investigations are reported in Table 2. 3.3 Macro-roughness behavior The collected field data has been compared with results obtained by Gomez on a stable armored surface in a laboratory flume. With reference to Figures 8-10, field data representing the effective roughness height have been plotted against the median particle size for each stream, and compared with laboratory data by Gomez. Note that to make the two sets of results comparable both the roughness height and median particle size are made dimensionless with the D 90 of the respective surface bed material. Agreement between field and laboratory bed surface roughness heights appears very good in terms of pattern. In terms of absolute values, field effective

Figure 8. Dimensionless effective roughness height ver

sus dimensionless particle size. Triangle and square repre

sent respectively Navale field results and Gomez laboratory

results. Solid symbols indicate effective roughness elements,

respectively Picignana field results and Gomez laboratory

results. Solid symbols indicate effective roughness
elements,

≥h 95 in height.

roughness heights for h≥ h 95 seem to be fairly greater

than laboratory values.

In Figure 11 a comparison between all the three

field sites under investigation and laboratory results

is reported. It emerged that the most contribute to

flow resistance is due not to a single particle size,

but to all the sediment particles characterized by an

intermediate axis grater than D 90 (except for the first

effective roughness element, ≥h 95 in height, in the

Navale Creek reported in Table 2). Thus, in the present

study the coarser particles of the bed surface appear to

be the only responsible of the representative rough

ness height. The protrusions above the stream bed

are not due to the finer particles because they are

not exposed on the stream bottoms as result of the

armoring processes. Figure 10. Dimensionless effective roughness height versus dimensionless particle size. Circle and square represent respectively Resco field results and Gomez laboratory results. Solid symbols indicate effective roughness elements, ≥h 95 in height. Figure 11. Dimensionless effective roughness height versus dimensionless particle size. Solid symbols indicate effective roughness elements, ≥h 95 in height. 4 CONCLUSIONS A criterion for the characterization of the representative roughness height of the protrusion arrangement on the bed surface in a mountain river is proposed. The methodology by Gomez has been extended to natural rivers. The effective roughness height is not

defined using empirical relations based on particle-size distributions, but it involves the height and the distribution of protrusions derived from bed surveys and vertical photographs. The effective roughness height from field measurements and from Gomez laboratory flume, make dimensionless with D_{90}, show a good agreement in terms of pattern, while in terms of absolute values field data seem to be fairly greater than laboratory values.

The representative roughness height of the bed surface has been determined as the average value of the effective roughness heights for $h \geq h_{95}$, assuming these heights as the most responsible of the flow resistance.

Present results underline that the effective roughness height with $h \geq h_{95}$ are characterized by an intermediate axis grater than D_{90}. Thus, the coarser particles of the bed surface appear to be the only responsible of the representative roughness height.

ACKNOWLEDGMENTS

This research was funded by the Istituto Nazionale per la Ricerca Scientifica e Tecnologica sulla Montagna (INRM) in the framework of the research program “Dinamica e regimazione del trasporto solido in relazione della difesa del territorio montano” 2001.

Moreover, the Authors wish to thank Miss Giulia Gianassi for her important role in carrying out the field measurements.

NOTATIONS

The following symbols are used in this paper:

D_{50} = median diameter of surface bed material;

D 90 = the sieve size for which 90% of particle size are smaller;

h = effective roughness height of a particle;

k = representative roughness height.

ABSTRACT: Results from an experimental study of the interaction between turbulent open-channel flow

and the flow in a porous subsurface gravel layer are presented. Synchronous measurements are carried out

with miniature temporally high resolution pressure sensors and with 3D-PTV (particle tracking velocimetry).

First data sets are analysed in detail. The ultimate results may help in understanding the processes of erosion

and sedimentation, as well as mass exchange processes. The long-term goal of this project is to improve the

engineering design of stable beds for waterways.

1 INTRODUCTION

Many problems in hydraulic engineering deal with

the morphodynamic changes due to construction of

hydraulic structures such as groynes, weirs or mounted

embankments. The efficiency of hydraulic construc

tions depends on the stability of the river bed or the

artificial geotechnical armoring layer, respectively.

For example, the Iffezheim barrage at the Rhine-river

near Karlsruhe needs about 200.000 m 3 of gravel per year additionally to avoid erosion in the downstream river bed.

Over the last 100 years much research work has been done to gain insight into the theoretical back ground of river bed stability. However up to now no satisfactory, physically founded formula has been established to answer definitely the question of river bed stability. The understanding of the individual pro cesses, the functional chain of cause and effect is not developed far enough to predict destabilization. Hence, the success of a hydraulic construction cannot be guaranteed satisfactorily.

2 BACKGROUND

The stability of a gravel bed in an open-channel flow is usually described by the Shields (1936) parameter, τ∗. It is defined as the ratio of the frictional load on the grain (~ρ w u∗ 2 d 2) to the gravitational force on the grain that may resists against movement (~g (ρ s − ρ w)d 3). The value of τ∗= 0.03 to 0.06 is often used as the limit for bed protection. This and other correlations, e.g. Meyer-Peter/Müller (1949), yield a good estimation for most practical engineering problems. However, these equations consider uniform flow. They do not reproduce the local unsteady physical processes on the gravel bed due to turbulence. For a more detailed consideration of stability problems the analysis of the influence of fluctuating forces is important. Fluctuating forces might be caused by turbulence of open-channel flow including the occurrence of coherent structures as well as the involvement of the whole hydrodynamic system which consists of free surface flow, combined with the subsurface gravel layer and eventually the groundwater flow. The discovery of the so-called bursting phenomenon in turbulent flows by Kline (1967)

generated a new interest in studying the structures of boundary layer turbulence.As is described by Grass (1971), fluid near the bottom is thrown upwards during an ejection phase, during a sweep phase fluid is pumped towards the bottom. Burst-cycles occur over both smooth and rough surfaces. They have a strong impact on pressure peaks on the bottom which might cause the erosion of single grains (Drake, 1988; Hoyal, 1985; Gyr et al.,

1996). Emmerling (1973) noticed instantaneous pres

sure peaks max(p) as high as six times the medium

pressure fluctuations rms(p). Raudkivi (1982) as well

as Dittrich et al. (1999) correlate rms(p) to shear stress

τ_0 as rms(p)=C τ_0 , with C varying from 0.5 to 5.0,

with an average of 3.0. Referring to Emmerling max(p)

must be taken into consideration up to 18 τ_0 !

Recent developments in measuring techniques

allow new methods for observing the above men

tioned processes using piezometric pressure sensors

with high resolution in time (Aktiv Sensor, 2003;

Hofland et al., 2003) and 3D-PTV, i.e. particle tracking

velocimetry (Klar, 2001). Hence a Filter and Ero

sion Research Club (FERC) was initiated by Dienst

Wegen Waterbouwkunde (DWW) Rijkswaterstaat

(Netherlands), Kingston University (Great Britain),

the Federal Waterways Engineering and Research

Institute (BAW), the Interdisciplinary Center for Sci

entific Computing (IWR) and the Institute for Hydro

mechanics (IfH) for using a combination of these

above mentioned techniques.

The primary motivation of this study is to improve the understanding of the influence of hydrodynamic structures on the behavior of a gravel layer. An additional focus lies on the optimization of a gravel layer as a filter layer for protection for an underlying sand layer.

The long-term goal of this project is to improve the safe design of stable beds for waterways.

3 EXPERIMENTAL SETUP

3.1 Flume

The measurements are performed in an open channel flume with length L= 40 m, breadth B= 0.9 m and a maximum flow rate Q max = 0.275 m 3 /s. Figure 1 shows a sketch of the experimental setup.

A sand layer of H S = 0.5 m height covered by a porous gravel layer of H P = 0.04 to 0.20 m height is placed in the flume over a length of L= 30 m, optionally with and without hydraulic contact to the sand layer. This is achieved by omitting or inserting a rubber mat, respectively. The measuring-area is located at 15 m; hence influences of inlet and outlet are supposed to be negligible. The grain diameter of the gravel is d 50 =~10 mm, with a degree of non-uniformity Cc= d 60 /d 10 = 1.25. The mean grain diameter of the uniform sand is about d 50 =~1 mm.

The measurements are made simultaneously by

miniature pressure sensors with high temporally reso

lution and 3D-PTV in three artificial gravel pores. In

addition, up to seven more pressure sensors and endo

scopic observation of the sand-gravel-boundary can be

applied. The measurement program is given in Table 1.

The measuring program is defined for water

depth of H A /d 50 = 20 and H B /d 50 = 40. Variation in discharge and water depth provides flow conditions up to low mobility transport conditions based on the Shields parameter, τ∗. Supplementary measurements are done with glass spheres, having a d 50 = 10 mm. Long waves are generated artificially by a wave generator located 9.25 m downstream the measuring-area. Thus, the influence of an oscillating water level will be studied. The flow rate is measured by a magnetic inductive flowmeter, the water level is detected by an external Figure 1. Sketch of experimental setup, dimensions [cm], not scaled. Table 1. Measuring program, increasing shear stress τ 0 /τ cr = 0.1 to 1.0, τ cr = 6.8 Pa.

ultrasonic probe with hydraulic contact to the flume.

Steady flow conditions for each measurement are pro

vided by controlling the gate valve at the inlet and the

movable weir at the outlet automatically.

3.2 Micro-pressure sensors

The micro-pressure sensors were manufactured in

a development cooperation of Aktiv Sensor GmbH

(Berlin) and the Institute for Hydromechanics (IfH).

The principle of these in-situ micro-pressure sen

sors is based on the ‘piezoresistive’ effect. The initial

point is an element of silicium, with implanted

resistances in its bending panel. Figure 2 and 3 show photographs of the essential sensor components and three versions of testing sensors.

Figure 4 shows a photograph of the encapsulated head of the pressure pickup and its flexible tube for pressure equalisation as it was used for the measurements.

The differential pressure is measured with reference to atmospheric pressure, here additionally with compensation of temperature. For water resistance, the housings of the sensors are encapsulated with slowly hardening epoxy resin and sealed up with clear varnish. The maximal dimensions of the sensors are as small as 2× 1.2× 1.2 cm 3 , with a shape similar to a bigger gravel grain. Due to signal conditioning by the purpose-built amplifier the guaranteed maximum measurable frequencies are 100 Hz. Hence,

Figure 2. Micro-pressure sensors components, from left to right: amplifying blank (pressure transducer, series AU), piezoelectric pressure pickup (series AT, not encapsulated) and cap (series C) with drilled hole and flexible tube for pressure equalisation.

Figure 3. Testing micro-pressure sensors, from left to right:

encapsulated with epoxy resin, with plastic and with brass.
measurements of pressure fluctuations up to the estimated

Kolmogorov-scale-frequency of 50 Hz (Nezu et al., 1993) is possible. To avoid aliasing effects, the measurements are performed at a rate of 500 Hz. The sensor elements are deliverable for maximal pressures of 1.6 to 10 7 kPa. 6 kPa were chosen to be appropriate for the provided flow conditions with maximal 60 cmWC within the gravel layer. Thus the absolute range of the pressure sensors is 0 to 6 kPa. Due to the analog-digital-card, the increment of discretisation is 1.5 Pa (0 to 6 kPa) or 0.7 Pa (0 to 3 kPa). The ready-built sensors were calibrated by Aktiv Sensor GmbH to 0 to 10V according to 0 to 6 kPa at pressure of 3 and 6 kPa with a tolerance in accuracy of less than 1.0% full scale. Within a range of pressure fluctuations of e.g. 150 Pa the accuracy is less then the increment of discretisation. After a few months in use the sensors showed an offset of up to 1V corresponding to 0 Pa. As tests showed the calibrating factor of 1.67V/kPa stayed the same. Thus, on the one hand the maximal detectable static pressure is reduced up to 90%, on the other hand the measurement of fluctuations is not affected.To gain the right static pressure the sensors were calibrated before every measurement by comparing the measured signal with the water level detected by an ultrasonic probe. Tests under flume-conditions showed that extraneous high frequency noise was disturbing the amplified signal, as it can be seen in Figure 5. Therefore, a low-pass filter with RC= 0.33 ms was interposed. Its theoretical damping H(f) can be calculated by where f = frequency [Hz]; RC= time constant. Thus, the filter leads to damping of signals e.g. with 50 Hz to 99.5% and signals with 10 kHz to 4.8% which Figure 4. Head of micro-pressure sensor above gravel d 50 =~10 mm.

is acceptable for the provided flow conditions. The

clarifying effect on the signal is shown in Figure 6.

Only a few pressure sensors started drifting with

out any obvious reason as shown in Figure 7. Figure 8

shows a signal gauged simultaneously under the same

flow conditions which is not drifting. Thus, the pro

vided flume conditions must have been constant.

Gauged drifting signals like this were simply rejected.

Pressure sensors are located at vertical positions of

y/d 50 = 1.0 (above), 0.0 (at top) and at various posi

tions within the gravel layer. Each three sensors are

adapted on three artificial gravel pores to gain simulta

neously insight in pressure and velocity. Simultaneous

Figure 5. measuring was performed additionally by up to seven pressure sensors over two minutes. These sensors are locally fixed on a grid as shown in Figure 9. Compared with standard mechanical pressure sensors the miniature pressure sensors including an amplified calibrated signal are low-cost sensors. 3.3 3D-PTV Pore flow is measured by tracking tracer particles with two flexible fiber optic endoscopes, integrated into each artificial pore. Synchronized CMOS-cameras are used to acquire stereoscopic image sequences of the tracer particles in real-time with a frame rate of up Figure 7. Signal [Pa] with drifting, τ 0 /τ cr = 0.1, τ cr = 6.8 Pa, H A /d 50 =~21, H P /d 50 =~20, no hydraulic contact between gravel and sand layer. Figure 8. Signal [Pa] without drifting, gauged simultaneously with the example signal in Figure 7. Figure 9. Positioning of two sensors on a lattice (see dimensions of a floppy disc).

to 400 Hz. The 3D Lagrangian flow velocities of the

tracer particles along their trajectories can be deter

mined using a three-dimensional particle tracking

velocity (3D-PTV) algorithm, which is based on stereo

correlation of two-dimensional particle trajectories.

The free surface flow directly above one of the artifi

cial pores is explored by a conventional stereo camera setup applying the developed 3D-PTV algorithms. Sediment movements are analysed by three rigid endoscopes (periscopes) observing the interface between gravel and subsoil at three different positions. The image sequences are recorded by three standard CCD-cameras. Motion of sand or gravel is detected using techniques developed in digital image process ing. The calculation of the optical flow using the structure tensor technique allows to obtain a dense 2D displacement vector field (Jähne et al., 1998). Alto gether, 11 cameras are operated simultaneously with a total data thruput of about 125 MB/s. To keep the data amount within reasonable limits, the sequence dura tion for one measurement is 60 s (approximately 7 GB of image data).

Measurements of the whole 3D-PTV-system and micro-pressure sensors are carried out simultaneously (see also Klar et al., 2004).

3.4 ADCP

To gain additional insight into the velocity regime, a 1D-ADCP (Acoustic Doppler Current Profiler), namely a DOP 1000 (Signal Processing, Suisse) is used. The ADCP uses a pulsed ultrasonic echo tech nique to measure streamwise velocity profiles. The

parameters of the ADCP have to be adjusted opti

mally for each flow condition. Thus, the resolution

varies from 1 to 2 mm and 20 to 100 Hz. The maximal

velocity U in streamwise direction is 1.2 m/s.

Due to the measuring technique of the ADCP it is

only possible to measure probable velocity profiles

from y/d 50 = 1.0 to 12.0 above the gravel layer. Pro

files with duration of 30 to 45 s were measured at

various wall distances to get time averaged isoline

U-2D velocity plots. Working with the ADCP in the

measuring area is not possible because of spatial lim

its. Therefore this gauging instrument is located 3.3 m

downstream from the measuring area in order not to

disturb the pressure sensors and 3D-PTV.

3.5 Wave gauge

To detect variation and oscillation of the water level,

especially while generating waves with the wave

machine, a wave gauge is installed. Its principle is

similar to the ‘GHM – Dynamic Liquid-Level’ (Delft

Hydraulics, 2003) while measuring the resistance

between two vertical submerged rods of stainless steel.

Measurements are recorded at a rate of 500 Hz. 4 PRELIMINARY RESULTS AND DISCUSSION 4.1 Pressure fluctuations Each data set is smoothed with a simple moving average window of Δt= 0.006 s to eliminate outlying values. Thus, p m denotes the smoothed values. Figure 10 shows an example of the pressure fluctuations rms(p m) of the averaged pressure signal for increasing shear stress τ 0 /τ

cr up to low mobility conditions at τ cr = 6.8 Pa. Vertical positions of the piezometric pressure sensors vary from y/d 50 = 1.0 above to-7.5 within the gravel layer.The relative water depth is H A /d 50 =~20, the relative thickness of the gravel layer is H P /d 50 =~10. No hydraulic contact to the underlying sand layer is given. For τ 0 /τ cr = 1.0 and y/d 50 = 0.0 at the top of the gravel layer the rms(p m) is about 3.2 τ 0 which confirms Raudkivi (1982) and Dittrich et al. (1999) with C being mostly 3.0. Furthermore, the damping of the gravel becomes obvious. Whereas the ratio rms(p m)/τ 0 at y/d 50 = 1.0 above the gravel can be calculated to C= 10, the ratio is about C= 2.2 at y/d 50 =-1.0. Deeper down no difference between vertical positions can be detected.The ratio rms(p m)/τ 0 is given mostly by C= 1.8. Concentrating on the gradient of rms(p m) as a function of τ 0 it can be seen that, to a first approximation, the dependency is linear. Figure 11 shows the maximal pressure fluctuation of the averaged pressure signal max(p m) as a function of shear stress τ 0 . The flow conditions are the same as in Figure 10. For τ 0 /τ cr = 1.0 at y/d 50 = 1.0 at the top of the gravel layer max(p m)/τ cr leads to a ratio of rms(p m)= 18τ 0 which confirms the results of Emmerling (1973).As Figure 10 and 11 resemble each other, the dependence of max(p m) and rms(p m) seems to be linear. Figure 10. rms(p m)/τ 0 [-] for increasing τ 0 / τ cr , τ cr = 6.8 Pa, H A /d 50 =~20, H P /d 50 =~10, variation in vertical position. No hydraulic contact between gravel and sand layer.

Figure 11. max(p m)/τ 0 [-] for increasing τ 0 /τ cr , τ cr = 6.8 Pa,

H A /d 50 =~20, H P /d 50 =~10, variation in vertical position,

no hydraulic contact between gravel and sand layer.

In Figure 12 examples of analysed power spectral

densities PSD(p m) [Pa 2 /Hz] are shown for the same

flow conditions as mentioned before.

For at y/d 50 = 1.0 to 0.0 above and at top of

the gravel layer the results agree with Kolmogorov’s

k -5/3 law for the turbulence cascade in open-channel

flow (e.g. see Nezu et al., 1993). Within the gravel

layer a significant damping between 1 and 3 Hz can be recognized. Below y/d 50 =~-4.0 within the gravel layer there is no identifiable difference in damping pressure fluctuations higher than 3 Hz. The pressure fluctuations seem to be dominated by the long wave fluctuating water level. For designing a stable filter thinner than H P /d 50 = 4 the influence of turbulence of open-channel flow has to be taken into consideration.

4.2 Other results

Figure 13 shows an example for analysing data-files from the ADCP. The isoline plot shows the medium velocity u/U in streamwise direction. The influence of the walls becomes obviously. More analysing with respect to fluctuations and statistics still has to be done. Results regarding both the velocity and fluctuations in the velocity gained by 3D-PTV within the artificial gravel pores and in the free surface flow will be carried out soon. They will be compared with the synchronous pressure measurements. Furthermore possible sedi ment movements observed by the three endoscopes have to be analysed in detail and have to be correlated to an oscillating water level, respectively.

5 CONCLUSIONS

Results from an experimental study of the interaction between turbulent open-channel flow and the hydro

dynamic reaction in porous gravel layer are shown. τ 0 /τ cr = 0.1 τ 0 /τ cr = 0.4 τ 0 /τ cr = 1.0 Figure 12. Power spectral density [Pa 2 /Hz] for increasing τ 0 /τ cr = 0.1 (above), 0.4 (middle) and 1.0 (below), variation in vertical position, τ cr = 6.8 Pa, H A /d 50 =~20, H P /d 50 =~10. No hydraulic contact between gravel and sand layer. A new method of measuring pressure fluctuations due to open channel flow both on subsurface and within a gravel layer has proved its functionality. Pressure fluctuations are measured with miniature and u/U

Figure 13. Example for analysing data-files from ADCP,

here isolines of u/U [-], view in streamwise direction,

y/H A = 1.0 to 12.0 (vertical). U= 670 mm/s, τ 0 /τ cr = 0.4,

H A /d 50 =~20, H P /d 50 =~10. No hydraulic contact between

gravel and sand layer.

temporally high resolution piezoelectric sensors which

are very flexible in use.

Results for the power spectral density of pressure

fluctuations in the water column and at top of the

gravel layer agree with Kolmogorov’s k −5/3 law for

the turbulence cascade in open-channel flow. Within

the gravel layer an essential damping between 1 and

3 Hz can be recognized. Below y/d 50 =~−4.0 within

the gravel layer there is no identifiable difference in

damping pressure fluctuations higher than 3 Hz. Thus,

the pressure fluctuations are dominated by the long

wave fluctuating water level. For dimensioning stable

filters thinner than four times the gravel diameter the

influence of turbulence of open-channel flow has to be

taken into consideration.

Furthermore, the experimental setup allows syn

chronous measurements of pressure and velocity

within three artificial pores and in open-channel flow

via 3D particle tracking velocimetry. First results are

promising.

ABSTRACT: An experimental setup for the simultaneous analysis of flow, pressure and sediment movement within and above a gravel layer covering a sand base layer in an open-channel flow is presented. A multi-camera setup is used to acquire digital image sequences from various locations of the flow field. Optical access to the

gravel layer is provided by endoscopic imaging. The image sequences are analysed by a 3-D Particle-Tracking

Velocimetry algorithm and optical flow techniques to calculate 3-D Lagrangian trajectories of seeding particles

resp. 2-D displacement vector fields of sand particles. Special micro-pressure sensors based on the piezoelectric

effect have been developed, which can be inserted into the gravel layer at arbitrary locations. The system is used

to perform extensive measurements in an experimental flume under a wide range of flow conditions, including

surface waves. The goal of the experiments is to gain new insight into the physical flow processes inside the

gravel layer and to quantify the influence of turbulent fluctuations on the stability of both the gravel and the sand

grains. This paper focuses on the description of the measurement system. A detailed analysis of the results will

be given in a later publication.

1 INTRODUCTION

An experimental setup for combined measurements

of pressure, flow and sediment transport processes is

presented. The physical system under investigation is

an open-channel flow above a base layer of fine sand,

which is covered by a gravel filter layer. Of partic

ular interest are the hydromechanical processes and

flow fields within the gravel layer and at its interfaces

with the free surface flow above and the sand layer

below are of particular interest, e.g. for the analysis

of erosion and sedimentation in the context of river

bed stability. We have developed an experimental setup

that enables a quantitative study of pressure and flow

in such a configuration. The system consists of two

major parts:

- a multi-camera arrangement together with endoscopic imaging to record digital image sequences of the flow fields at various locations within and above the gravel layer,

- micro-pressure sensors to measure the pressure at up to 10 arbitrary locations. Digital image processing techniques are used to extract velocity data from the image sequences, namely a 3-D Particle-Tracking Velocimetry (3-D PTV) algorithm and an optical flow technique. The paper is organized as follows: section 2 gives a detailed description of the measurement setup. The digital image processing is briefly explained in section 3. In Section 4 some of the first results gained from the test series carried out are presented. Further measurements and final results of the ongoing intensive evaluations and interpretations of the flume test are scheduled to be published in the near future. Conclusions are given in section 5. 2 EXPERIMENTAL SETUP 2.1 Flume The experimental system has been implemented in an open channel flume located at the Federal Waterways Engineering and Research Institute (Bundesanstalt für Wasserbau, BAW). The flume is L= 40 m long

and B= 0.9 m wide. The maximum flow rate is

Q max = 0.275 m 3 /s. A sand layer of height H S = 0.5 m

covered by a porous gravel layer of height H P = 0.04

to 0.20 m is placed in the flume over a length of

L= 30 m, optionally with and without hydraulic con

tact to the sand layer. This is achieved by omitting or

inserting a rubber mat. The measuring-area is located

at 15 m, hence influences of inlet and outlet are sup

posed to be negligible.The grain diameter of the gravel

is d 50 =~10 mm, with a degree of non-uniformity

C c = d 60 /d 10 = 1.25. The mean grain diameter of the

uniform sand is about d 50 =~1 mm. The measuring

program is defined for water depth of H A /d 50 = 20 and

H B /d 50 = 40.

Figure 1 shows sketches of the experimental setup;

the measurement program is given inTable 1.Variation

in discharge and water depth provides flow condi

tions up to low mobility transport conditions based

on Shields parameter, τ * . Supplementary gauges will

be made with glass spheres, having a d 50 = 10 mm.

Long waves are generated artificially by a wave gen

erator located 9.25 m downstream from the measuring

area. Thus, the influence of an oscillating water level

can be studied. Figure 2 shows a photograph of the

wave generator.

The flow rate is measured by a magnetic inductive

flowmeter, the water level is detected by an external

ultrasonic probe with hydraulic contact to the flume.

Figure 1. Sketch of experimental setup, dimensions [cm],

not to scale. Steady flow conditions for each measurement are provided by controlling the gate valve at the inlet and the movable weir at the outlet automatically. At the measurement area, optical access to the flume is given by plexiglass windows inserted into the channel walls over a length of 4 m. Different experimental instrumentation is installed, compare the sketch in Figure 1. In particular, the setup consists of the following parts: - a stereo camera setup for the investigation of the free surface flow immediately above the gravel layer, - three endoscopic

stereo setups to record the flow fields inside specially prepared artificial gravel pores inside the gravel layer, - three rigid endoscopes inserted from below the channel to observe the sand-gravel-boundary, Table 1. Measuring program, increasing shear stress τ 0 /τ cr = 0.1 to 1.0, τ cr = 6.8 Pa. Figure 2. Wave generator.

- up to ten pressure sensors at arbitrary locations within the gravel layer (three of the sensors are attached to the artificial gravel pores used for the flow measurement).

The data acquisition is carried out simultaneously by

all these subsystems, which are described in more

detail in the following.

2.2 3-D PTV: Free surface flow

In order to acquire stereoscopic image sequences of

the free surface flow, two CCD-cameras (Pulnix TM

6701 AN) are mounted on the left and right side of the

flume, viewing the center of the channel in upstream

direction through the glass windows (Figure 3). The

optical axes of the two cameras enclose an angle of

about 90 degrees, maximizing the size of the stereo

volume (about 5 cm in all directions), which is viewed

by both cameras.Two glass prisms filled with water are

attached to the channel side windows to make the opti

cal axes of the cameras perpendicular to the air-glass

interface. In this way, refraction effects of the optical

rays passing the multimedia interfaces are minimized.

Three halogen lamps are used to illuminate the stereo

volume from above the water surface. Visualization of

the flow is provided by small air bubbles suspended in

the water.

To enable particle tracking at large flow velocities,

the frame rate of the cameras must be high enough

to keep the displacements of the particles between

Figure 3. Top view of the stereo camera setup for 3-D PTV

above the gravel layer. The cameras view the channel in

upstream direction through water-filled glass prisms attached

to the channel side walls. successive images within certain limits. For standard video capturing, the Pulnix TM 6701 AN delivers images of 640 by 480 pixels at a frame rate of 60 Hz. However, the camera also offers a partial scan mode, reducing the image size to 640 by 200 pixels, but increasing the frame rate up to 125 Hz. This mode has been used for the measurements. The acquired image sequences have to be stored in the computer memory before they are written to a harddisk. Thus, the maximum duration of one stereo image sequence of the free surface flow is about Δt= 20 s, limited by the PC memory. 2.3 3-D PTV: Pore flow Flow measurements inside three single pores of the gravel layer are carried out using three miniaturized endoscope stereo setups. The basic principle of these setups is the same as for the free surface flow, namely to acquire stereoscopic image sequences of the flow field inside the pore volume by viewing it from two different directions. Two flexible fiber-optic endoscopes of 2.4 mm diameter are attached to an adapted artificial gravel pore made of grains fixed to each other (Figures 4 and 5). Illumination of the pore volume is provided by an optical fiber-bundle guiding the light from a halogen cold light source into the pore. The purpose of the artificial pore is to hold the endoscopes and the illumination fiber at a fixed relative position and to keep surrounding grains in the gravel layer from blocking the endoscope view. To perform flow measurements, the three artificial pores are embedded in the gravel layer at different positions (Figure 6). A solution of tracer particles is added to the flow upstream of the pores, and particle image sequences of the two different endoscope views are recorded simultaneously. Figure 4. Endoscope stereo setup. For velocity measurements in the gravel layer, this stereo rig is attached to the artificial pores, viewing the pore volume inside.

The size of the observation volume inside the pores is about 5 mm in all directions. Since the tracer particles cover this small volume very rapidly, the cameras must have even higher frame rates than in the case of the free surface flow. Hence, two of the three artificial pores are equipped with high-speed Megapixel CMOS-cameras (Photonfocus MV-D1024). These cameras allow to read out only a region of interest on the sensor, which has been set to a size of 184 by 184 pixels. Zoom optics are used to fit the endoscope image to this image size on the sensor.

By decreasing the image resolution in this way, a maximum frame rate of 400 Hz can be achieved. The third endoscope setup is working with standard CCD cameras running at 50 Hz. This setup can only be used in the lowermost position within the gravel layer, where the flow velocities are expected to be lowest.

The image data of all three setups are written to RAID hard-disk arrays in real-time during the acquisition.Thus, the duration of the sequences is only limited by the RAID capacity. For a single measurement, a sequence duration of 60 s has been chosen.

Figure 5. Artificial gravel pore.

Figure 6. Installation of the three artificial pores in the gravel layer. 2.4 Sand movement Sediment movement is

detected by three rigid endoscopes (Figures 7 and 8), inserted into the flume from below. The effects of sediment motion are expected to occur at the gravel-sand interface. Goal is to record a sequence of two-dimensional images, which can be analyzed by optical flow techniques described below. Thus, the requirements of the endoscopic setup are:
- Observation of the process of sediment motion should be as contact-free as possible. Figure 7. Rigid endoscope for subsoil observation. The endoscope is inserted into a protection tube containing the illumination fibers, which can be seen at the corners of the glass window. Figure 8. Rigid endoscopes inserted into the flume from below to observe motion of sand grains.

- A large observation area is needed.

- A working distance of a defined distance should be

kept.

- Sufficient and homogeneous illumination should be

provided.

- The setup has to be reliable in the rough environment

of the flume.

In order to meet these demands, special protection

heads have been designed (Figure 6). With an aper

ture angle of 90 degrees and a viewing distance of

approximately 7 mm, a circular area of about 12 mm

in diameter can be observed.

Standard CCD-cameras (SONY XC-73CE) have

been used for image acquisition. Image sequences are

acquired at a resolution of 512 by 512 pixels and a

frame rate of 25 Hz. Thus a data thruput of approxi

mately 20 MB/s is achieved for all three endoscopes.

Image sequences can be written to a RAID system in

real-time during the acquisition.

2.5 Micro-pressure sensors

The micro pressure sensors were manufactured in a development cooperation of Aktiv Sensor GmbH (Berlin) and the Institute for Hydromechanics (IfH). The principle of these in-situ micro-pressure sensors is based on the “piezoresistive” effect. The initial point is an element of silicium, with implanted resistances in its bending panel. Figure 9 shows a photograph of the encapsulated head of the pressure pickup and its flexible tube for pressure equalisation. The differential pressure is measured in reference to atmospheric pressure, here additionally with compensation of temperature. For water resistance, the housings of the sensors are encapsulated with slowly

Figure 9. Head of micro pressure sensor outside the flume

and above gravel d 50 =~10 mm. hardening epoxy resin and sealed up with clear varnish. The maximal dimensions of the sensors are as small as 2× 1.2× 1.2 cm 3 , with a shape similar to a bigger gravel grain. Due to signal conditioning by the purpose-built amplifier the guaranteed maximum measurable frequencies are 100 Hz. Hence, measurements of pressure fluctuations up to the estimated Kolmogorov-scale-frequency of 50 Hz (Nezu et al. 1993) is possible. To avoid aliasing effects, the measurements are performed at a rate of 500 Hz. The absolute range of the pressure sensors is 0 to 6 kPa. Due to the analog-digital-card, the increment of discretisation is 1.5 Pa (0 to 6 kPa) or 0.7 Pa (0 to 3 kPa). The ready-built sensors were calibrated by Aktiv Sensor GmbH to 0 to 10V according to 0 to 6 kPa at pressure of 3 and 6 kPa with a tolerance in accuracy of less than 1.0% full scale. Figure 10 shows an example of a recorded signal. Pressure sensors are located at vertical positions of y/d 50 = 1.0 (above),

0.0 (at top) and at various positions within the gravel layer. Each three sensors are adapted on three artificial gravel pores to gain simultaneously insight in pressure and velocity. Simultaneous measuring was performed by up to ten pressure sensors over two minutes. The sensors are locally fixed on a grid as shown in Figure 11. Figure 10. Pressure signal [Pa], τ 0 /τ cr = 0.1, τ cr = 6.8 Pa, H A /d 50 =~21, H P /d 50 =~20, no hydraulic contact between gravel and sand layer. Figure 11. Positioning of two sensors on a lattice (see dimensions of a floppy disc).

3 DIGITAL IMAGE PROCESSING

This section gives a very brief introduction to the digi

tal image processing techniques that are used to extract

velocity information from the image sequences. For

more information, the reader is referred to the refer

ences given below.

3.1 3-D PTV

In order to extract 3-D velocity information from the

image data, the stereo sequences are processed by a

3-D PTV algorithm. In the first step of the algorithm,

individual particle images are identified and tracked

from one image to the next throughout both image

sequences. The result of this step is a coordinate list

of the 2-D particle trajectories in the image planes. In

the second step of the algorithm, stereo correlations

between the 2-D trajectories are established. Finally,

if a unique correspondence of two trajectories in the

left resp. right image plane has been found, the 3-D

world coordinates of this particle trajectory are cal

culated by triangulation of the corresponding rays of

sight. More details about the image processing are given in (Klar 2001) and (Klar et al. 2002).

In order to establish stereoscopic correspondences between the images and extract metric information, i.e. the 3-D particle coordinates, it is necessary to perform a geometric calibration of the stereo system before the measurements are carried out. A special endoscope calibration setup is used to acquire images of a calibration target defining known 3-D coordinates.To provide the same optical conditions as in the measurements, the calibration images are recorded in a vessel filled with water. The mathematical model for all cameras is a standard pinhole-camera, extended by lens distortion parameters (Zhang 2000).The 3-D accuracy of the calibration has been determined by taking an additional view of the calibration target (not used to estimate the camera parameters) with known position and calculating the 3-D positions of the target points. The results have been compared to the known 3-D positions. The mean errors and their standard deviations are given in Table 2.

The values given in Table 2 provide only a rough estimation of the accuracy, since the latter is influenced by many factors, e.g. accuracy of feature extraction in the image plane, quality of fit result of the camera

Table 2. Errors of the 3-D coordinate calculation (endo

scopes). X and Y are the lateral, Z is the depth coordinate.

standard deviation (µm) 35 33 15 calibration and 3-D accuracy of the calibration target. A closer inspection of the accuracy will be part of future work. 3.2 Optical flow The main task of the image processing is to estimate the velocity of grain motion. Especially the flow and wave induced grain motion at the sand-gravel-interface is one of the targets of the flume tests in order to investigate the influence of the impounding pressure fluctuations on the underlying sand bed and the actual filter stability at the interface between sand and gravel. If erosion of sand grains were to be induced by turbulent flow conditions, the stability of the anticipated bed protection could be endangered (Davis et al. 2003). Taking the submerged soil under shallow water conditions as an unsaturated pore medium into account, pore pressure fluctuations may easily destabilize protection measures. Especially pressure fluctuations caused by waves may contribute to enhanced sand bed erosion (Schwab et al. 2003). Towards this end, the apparent motion in the images, the so-called optical flow, is calculated. The structure tensor technique proved to be well-suited for this task. The main idea is the estimation of orientation in a 2+ 1 dimensional spatiotemporal brightness distribution, which is composed of the recorded sequence of the two-dimensional images. This method yields good results on highly textured image regions and for velocities of the order of one pixel per frame and below. Both conditions are met by the sediment image sequences. In addition to the velocity, the structure tensor method also provides a confidence measure. From

Figure 12. Example of an acquired image.

the 2-D displacement vector field other quantities can

be derived, such as divergence and vorticity. Figure 13

shows a snap-shot of the vector field. A summary of

the image processing is shown in Figure 14 in terms of

a flowchart. A detailed description of each image pro

cessing step is given in (Jähne et al. 1998). The appli

cation of image processing to the analysis of particle

movement is explained in Spies et al. (1999) in detail.

Figure 13. Example of a displacement vector field. Arrows

express sediment motion occurring especially at the top of

the observed area.

Figure 14. Image processing flowchart. 4 FIRST RESULTS In this section, some results obtained with the presented setup are discussed. These results are part of an extensive series of measurements (see Detert et al. 2004) which are still in progress. Therefore the results shown here have to be considered as preliminary examples, showing the potential of the measurement techniques. A comprehensive analysis of all results will be given in a later publication. In the discussion, the following (right-handed) coordinate system will be used: x: coordinate in streamwise direction, increasing in flow direction y: vertical coordinate, origin at the gravelwater-interface z: spanwise coordinate, origin at the centerline of the flume In all experiments, the spanwise position of the artificial pores is at the centerline of the flume (z= 0). The basis for the further data analysis and reduction consists of three types of data, which are obtained simultanesously with the presented techniques: - 3-D Lagrangian flow trajectories inside the three artificial pores and in the free-surface flow straight above one of the pores, - 2-D displacement vector fields in three vertical planes at the gravel-sand interface, - time series of the pressure at up to eight locations in the gravel layer. 4.1 Pore flow: 3-D visualization Figure 15 shows a 3-D visualization of a reconstructed flow field. The Lagrangian particle trajectories within a time interval of 0.5 s can be seen in the image. The trajectories reveal that the flow field inside the pore Figure 15. 3-D visualization of the particle trajectories inside the pore volume.

is really three-dimensional, which underlines the need

for a three-dimensional measurement technique.

4.2 Pore flow: Velocity time series

In this experiment, two of the artificial pores, have

been positioned at the uppermost position in the gravel

layer at y=-2 cm, i.e. 2 cm below the interface

towards the free surface flow. The separation between

the pores in x-direction was 25 cm. The pore volume

of one of the pores was in direct contact with the

free surface flow via an opening in vertical direction

(this pore is referred to as “open” pore in the follow

ing). At the other pore, this opening was covered by

a pebble, so there was no direct contact with the free

Figure 16. Time series of streamwise (u) and vertical (v)

velocity in the “open” pore. The horizontal lines indicate the

mean velocities.

Figure 17. Time series of streamwise and vertical veloc

ity in the “closed” pore. The horizontal lines indicate the

mean velocities. Note the change of scale in the ordinate as

compared to Figure 16. surface flow in vertical direction (“closed” pore in the following). An experiment has been carried out with a flow discharge of Q= 0.056 m 3 /s and a water depth of H A /d 50 = 20. These values correspond to a mean velocity in the free surface flow of about 0.3 m/s and 10 % of the critical shear stress for (gravel-)bed destabilization. Figures 16 and 17 show the first 30 s of the time series of the streamwise (u) and vertical (v) velocities inside the two pores. The time series have been calculated by spatial averaging of all velocity vectors inside the pore volume. The plots show the damping effect of the pebble covering the “closed” pore: the flow velocities inside this pore are significantly lower than in the “open” pore, in spite of the fact that both pores are located in the same vertical position at the gravel-water interface. The velocity fluctuations in the “closed” pore are also dampened: the standard deviations in the “closed” pore are approximately 50 % smaller than in the “open”

pore. 4.3 Pore flow: Power spectra of fluctuations In a second experiment, one of the artificial pores has been put in different vertical positions sequentially: y/d 50 = -2,-8 and-16. For each position, an image sequence has been acquired under the same flow conditions as in the experiment in section 4.1. Time series of the absolute value of the 3-D velocity have been calculated, again by spatial averaging of all the vectors inside the pore. Figure 18 shows the power spectra of the three velocity time series.The spectra show that the significant frequencies are in the range of 1 to 5 Hz. Further, at y/d 50 =-16, the amplitudes are roughly two orders of magnitude smaller than at y/d 50 =-2. Fluctuations in the pore flow are dampened with increasing depth in the gravel layer. Figure 18. Power spectra of velocity data obtained from different vertical positions in the gravel layer. The damping effect of the gravel layer is evident.

4.4 Sediment motion: Velocity time series

These analyses have been carried out with a wave

height (bottom to top) of approximately W B /d 50 = 15

and a wave-period of approximately 2 s. Wave genera

tion was started 40 s before data was taken. Discharge

rate was Q= 0.026 m 3 /s, water depth was H B /d 50 = 40.

There was no rubber mat placed in the flume. The

height of the granular filter was H P /d 50 = 10.

From the displacement vector fields a horizontal

and a vertical mean velocity can be obtained by aver

aging the components of the velocity vectors in xand

y-direction. The averaging was performed on regions

with a high confidence measure only. In Figure 19

(lower part) the components of the mean velocity are

plotted against time. Figure 19 (upper part) shows

the corresponding measured wave gauge. Obviously,

there is a correlation between wave gauge and mean

velocity. The time series of mean velocity consists of a

Figure 19. Time series of wave gauge and mean velocity of

sand grains.

Figure 20. Vertical mean velocities of sand grains in the

upper half of the recorded images in comparison with the

mean velocities in the lower half. superposition of an undulating periodic part and some outliers.The outliers result from individual sand grains moving especially in the upper part of the recorded images. Evidence for this is given in Figure 20, where the vertical mean velocity in the upper half is compared with the vertical mean velocity in the lower half. The presented results demonstrate the correctness and accuracy of the used algorithm, which is confirmed by analyses based on simulated data. We would like to point out, that the analysed image sequence was chosen arbitrarily. A detailed analysis will follow in a later publication. 5 CONCLUSIONS An experimental setup for simultaneous flow and pressure measurements within and above a gravel layer covering a sand base layer in an open-channel flow has been presented.The flow fields at several positions within and above the gravel layer are analyzed using a multi-camera setup to acquire stereoscopic image sequences of the flow. Endoscopic imaging is applied to get optical access to the gravel layer. Another endoscopic setup is used to detect and quantify motion of sand grains in the base layer. Up to ten micro-pressure sensors based on the piezoresistive effect deliver time series of pressure data. All measurements are carried out simultaneously. To extract velocity information from the image sequences, digital image processing techniques are applied. A 3-D Particle-Tracking Velocimetry algorithm yields the Lagrangian particle trajectories inside three artificial pores and in the free-surface flow above one of the pores. Displacements of sand grains are calculated using an optical flow technique. The system is used to perform extensive measurements in an experimental flume under a wide range of flow conditions including surface waves. First results from an experimental study of the interaction between turbulent open-channel flow and the hydrodynamic reaction in the porous subsurface gravel layer have been presented. The damping of velocity fluctuations with increasing depth in the gravel layer is clearly reflected in the results. A spectral analysis shows that

the dominant fluctuation frequencies are in the range of 1 to 5 Hz. Future experimental work includes another series of measurements after the gravel in the measurement area has been replaced by glass beads of 1 cm diameter. Further, the influence of an obstacle on the gravel surface will be studied. The results of these experiments will be compared with LES-simulations (Stoesser et al. 2004) (glass beads) resp. LatticeBoltzmann-simulations (Davis et al. 2004) (obstacle), which are currently being carried out.

Bed load transport on arbitrarily sloping bed at low Shields stress:

preliminary experimental observations

S. Francalanci, E. Paris & L. Solari

Department of Civil Engineering (Florence)

ABSTRACT: Bagnold hypothesis is one of the fundamental assumption of many bed load transport model.

However the failure of the Bagnold hypothesis has been recently demonstrated. Based on this result an alternative

model has been proposed by Parker et al. (2003) for the

evaluation of bed load transport on arbitrarily sloping bed

at low Shields stress. In this work an experimental study to investigate the effect of relevant slopes on dynamics

of bed load transport, motion characteristics and transport dynamics of bed particles is carried out. Experimental

equipment and preliminary observations are presented and discussed in the context of verifying the theoretical

findings of Parker, Seminara, Solari (2003).

1 INTRODUCTION

One of the crucial aspect of any morphodynamic

model including therefore the complex topography

occurring in a gravel bed river, is to evaluate the sedi

ment transport when the bed is characterized by ‘steep’

slopes, such as near the banks and along the bar fronts.

The problem of evaluating bed load transport in the

case of gentle slopes under uniform equilibrium con

ditions has been widely investigated (see for instance

Ashida & Michiue, 1972, Engelund & Fredsoe, 1976,

Wiberg & Smith, 1985, Sekine & Kikkawa, 1992,

Nino & Garcia, 1994). In the case of steep slopes var

ious authors have proposed equations similar to the

ones derived for gentle slopes (Smart, 1984; Damgaard

et al., 1987) corrected through the introduction of an

empirical function depending on the local bed slope.

These analyses provide a deterministic description of

bed-load transport through two main steps.

In the first step an estimate of the average speed

of saltating particles is provided, either from a salta

tion model or, more simply, considering an equivalent

uniform translatory motion of particles in which the

effects of particle rebound are taken into account by

means of a bulk dynamic coefficient of Coulomb fric

tion. The latter approach, though it provides a more

schematic view of the particle dynamics, is suffi

cient to give an estimate of the mean particle veloc

ity in reasonable agreement with the experimental

observations.

The second step is devoted to the evaluation of the

average areal concentration of saltating particles, i.e.

the average volume of saltating particles per unit area. Evaluation of this quantity is not an easy task since the number of particles in motion is related to the spatial and temporal frequencies and on the intensity of near wall turbulent events. To overcome this difficulties many models rely on Bagnold assumption, according to which the areal concentration of particles in motion is such that the fluid shear stress at the bed must be reduced to the critical value corresponding to the incipient motion of bed particles. 2 THEORETICAL BACKGROUND The validity of Bagnold hypothesis has been questioned since the experimental work of Fernandez Luque and van Beek (1976) until the recent theoretical model proposed by Seminara G., Solari L. & Parker G. (2002) in which the failure of Bagnold hypothesis is theoretically demonstrated. Fernandez Luque & van Beek (1976) performed detailed observations of the dynamics of saltating particles at fairly low Shields stress and discussed the validity of Bagnold hypothesis: for values of the latter stress smaller than about 0.1 the assumption appeared to fail. Seminara G., Solari L. & Parker G. (2002), by means of a three dimensional generalization of Bagnold assumption, show that, for given particle Reynolds number and local longitudinal slope, Bagnold assumption can only be satisfied provided the local lateral slope does not exceed a threshold value, which depends on the applied

Shields stress.As the latter increases, the maximum lateral inclination allowed

for the occurrence of equilibrium bed load transport

decreases until to reach values ranging about few

degrees, well below the angle of repose. This failure

motivates the abandonment of the Bagnold constraint,

even for nearly horizontal beds.

Based on the experimental findings of Fernandez

Luque & van Beek, an alternative model for evalu

ating bed load transport on arbitrarily sloping beds

has been elaborated by Parker G., Seminara G. &

Solari L. (2003). This model, in which a three dimen

sional formulation of bed load transport is proposed,

preserves the overall structures of the Bagnolds for

mulation according to which the bed load layer is

described as a thin finite layer, at the base of which

the fluid shear stress is reduced to a value, denoted as

residual shear stress due to the transfer of streamwise

momentum from the fluid to the saltating grains. The

fluid shear stress at the bed drops to the critical value

for particle motion only when there is no motion (static

equilibrium), on the contrary when bed load transport

occurs, shear stress at the bed must be above the crit

ical value in order for the flow to be able to entrain

grains (dynamic equilibrium).

The Bagnold constraint is then replaced with

an Einsteins structure for entrainment formulation, according to which equilibrium of bed interface is dynamic rather than static, in that equilibrium is achieved through a balance between an entrained sediment flux and a deposited flux.

The analysis of Parker G., Seminara G. & Solari L. (2003) is here briefly summarized.

The vectorial bed load transport rate q^ made dimen sionless with Einstein's scale is given as

where §^=mean areal concentration of saltating par ticles made dimensionless with particle size D;

V^ P = layer-averaged mean velocity of bed load parti cles made dimensionless with the quantity √ (s- 1)gD where g is gravity and s relative density of particle.

The averaged particle velocity vector V^ P is obtained by imposing a vectorial balance between averaged active and resistive forces. The former are represented by drag force and the tangential component along the bed of the submerged particle weight; the latter inter prets the effect of interactions of particles with the bed and is estimated through a coefficient of dynamic friction.

The averaged concentration of particles in motion is determined from a generalization of the experimental results of Fernandez Luque & van Beek (1976). In

particular §ˆ appears to be in a quasi linear increasing

relationship with the excess of residual shear stress.

This quantity is represented by the difference between

the residual shear stress at the bed and the critical shear

stress for the onset of particle motion. The excess of
Figure 1. Plot of qˆ predicted from the theoretical model Parker, Seminara & Solari (2003) as a function of τ∗/τ∗ co for various combinations of streamwise and transverse inclination. residual shear stress maybe taken as a measure of the residual turbulent activity at the bed which appear to be responsible for the entrainment of particles into the bed load layer. In the following τ∗ is the dimensionless applied shear stress, and τ∗ co is the critical Shields stress for the onset of sediment motion in the case of vanishing longitudinal and transversal inclination, while the dimensionless excess of residual shear stress is denoted as τ∗ b − τ∗ co . As a summary of the model results, it is shown in figure 1 the dimensionless volume sediment transport rate per unit width for different values of longitudinal and transversal inclination. Moreover the fully nonlinear results of the entrainment formulation for bed load transport on a finite, arbitrary slope, are compared with the linear approximation to which the analysis reduces when the bed inclinations are sufficiently small. The linear and nonlinear formulations obviously yield the same result for the case of horizontal bed. But on sloping beds the intensity of bed load transport increases with the external applied stress faster than on horizontal beds, the more so as the longitudinal and lateral slopes increase.

3 EXPERIMENTAL ACTIVITY

In the present study it is investigated the bed load trans

port mechanism when transversal and longitudinal

slopes are not negligible and low values of the applied

Shields stress occurs. The general aim of such inves

tigation is to provide an experimental verification of

the theoretical model proposed by Parker et al. (2003).

The experimental activity is carried out as follows:

(i) preliminary set of experiments on a plane, fixed,

artificially roughened bed, with no transverse slope;

the channel is fed with uniform sediment; (ii) fixed bed

experiments with laterally tilted bottom and uniform

sediment; the longitudinal inclination is 5 ∘ , 10 ∘ , 15 ∘
,

while the transversal inclination is 5 ∘ , 10 ∘ , 15 ∘ , 20
∘ ,

combined together; (iii) set of experiments (a) repeated

with mobile bed.

4 EXPERIMENTAL SET-UP

The experimental set-up is characterized by different

layouts in the case of fixed and mobile bed; in this

paper experimental results are only presented for the

case of fixed bed.

4.1 Laboratory apparatus

The motion of saltating bed load particles is investi

gated in a free surface laboratory flume (figure 2).

The main apparatus consists of a tilting, recirculat

ing flume, 10 m long, 0.365 m wide and 0.45 m deep,

equipped for clear water flows up to 28 l/s and slope

adjustment up to 5 ∘ . In order to obtain higher bed incli

nations, a 2 m long 0.23 m wide plane has been built

inside the flume with inclination adjustable up to 15 ∘ .

Due to entrance effects the length of measuring reach

is only about 1 m.

The sediment particles are fed at a constant dis

charge by means of a sediment feeder.

Particle velocity field is studied through PIV (parti

cle image velocimetry), in order to measure the inten

sity and direction of the averaged velocity vectors.

A schematic representation of the fixed bed exper

imental setup is shown in figure 3. In particular, the

computer controls the digital camera and the illumi

nation system, for the acquisition of particle images,

through a timing control device; video images of bed

load particles saltating over the bed are taken from

the upper side of the flume and acquired by the frame

grabber. A collimated light source, located on a side

of the flume, illuminates the bed load layer, not inter

fering with free water surface. The interrogation area

has a length of about 0.5 m.

A mono-component laser Doppler anemometer has

been employed to measure both sediment particle

velocity and flow velocity distribution. 2.0 m Reservoir tank Glass-walled flume length = 10.00 m width = 0.365 m height = 0.45 m Centrifugal pump Electromagnetic flowmeter Adduction pipeline Adjustable support columns Manually operated valves for controlling flow discharge 3 m210 Horizontal scale for flume Arbitrarily sloping bed Particles feeder Measuring reach width = 0.22 m Figure 2. Laboratory flume. Figure 3. Fixed bed experimental set-up. 4.2 Particle properties The particles must satisfy the following requirements in all the range of investigated of bed slopes: mobility at low Shields stress; ratio water depth to particle size sufficiently high to allow particle

saltation, even in the case of high slope; relatively high friction angle thus allowing particles disposition according to a given transversal inclination. The selected material is represented by steel particles with a density of 7850 kg/m 3 , shaped like disks with almost uniform size of 3 mm of diameter and of 0.6 mm of thickness. 4.3 PIV system Measurements of particle motion are obtained through PIV technique, which is based on the following components: seeding, illumination, image recording and image processing. The seeding is based on particle tracers lightened from pulsating light and visible from digital camera: in the experiments the steel sediment particles act as tracers and their velocity is then measured. In fact, steel material is highly reflecting and so visible to the

camera, while the fixed bed is black dyed to observe

the particles moving on it.

The illumination system, with stroboscopic pulsat

ing light, is able to produce couples of lamp light

to acquire couples of images. The frequencies range

of couple images is of 0.5–5 Hz with a resolution

of 0.1 Hz, while the interframing time between two

images of a single couple is in the range 1–10 ms with

a resolution of 0.1 ms.

The digital camera for the image recording is

characterized by high resolution (max resolution

1360× 024 pixel), that allows to take images in which

single particle consists of a bulk of pixel, and a short

interframing rate, that allows to capture two images

in which particle tracers cover a relative small dis

tance into the bed plane. Both digital camera and

system illumination are controlled and synchronized

by a computer. The CCD (Charge Coupled Device)

plane is oriented parallel to the sloping bed layer. The

particle velocity measured field is the one projected

on the bed load saltation layer.

Image processing is carried out through a commer

cial software for PIV data analysis. In figures 4-5 a

couple of analyzed images are presented.

Figure 4. Image of moving particles a.

Figure 5. Image of moving particles b. 5 EXPERIMENTAL INVESTIGATIONS 5.1 Preliminary activity Preliminary experiments have been carried out in order to check the behavior of the experimental set-up and to define basic parameters such as equivalent roughness of fixed granular bed and critical Shields stress for the onset of sediment motion. The equivalent roughness of fixed granular bed has been evaluated in condition of fully turbulent flow and it appears to range around 0.8-1.2 times the particle diameter. The critical Shields stress τ* co for the onset of sediment motion in the case of vanishing bed slopes has been experimentally estimated to be about 0.03. Tests on the sediment mobility in the case of a streamwise finite slope have shown a reasonable agreement with the Shields value. Moreover preliminary tests have been performed on the PIV system. An example of particle velocity field obtained by means of PIV technique is reported in figure 6, in the case of a longitudinal inclination of 5 ∘ . Notwithstanding the experimental variability of the particles velocity field, due to the fact that there are relatively few particles in motion, it appears that on average the particle velocity is in agreement with the measurements obtained in the same condition with laser Doppler anemometer. 5.2 Experimental data Experimental data here discussed have been obtained during the first sets of experiments on a plane, fixed, artificially roughened bed, with no lateral slope. In particular results are referred to three sets of experiments in the case of longitudinal inclinations of 1.7 ∘ , 5 ∘ and 10 ∘ and for various flow conditions. As regards the liquid phase, measurements of flow discharge and flow velocity have been carried out by means of electro-magnetic flow meter and laser Doppler anemometer. In particular, for a given bed location, vertical velocity profile have been defined Figure 6. Particle velocity field (α= 5 ∘).

through at least 10 points along the flow depth. The

friction velocity u∗ and the bed roughness length ε

have been estimated via regression analysis assuming

a logarithmic velocity profile in the near bed region.

The experimental conditions and the results obtained

from the regression analysis are reported in Table 1 for

each slope S, together with the dimensionless applied

shear stress τ∗, estimated from u∗.

As regards the solid phase, feeding of sediments into

the channel was in dynamic equilibrium with the given

flow conditions. Input solid discharge was established

to match the maximum rate of particle leaving the

downstream end of the measuring reach, without any

deposition phenomena.The profile of particle velocity

within the saltation transport layer has been measured

with laser Doppler anemometer and a layer-averaged

value has been evaluated. Measurements of sediment

velocities and solid discharges for the flow conditions

in Table 1, are reported in Table 2.

6 DATA ANALYSIS

Mean value of sediment velocity, bed load transport

rate and mean areal concentration are presented and

compared with the theoretical results predicted by

Parker et al. (2003) and the experimental findings of

other Authors. Table 2. Sediment bed load transport and mean particle velocity in the experimental conditions. Figure 9. Dimensionless mean areal bed load concentration

(α= 1.7 ∘).

The dimensionless values of areal concentration

of particles in motion, estimated from the measure

ments of bed load discharge and particle velocity, are

reported in figure 9 and compared with the theoretical

ones, in terms of ratio excess of residual stress to τ* co .

This first set of data shows good agreement with the

theoretical model, and the particles velocity data are

in the same range of values observed by other Authors.

Moreover, experimental conditions with stream

wise inclination of α= 5 ∘ and α= 10 ∘ , and no trans

versal slope (ϕ= 0 ∘), are here analyzed. The flow conditions were adjusted to obtain values of the τ∗/τ∗ co ranging from 1 up to 4.

The measured values of particles velocity are well predicted by the theoretical model, as it can be noted from figure 10.

In figure 11 the measured values of bed load trans port rate are compared to the corresponding theoretical ones, for each different slope.

In figure 12 the values of areal concentration of bed load transport, evaluated from the experimental data, are compared with the theoretical ones.The agreement is quite good, and the relation between the areal con centration and the excess of residual stress is close to the linear one. 0 0.5 1 1.5 2 2.5 3 3.5 4 1 1.5 2 2.5 3 3.5 4 4.5 Parker et al. (2003) - 5 ° § ˆ (τ∗b −τ∗co)/τ∗co Figure 12. Areal bed load concentration (α= 5 ∘ , α= 10 ∘). The value of the coefficient of dynamic friction on a nearly horizontal bed has been fitted to different values ranging from 0.3 up to 0.6 to obtain a good agreement of the experimental data. This parameter may be influenced by the flow conditions. Further investigations are needed to clarify this point. Finally, the fitting of the experimental data with the theoretical line is very good and induces to predict the reasonable

validity of the model Parker et al. (2003) for bed load transport on arbitrarily sloping bed.

7 CONCLUSIONS

An experimental activity aimed to study the particle dynamics and bed load transport on arbitrarily sloping bed at low Shields stress has been carried out.

The effects of steep bed slope on dynamics of bed load transport are investigated to test the validity of the theoretical model proposed by Parker et al. (2003) and the reliability of available experimental data from other sources (Abbott & Francis (1977), Fernandez Luque & van Beek (1976), Nino & Garcia (1994)).

The experimental set-up, here presented, allows the measurements of sediment transport rate, particle velocity and field particle motion through PIV technique and laser Doppler anemometer. Preliminary activity has been devoted to determine the basic parameter such as critical Shields stress for the onset of sediment motion.

The first set of experiments, with a slope S= 3%, shows good agreement between measured particle velocities and the ones collected by other Authors.

The other sets of experiments, characterized by higher values of slope, seem to confirm the theoretical model proposed by Parker et al. (2003) in terms of prediction of particle velocity, concentration of particles

in motion and bed load transport rate.

Further investigation on particle dynamics will be

carried out by means of PIV technique.

The case of bed with both longitudinal and transver

sal inclination, considering also the case of mobile bed,

will be carried out in the future experiments.

ABSTRACT: The work focuses on the interaction between the solid (spherical particles) and the fluid phases

in the near-wall region of an open channel flow. In the experiments the velocity field is measured with a Phase

DopplerAnemometer. In comparison to the clear-water conditions, in the particle-laden flow the streamwise mean

velocity are reduced in the outer layer (y + > 20), while increased in the viscous sublayer; turbulence intensities

of both the streamwise and vertical velocity components are damped in the outer region, while enhanced in the

near-wall region. Particles are faster than the fluid at the wall and are slower than the fluid in the outer layer.

An original explanation to these findings is proposed, related to the mechanism of particle entrainment and

deposition. The damping of turbulence is explained as a conseguence of the momentum exchange between the

phases in the buffer region during the burst events. The quadrant analysis of the Reynolds stresses corroborates

this hypothesis.

1 INTRODUCTION

Several theoretical, numerical and experimental stud

ies have tried to model two-phase flows, but this is a

hard task whenever particle-particle interactions have

to be taken also into account (high particle concentra

tions).This is especially true for the near-wall region of

open channel flows, where the particle concentration

increases towards the bed. Early investigations, con

cerning the sediment transport in open channel flows,

accounted for particles by empirical changes of the

fluid streamwise mean velocity profile (Vanoni 1946;

Itakura & Kishi 1980; Coleman 1981), while expres

sions for the sediment concentration were obtained by

diffusive theories (e.g.Yalin 1972). Generally, the par

ticles are assumed as a passive scalar, for which the

velocity is assumed substantially equivalent to the fluid

velocity, except for the vertical component which is

given by the fall velocity. Refined measurements in

two-phase flows (Lyn 1986, 1988; Tsuji & Morikawa

1982;Tsuji, Morikawa & Shiomi 1984; Kulick, Fessler

& Eaton 1994; Kaftori, Hetsroni & Banerjee 1995;

Muste & Patel 1997; Best et al. 1997; Greimann, Muste

& Holly 1999), point out the modifications not only

of the fluid mean velocity profile, but also of the fluid turbulence intensity profile; it is also noticed a difference between particle and fluid longitudinal velocities (the particle velocity lag). In particular, for sediment-laden flows, Coleman (1986), Lyn (1988) (in the smooth bed regime) and Best et al. (1997), Muste & Patel (1997) (in the transitional bed roughness regime) have observed a decrease of the whole fluid velocity profile in comparison to clear water conditions. Coleman (1986) tried to explain such a reduction using two mechanisms; one due to “boundary roughness” and the other to “suspended sediments”, while Best et al. (1997) and Muste & Patel (1997) ascribed the velocity reduction only to the former. However, in the measurements over a rough wall at low particle concentration (as those by Best et al. (1997) and Muste & Patel (1997), it appears difficult to explain the observed downward shift of the velocity profile only through an enhancement in wall roughness. This suggests the existence of another mechanism of interaction, which could be related to the momentum exchange between the solid and the fluid during the particle settling and suspension. As far as the effect of particle presence on turbulence characteristics is concerned, the first theoretical attempt of explanation was made by Owen (1969)

who defined the particle relaxation time ($t^+ = \rho_p d_p^2 / 18 \rho_f \nu_f$, according to the Stokes' law), and suggested that small particles, which have a relaxation time smaller than the characteristic time of energy-containing eddies ($t_e = l/\sigma_u$, where l is the integral length-scale, which is proportional to the distance from the wall and σ_u is the measured turbulence intensity at the same distance), follow the flow with some delay which causes damping of turbulent fluctuations; on the other hand, "large" particles (i.e. having $t^+ >> t_e$) can enhance the turbulent intensity. Even if there is an agreement between the different authors as far as the logarithmic region is concerned, the behaviour for $y^+ < 10$ remains unclear, as also the dependence on the particle concentration and size.

Moreover, the particle dynamics and the mechanisms of entrainment and deposition have been related to the dynamics of the burst-sweep cycle which characterises the near-wall turbulence (Grass 1974; Sumer & Oguz 1978; Sumer & Deigaard 1981; Niño & Garcia 1996; Shen & Lemmin; 1999). The main conclusions of the experiments and numerical simulations concerning the relation between particle lifting and the bursting phenomenon are that the bursting process is effective in entraining particles, giving rise to fluc

tuations of the local concentration in phase with the burst-sweep cycle, as reported by Shen & Lemmin (1999). However the dynamical interaction (momentum exchange) between the two phases during the burst-sweep cycle and the effect of particle size and concentration must be also investigated and it is one of the aims of the present work.

2 EXPERIMENTAL SETUP

2.1 The facility

A closed-circuit rectangular Plexiglas open channel is used with the axes aligned along the streamwise (x), vertical (y) and spanwise (z) directions. The channel dimensions are 3 m along x, 0.1 m along z with a free surface height, h, equal to about 0.02 m (Figure 2). The channel is inclined by a traversing mechanism which allows the channel slope, i_f, to be fixed with an error of±0.05% (the effective slope measured with the 100μm and 200μm particles ranges between 0.70% and 1.5%); this slope was measured at rest by means of water level staffs at four sections along x and at three locations along z in each section. The measurement system consists of a Phase Doppler Anemometer (PDA), which employs the green and blue light of a 2 W Laser scattered from the tracers. The PDA enables one to obtain both the velocity (as an usual Laser

Doppler Anemometry (LDA) system) and the size of

particles from the phase difference of the Doppler

signals between photo-receivers placed at different Table 1. Experimental conditions for the five runs performed. h U f u ∗ (d p) (cm) (cm/s) (cm/s) (µm) C av Re Fr 2.3 clear water 63 3.10 – 0 14500 1.3 2.3 low conc. 57 3.40 100 1.6 14500 1.18 2.3 high conc. 63 3.59 100 4 15500 1.2 2.0 low conc. 60 4.15 200 1.2 12900 1.37 2.5 high conc. 67 3.78 200 3.8 16750 1.28 positions. Experiments were performed both for clearwater and for particle-laden flows; the test section was located at about 2.0 m downstream of the inlet section (x/h ~ = 100, where x starts at the inlet). Distilled water was used as the carrier phase seeded with polymer particles as tracers (mean diameter 12µm, density 1.05 g/cm 3), whereas two glass spherical particle sizes (mean diameter 100µm and 200µm, density 2.6 g/cm 3) were used as the solid phase. The average volumetric particle concentration (C av) in sedimentladen flow was evaluated by weighing particles and water; it was in the order of 10 −3 . Profiles of the vertical distribution of the solid particle concentration have been measured for the two size classes (not shown); the experimental data reasonably follow the Rousean distribution and this could be an indication that the suspended particles are in equilibrium conditions (Vanoni 1946). 2.2 The experiments The experiments were conducted in uniform flow conditions, at Reynolds numbers Re=U f h/ν f (where U f is the depth-average streamwise flow velocity) ranging from 13000 up to 16500. For each experiment, the flow depth ranges from 2 cm to 2.5 cm about, thus the width to depth ratio is quasi-constant, ranging from 4 to 5. It is important to point out that all the experiments were performed with Froude numbers, Fr, larger than one (supercritical regimes). These conditions were selected after observing that for the sediment-laden experiments when moving from the sub-critical to the super-critical regime the bed forms change from dunes to a plane bed configuration (without bed forms, see e.g. Yalin 1972). The experimental conditions for the clear-water and sediment-laden conditions acquisitions are summarized in Tables 1 and 2. For each experiment in sediment-laden conditions, the average volumetric concentration is between 1.2 ∗ 10 −3 and 1.6 ∗ 10 −3 ; the bed is only partially covered by the solid particles. This fact strengthens the opportunity to compare the sediment-laden flow with the clear water on a smooth rather than on a rough

wall; therefore, the origin of the vertical axis is taken exactly at the wall for all the experiments (clear-water and particle-laden experiments).

All the results will be presented in a dimension less form by using wall variables. The evaluation of the friction velocity (that is the shear at the wall) is one of the crucial problems in near-wall flow measure ments. As pointed out by Muste & Patel (1997), small variations of it strongly affect the plot of the mean velocity. Therefore, special care is given to determine this velocity.

The uncertainty in friction velocity depends on the evaluation method used; two possibilities have been considered (the logarithmic law was not used because in a two-phase flow the value of the von Karman constant could be a priori unknown):

- to compute the wall shear from the momentum

balance equation

where γ f = ρ f g (g is the gravitational acceleration),

R h is the hydraulic radius and i f is the channel slope;

– in analogy with the method proposed by Harder &

Tiederman (1991), to compute the wall shear by the

Reynolds stress profile,

where c¯ (y) is the mean volumetric concentration at

distance y from the wall (u and v are used for the fluc

tuating velocity components, while u ′ and v ′ for the

rms values). In the previous relation, the viscous stress

term was not considered because the friction velocity

was determined by an extrapolation down to the wall of

the total stress measured for y/h> 0.1; in this region,

the viscous stress is negligible in comparison to the

Reynolds stress.

For the clear water conditions, the difference

between the two estimates of shear velocity is less than 3%, in agreement with Nezu & Nakagawa (1993). On the other hand, for the experiments with particles (sediment-laden flow), the difference is much higher (up to 15/20%). This difference, especially for high particle concentrations, could depend on extra terms that should be included in eq. (2); they consider the mutual interactions between solid and fluid phases and other contributions (Ishii 1975). Therefore, in sediment-laden flows the measured Reynolds stress profile does not necessarily follows the classical linear trend along the flow depth and the first evaluation was preferred over the second. 3 RESULTS 3.1 Mean velocity and turbulence To assess the reliability of the present measurements, a comparison with results given in the literature for the near-wall region of a single-phase flow has been performed (not shown), the measured data agreed satisfactorily with experimental results obtained by Laufer (1950), Karlsson & Johansson (1986) and Wei & Willmarth

(1989), at nearly the same Reynolds number.The clear-water data are acquired with exactly the same set-up used for the two-phase flow but without solid particles in the flow. In Figures 1, 2 and 3 the experimental values of the mean streamwise velocity profile U + are reported and compared with the linear , the “classical” logarithmic laws of the wall and the law of White (White 1974): For the particle-laden flows, the contributions of the solid and fluid phases are separated. The values of k ≈ 0.4 and B≈ 5.5 as proposed by Nikuradse, are assumed, d + is the dimensionless particle size. The figures show that the velocity profiles of fluid and solid phases decrease, if compared with the clear-water, similarly to the observations of Coleman (1986), Valiani (1991), Muste & Patel (1997) and Best et al. (1997). In the following the experiments in sediment laden conditions are examined and discussed. For the fluid phase, the decrease in the logarithmic region is almost independent of the distance from the wall and the von Kármán constant k remains equal to about 0.4. The effect of particles is also to erode the extension of the logarithmic law, from the bottom (i.e. the buffer zone) and from the top (i.e. the wake region). Moreover, the amount of the decrease is smaller than by assuming a wall roughness equivalent to the particle diameter, but, nevertheless, it is proportional to the particle concentration.

Figure 1. Mean velocity profile for the fluid phase.

tion©; 100µm particle laden flows at low concentration.

Figure 2. Mean velocity profile for the fluid phase. 200µm

particle laden flows at high concentration ⊗; 200µm particle

laden flows at low concentration .

A better insight into the kinematics of heavy par

ticles is achieved by considering Figures 3, 4, where

the streamwise velocity difference between fluid and

solid is plotted for the two particle sizes.

In the figures, the different values attained by the

Stokes number are also indicated; the Stokes num

ber was evaluated roughly estimating the characteris

tic time of energy containing-eddies by the relation

(Tennekes & Lumley 1972).

In a layer close to the wall (y + < 20), with an

extension almost independent of the particle size, Figure 3. Difference between mean velocity of the fluid and solid phases for the 100µm particles. High concentration ©, low concentration . The regions with different values of the Stokes number are indicated. The dashed lines represent predictions by the model of Greimann, Muste & Holly (1999).
Figure 4. Difference between mean velocity of the fluid and solid phases for the 200µm particles. High concentration, low concentration ⊗ . The regions with different values of the Stokes number are indicated. The dashed lines represent predictions by the model of Greimann, Muste & Holly (1999).
the particles are faster than the fluid (the difference between the two velocities is up to 0.4 u ∗). This difference is lower for the largest size particles,seems to be slightly dependent on the particle concentrations and is approximately constant when approaching the wall. Across the region 20< y + < 50 (the amplitude of this interval seems to depend on the Stokes number, i.e. on

the particle size), there is an abrupt change in the sign

of the fluid-particle velocity difference and the fluid

becomes faster than the particles (the velocity differ

ence is between 0.8 u ∗ and 1.2 u ∗). Here, the maximum

velocity differences are achieved; the 100µm parti

cles show a velocity lag that is about 1.3÷ 1.5 times

lower than the larger particles. This region is just the

one where wall-burst phenomena are stronger. Moving

further from the wall, in the region where the Stokes

number is smaller than 1/10, the fluid-particle velocity

difference decreases to zero.

The previous behaviour could be explained as fol
lows: far from the wall ($y^+ > 200$), the solid particles
follow quite accurately and immediately fluctua
tions of the fluid velocity field, being the time
scale for particle modifications (particle relaxation
time) much smaller than the characteristic eddy time
scale ($St << 1$). When moving closer to the wall
($20 < y^+ < 100$), where the velocity fluctuations are
larger than far from the wall (see next section), the
particles are not longer able to respond promptly to
the turbulent fluctuations, thus exhibiting an increas
ing deviation from the fluid velocity ($St \leq 1$). Such a
velocity lag can be explained if the particle motion is
associated to the dynamics of the wall vortical struc
tures. As reported in the model by Adrian, Meinhart
& Tomkins (2000), flow ejections are related to the
velocity field induced by a primary hairpin and repre
sent the dominating part of the near-wall dynamics
at these distances from the wall (Lu & Willmarth
1973). In this region, the particles are convected and
lifted up by ejections of low momentum fluid from
the wall region; due to their inertia ($St \leq 1$), they take
memory of such a low momentum, thus exhibiting a
velocity lag in comparison to the surrounding fluid.
In the very near-wall region ($y^+ < 10$), injections of

high momentum fluid dominate the wall dynamics;

high momentum particles are carried on the wall by

such events. These particles respond very slowly to

the local velocity field and, due to their inertia, they

retain their velocity which is higher than that of the

surrounding fluid (St > 1). This fact leads to the non

zero longitudinal mean velocity at the wall.This mech

anism is similar to that provided by Kulick, Fessler &

Eaton (1994) i.e. a transfer of momentum due to the

solid particles moving towards the wall from the faster

upper layer. The momentum exchange between solid

and fluid phase will be investigated in the next.

The dimensionless rms velocity fluctuations along

the streamwise and vertical directions are given in Fig

ures 5, 6, 7 and 8 together with the corresponding

clear-water profiles. For the streamwise component

(Figs. 5, 6), from the outer region down to $y^+ \approx 30$, the

fluctuations of both fluid and solid phases in particle

laden conditions are similar to those in clear-water;

only a very slight damping is noticed in this region for

both the size classes in comparison to the clear-water
Figure 5. Rms profiles of the streamwise velocity component for the 100μm particles, compared with clear-water measurements; solid symbols are for the solid phase and open symbols for the fluid phase, circles for high conc. experiments, square boxes for low conc.; ___ clear-water measurements. Figure 6. Rms profiles of the streamwise velocity component for the 200μm particles, compared with clear-water measurements; symbols as in Figure 5. profile, the damping being enhanced for higher concentrations.

Closer to the wall, these fluctuations are firstly damped (7< y + < 20) and then enhanced (y + < 7) in comparison to the clear-water profile by amounts that increase as the particle size and concentration. Accordingly to Owen (1969), the region where substantial modifications of the streamwise

Figure 7. Rms profiles of the vertical velocity compo

nent for the 100μm particles, compared with clear-water

measurements; symbols as in Figure 5.

Figure 8. Rms profiles of the vertical velocity compo

nent for the 200 mm particles, compared with clear-water

measurements; symbols as in Figure 5.

fluctuation profile are observed roughly corresponds

to t * > te or St > 1 (the intervals for the different val

ues of the ratio St= t * /t e are also reported in the

figures). It is important to notice that, in the present

particle-laden conditions, the streamwise rms veloc

ity of the solid phase is larger than that of the fluid, all

along the vertical profile.

For the vertical fluctuations in particle-laden con

ditions (Figs. 7, 8), down to y + ≈ 30 the damping in

comparison to the clear-water profile is stronger than for the streamwise fluctuations (more than 20%) for both size classes. In contrast to the horizontal fluctuations, substantial modifications of the vertical fluctuation profile are observed already for 0.1< St < 1. This is not what can be expected for rough walls, where velocity fluctuations in the outer region are enhanced rather than damped (Nezu & Nakagawa 1993; Krogstad & Antonia 1999); therefore, in the outer region the effect of the solid phase cannot be represented merely by an increased wall roughness. For y + < 30, a strong enhancement of vertical velocity fluctuations (dependent of the particle concentration) is noticed. Moreover, in particle-laden

conditions, while in the outer region the fluctuations of the solid phase are larger than those produced by the fluid, in the region $y+ < 30$ they are smaller. In order to explain these observations, it is necessary to follow the considerations previously outlined, i.e. that the solid particles are mainly driven by the fluid wall dynamics (mean field, as depicted in Figures 1…4). As a consequence, particles carry momentum and momentum fluctuations from the regions where they are moving from. In this sense, the behaviour of the particles at a given distance from the wall is influenced by that of the fluid at another distance if there is a dynamic connection between the two; as pointed out in the dynamical model by Adrian, Meinhart & Tomkins (2000), this connection is particularly effective for $y+ < 200$. Therefore, if this point of view is admitted, in order to explain the behaviour of the turbulence intensity (fluctuating field) in the buffer and in the outer region ($y+ > 20$), the behaviour in the very near-wall region cannot be neglected. Providing that the intense fluid ejections from the inner wall region lift up the solid phase, the differences in time scales between the fluid and the particles ($St \leq 1$) indicate that the latter retain the low momentum and the high velocity fluctuations experienced by the fluid during the bursting events. This circumstance could explain why in the outer region the particle rms fluctuations are systematically larger than those of the fluid, along both longitudinal and vertical directions. Nonetheless, fluctuations are still smaller than in clearwater; this could be due to ejected lumps of fluid which have to spend part of their vertical momentum in order to overcome the gravity force and to lift up the solid particles. The longitudinal particle-fluid velocity differences suggest that, at the same time, a momentum exchange between the two phases in streamwise direction also occurs. The observation that in particle-laden conditions both the streamwise but especially the vertical fluid fluctuations are damped in comparison to the clear-water (in the outer region), suggests that this momentum exchange is more effective along the vertical. Owing to this momentum exchange, part of the turbulent kinetic energy produced during the bursting events is transferred to the particles and it is no more

at disposal of the turbulent diffusion process that takes

place in the outer layer.

The previous explanations of the observed results in

terms of fluid wall dynamics call for an investigation

of wall events using measurements of the Reynolds stress.

3.2 Reynolds stresses and quadrant analysis

In order to have a deeper insight onto the mechanisms specifically involved in particle motion close to the wall, the quadrant analysis of the Reynolds stress is performed (Lu & Willmarth 1973). In the following only the results for clear water, 100μm and 200μm low concentration experiments are reported, being the results for the other particle laden experiments ana logue. At each distance from the wall, the average contribution to the Reynolds stress of the i-th quadrant on the (u, v) plane can be evaluated as

where uv i(t) is the contribution of the Reynolds stress to the i-th quadrant, T is the acquisition time inter val and the function S is defined as S i (t, H)= 1 if |uv|i>Hu ′ v ′ and S i (t, H)= 0 otherwise (where |uv| i indicates the absolute value). The sum of contribu tions from all quadrants must be exactly equal to the total Reynolds stress. The threshold level H (defined in terms of the local rms velocity fluctuations u ′ and v ′ ,
which is a crucial parameter for such an analysis, has been changed between 0 and 1. The following results refers to the value H = 0.

Another average can be evaluated by computing the intensity of the i-th quadrant, i.e. by weighting the Reynolds stress with the time spent within the quadrant itself (T i):

where the sum of all contributions, 〈 uv 〉 , is now different from the total Reynolds stress; due to the time-weighting. The aim of the quadrant analysis is to achieve a deeper insight into the possible reasons for damping effects acting on the turbulence structure and on the mechanisms of entrainment due to the solid par ticles; from this point of view, the intensity of Reynolds stress is considered a better indicator than the average contribution.

In Figures 9, 10, 11, the quadrant profiles (obtained using eq. (5)) are shown for the fluid phase of the 100µm and 200µm particles at lower concentrations and compared to the result in clear-water conditions.

Figure 9. Profiles of intensity of Reynolds stress from each quadrant for clear water ; ..... , quadrant I; , quadrant II; -, quadrant III; , quadrant IV; —, whole Reynolds stress. Figure 10. Profiles of intensity of Reynolds stress from each quadrant for the fluid phase of the 100 µm particles and for the clear water. 100 µm particles:, quadrant II; ....., quadrant I and quadrant III; , quadrant IV; —, whole Reynolds stress. Clear water: —, quadrant II; quadrant IV. The results obtained in clear-water are in agreement with those of Lu & Willmarth (1973) for a smooth bed. The quadrant profiles for clear-water and sedimentladen conditions have a similar behaviour; however, all quadrant intensities in the sediment-laden profiles are enhanced for y + < 20 (similarly to rms and Reynolds stress profiles). In particular, close to the wall, the second (u< 0, v> 0) and fourth (u> 0, v< 0) quadrant

Figure 11. Profiles of intensity of Reynolds stress from each

quadrant for the fluid phase of the 200 μm particles and for

the clear water. 200μm particles:□, quadrant II; ....., quad

rant I and quadrant III; □, quadrant IV; —, whole Reynolds

stress. Clear water: —, quadrant II; quadrant IV.

events have intensities more than two times larger

than in clear-water conditions. As it is well known,

a second quadrant event corresponds to an ejection,

while a fourth quadrant to a sweep (Lu & Willmarth

1973). The crossover between the second and fourth

quadrants and between the first and third quadrants at

$y^+ \approx 20$ is almost unaffected by the particles. In the

region $20 < y^+ < 200$, there is an overall damping of

the quadrant intensities, which is especially apprecia

ble for the second quadrant (at $y^+ \approx 40$ about 30%).

The described effects are observed to increase with the

particle size and concentration.

As conjectured in the previous sections, the wall

dynamics phenomena have a complex interaction with

the solid particles; in particular, the flow ejections (sec

ond quadrant) are responsible for particle lift up and

are supposed to yield a significant part of their momen

tum to the particles. Thus, as observed, ejections are

expected to be damped in sediment-laden conditions,

whereas this phenomenon must be less effective for

sweeps (fourth quadrant).

For the outer layer the results are similar to those of

the logarithmic region.

So, summarizing, in the region 10< y + < 30 (and

on a lesser extent in the region 30< y + < 100), the

whole “coherent” averaged intensity of the fourth but

especially of the second quadrant is reduced in com

parison to the “incoherent” part; it decreases from

78% to 67% respectively for the clear water and

the 200μm particles (accordingly the “non-coherent”

averaged intensity increases from 22% to 33%). This

effect is consistent with the previously described phenomenon of a reduction in the intensity of fluctuations and Reynolds stress as a consequence of the fluid momentum loss due to particle lift up. 4 CONCLUSIONS Experiments were performed to analyse the effect of solid particles on the velocity field in near-wall turbulence. Glass spheres of diameters equal to 100 mm and 200μm, with a mean volumetric concentration equal to 10 −3 , were employed. The experiments were performed at Froude numbers larger than one (supercritical regimes) to attain a plane bed configuration (without bed forms); these conditions are different from those encountered in some practical applications where the regime is subcritical. The experiments were performed at a Reynolds number equal to about 15000 (based on the water height and on the average streamwise velocity), where data from other authors are widely available. The minimum distance from the wall at which measurements were made was equal to about 3 wall units, i.e. well inside the viscous sublayer. For sediment-laden flow, the mean velocity profile exhibits in the logarithmic and outer regions a noticeable decrease, increasing as the dimensionless particle size d + and the particle concentration, that is in agreement with the hypothesis of considering the particles as mostly standing on the wall and acting on the flow similarly to a rough

wall. The simultaneous increase of the profile in comparison to clear-water in the inner region ($y+ < 5$), leads to a velocity gradient normal to the wall for the sediment-laden flow which is smaller than in clear-water and to a non-zero velocity at a distance from the wall equal to about 2 wall units. This is a consequence of the "sliding and rolling" particle motion at the wall which also drives the surrounding fluid. Considering the differences between the velocity of the fluid and of the particles, it has been measured that this difference is negative (particles faster than fluid) close to the wall ($y+ < 20$), while it becomes positive (fluid faster than particles) further from the wall ($y+ > 20$). This change in the relative velocity occurs in the region where the particle relaxation time is of the same order of magnitude of the characteristic time of energy-containing eddies (Stokes number close to one), so that particles slowly respond to changes of the local fluid velocity. Moreover, in the same regions the interaction of particles with the sweep-burst cycle takes place; for $y+ > 20$, particles are convected and lifted up by intense fluid ejections (bursts) carrying low momentum fluid from the wall region (thus exhibiting a lower velocity in comparison to the surrounding fluid), whereas close to the wall ($y+ < 20$) fluid injections (sweeps) carry on the wall

high momentum particles (which retain their velocity

which is higher than that of the surrounding fluid).

The profiles of the rms fluctuations of the stream

wise and vertical velocity components are damped

in the outer layer (especially for the vertical compo

nent) while enhanced in the inner part in comparison

to the clear-water measurements. The results in the

outer layer are different from what expected for a

rough wall, where the rms fluctuations are observed

to increase over the whole layer; therefore, the mech

anism of particle-fluid interaction must be different

from a simple increased equivalent wall-roughness

due to particles. Moreover, in the experiments with particle-laden conditions, the streamwise rms velocity of the solid phase is consistently larger than that of the fluid all along the measured vertical profile. On the other hand, the vertical fluctuations of the solid phase are larger than those produced by the fluid in the outer layer while smaller in the region $y^+ < 30$. The momentum balance along the vertical reveals a significant momentum exchange between the two phases, particularly effective in the buffer region where bursts are intense; the present measurements reveal that this momentum transfer is predominant along the vertical direction. This exchange leads to a reduction of the turbulent energy production in the buffer region that is no more at disposal for the turbulent diffusion processes in the outer layer. This mechanism could, at least in part, explain the turbulent damping observed in the outer layer. These considerations are clarified by considering the dynamics of the near-wall structures which makes a connection between the behaviours in the buffer and outer regions ($y^+ > 20$) and those in the very near-wall region. In particle-laden conditions, for $y^+ > 20$, particles are lifted up by bursts, gain momentum from the fluid phase and carry fluctuations levels which are higher than those of the surrounding

fluid (but still lower than in clear-water). For $y^+ < 20$ sweeps carry particles with high rms velocities close to the wall and the observed fluctuations are even larger than in clear-water. In the last condition, the difference between particle and fluid fluctuations also depends on the presence of the wall which bounds the vertical fluctuations of the particles.

The question of particle-flow interaction is lastly addressed by separating the Reynolds stress intensity in "coherent" or "incoherent" events using the quadrant analysis. For "coherent" events, the second quadrant corresponds to ejections, while the fourth to sweeps; first and third quadrant events are referred as "incoherent". The quadrant analysis indicates substantial differences in particle-fluid interactions between the wall ($y^+ < 10$) and the buffer regions. For $y^+ < 10$, the intensity of ejection events (second quadrant) gains importance over sweeps in sediment-laden conditions (in comparison to clear-water). On the other hand,

Studies of sedimentation in a large-scale reservoir for power generation

T. Shinjo

Electrical Engineering Dept., Electric Power Development Co., Japan

Y. Fujita

River Basin Research Center, Gifu University, Japan

ABSTRACT: The initial total storage capacity of 327 Mm 3 of Sakuma dam reservoir in 1957 has been reduced

to 213 Mm 3 in 2002 due to sedimentation of 114 Mm 3 . In order to reduce flood damage in the upstream area

caused by the sedimentation, attempts to lower the riverbed is being continued by dredging and flushing with

river water. However, riverbed has not been lowered sufficiently, hence more efficient measures are required.

So, accumulated reservoir data of flow discharge, cross sectional surveying and grain size distribution were

examined to clarify actual state of the sedimentation. Results of the examination show that sediment concentration

is decreasing. Another results of sediment movement were compared with those evaluated from 1-D analyses

of non-uniform flows, indicating the efficiency of the sediment flushing. Accumulation curves of volumetric

changes of cross sections were obtained for individual grain sizes, which can express sediment movement in the

reservoir properly.

1 INTRODUCTION

The central part of Japanese archipelago has a large

amount of sediment yield and a large scale dam reser

voir for power generation, Sakuma Dam, is located there. The Sakuma Dam is constructed at middle reach of The Tenryu River, which flows southward to the Pacific Ocean through the Inadani Valley between the Central and Southern Japan Alps, starts from Lake Suwa located almost center of Japan. It has trunk length is 213 km and drains a catchment area of 5,090 km 2 . It also has a large river with a high flow volume. The Tenryu River Basin consists of strata from Paleozoic to Alluvium, and includes vis ible igneous, sedimentary, and metamorphic rocks. Because of its particularly steep topography accom panied by the fragile geology of the Median Tectonic Line, heavy rains and flood flows erode, discharge, and transport extremely large quantities of sediment. Figure 1 is a map of the Tenryu River Basin .

Dams constructed on the main course of the Tenryu River are, from the upstream end, the Yasuoka Dam and the Hiraoka Dam operated by the Chubu Elec tric Power Co. and the Sakuma Dam, Akiha Dam, and the Funagira Dam operated by the Electric Power Development Company (EPDC). There are 10 dams on its tributaries including the Miwa Dam and the Koshibu Dam that are operated by the MLIT. The total sedimentation rates (total sedimentation/total storage capacity) of two of these dams, the Ya suoka Dam and the Hiraoka Dam, were 80.1% and 84.9%* respectively in 2002,

and because there has been only a slight change in these numbers during the past 20 years**, it has been concluded that almost all of the sediment that flows down the Tenryu River and its tributaries flows into the Sakuma Reservoir. The Sakuma Dam located near the end of a narrow gorge directly downstream from the Inada Valley and about 70 km from the mouth of the river. A concrete gravity dam that is 293.5 m long and 155.5 m high, and has dam volume of 1.12 Mm 3 , it was completed in 1956. The water stored in the reservoir of the Sakuma Dam having initial capacity of 327 Mm 3 is used to generate electric power at the Sakuma Power Station (max. output 350 MW), producing more electric power than any other hydropower plant in Japan (approx. 1.5TWh/year). Part of the stored water is directly supplied to agricultural and industrial water users and to public water supply systems. Water that has been used to generate electric power at the Sakuma Power Plant is used again by five more downstream power plants (Sakuma No. 2, Akiha No. 1, 2, and 3, and Funagira, total maximum output 1.911 GW) and is also used to maintain the river's normal flow volume that includes water for agricultural users and public water supply systems. The average annual inflow water volume to

Figure 1. Location of the Tenryu River and a map of its

basin.

the Sakuma Dam is extremely high, at 5 Gm 3 /year,

and because of the river basin conditions described

above, this water carries a large quantity of sediment.

Therefore the total volume of sediment in 2002 reached

114 Mm 3 that equaled approximately 35% of the total

reservoir capacity of 327 Mm 3 , and was the highest in

Japan.

This paper reports first an outline of the sedimen

tation in the Sakuma Reservoir and countermeasures

taken to deal with this problem, and clarifies sediment

behaviors in the reservoir, including the results of a

study of the properties of the inflow of sediment and

effects of promotion of sediment movement (flushing

sediment with flowing water). This study is attempt to

use existing data and from the view point of river mech

anism towards future development of countermeasures

against of reservoir sediment.

2 SEDIMENT PROCESS OF THE SAKUMA

RESERVOIR

2.1 Volumetric changes in annual sedimentation

Figure 2 shows volumetric changes in annual sedi

mentation of the Sakuma Reservoir as change over the Figure 2. Volumetric changes in annual sedimentation of the Sakuma Reservoir. Figure 3. Change of the longitudinal profile of the riverbed in the Sakuma Reservoir. years of the inflow sediment volume, total accumulative sediment, and effective storage capacity. This figure shows that about 10 years after the dam was completed, large quantities of sediment continued to flow into the reservoir at a rate of 4.2 Mm 3 /year, but later, in years such as 1970 and 1983 when large-scale runoff occurred, quantities of sediment greater than 5 Mm 3 /year flowed into the reservoir, but the inflow sediment volume has tended to decrease, reaching an average of about 1.2 Mm 3 /year during the past decade. 2.2 Sediment process in the reservoir Figure 3 shows change of the longitudinal profile of the riverbed in the Sakuma Reservoir. The high water level of the reservoir is EL. 260 m (dam water level; 40 m), the low water level is EL. 220 m, (reference level of dam water; 0), and the available depth is 40 m. According to Figure 3, sedimentation has progressed gradually from the upstream end of the reservoir, and in about 1970, the delta shoulder formed near the EL. 236 m point approximately 18 km from the dam (below, distances represent distances from

the dam). During the winter of 1971-1972, the con

struction of the Shintoyone Pumped Storage Power

Station was accompanied by a decline of the water

level in the Sakuma Reservoir to below 220 m, flush

ing the deposited sediment, and by about 1980, the delta shoulder had formed not only near EL. 230 m, but also near EL. 220 at a distance of about 12 km. Since the Shintoyone Pumped Storage Power Station began operating in 1972, the Sakuma Reservoir has almost constantly maintained a water level higher than EL. 230 m. The elevation of the delta shoulder is fixed at approximately EL. 230 m as it was shaped in 1990, and upstream from the delta shoulder, sedimentation advanced forming a gentle sedimentation gradient, but the riverbed is almost unchanged upstream from the 30 km point. And beginning in 1991, as one of the sedimentation countermeasures described below, the reservoir level was lowered to a target level of EL. 232.5 m where it was maintained for about one month in the winter dry period, resulting in the delta shoul der advancing to about the 10 km point by 2002 while maintaining an elevation close to EL. 232.5.

2.3 Current countermeasures against the sedimentation***

At the Sakuma Dam, the following sedimentation countermeasures were implemented in order to “pre vent submergence of the land during flooding in the upstream river basin” because a large quantity of sediment was deposited in the reservoir, raising the upstream riverbed.

(a) Flushing operation with river water For 35 days from mid February to late March during the dry period, the water level in the reservoir of the Sakuma Dam was reduced, maintaining the water level at a target of EL. 232.5 m in order to form a natural river course inside and upstream from the reservoir, and to use the river water in this area to move deposited sediment below the effective capacity in the downstream part of the reservoir. The results of measurements show that between 1 M to 2 Mm 3 /year of sediment was moved.

(b) Artificial transport to the dead capacity of the reservoir A dredge was used to dredge sediment from the middle part of the reservoir, then the dredged sediment was transported and dumped at or below the effective capacity of the downstream part of the reservoir. The target was approximately 0.4 Mm 3 /year.

(c) Artificial removal from the reservoir Dredged sediment was used by quarry operators as concrete and asphalt aggregate and as sand for golf courses. The target was approximately 0.4 Mm 3 /year. But, of these sediment countermeasures, transport within and removal from the reservoir could only be applied in the middle part of the reservoir because of restrictions on the draft of barges. Because flushing operation is done during the dry season, the scale of runoffs that occur during that period is not large and it is difficult to move large particle size sediment in the river basin, so as shown in Figure 3, in the upstream river, the sediment has not been removed as the riverbed has fallen. 3 CHARACTERISTICS OF SEDIMENT INFLOW TO THE RESERVOIR Figure 2 shows that extremely small quantities of sediment flowed into the Sakuma Reservoir in the two years following 1961, 1970, and 1983 that were years when the annual sediment inflow was high. This is assumed to be the impact of measurement accuracy, but it is also hypothesized that the deposited sediment in the upstream river is excessively scoured by large scale runoffs that transport it all to the reservoir at one time, with the result that during the next two years, little sediment is carried down the river, lowering the quantity of sediment carried into the reservoir. Figure 4 shows the changes in annual inflow of water and sediment. The total annual water discharge has ranged from a little more than 3.0 Gm 3 /year to a little less than 8.0 Gm 3 /year since 1957 when the Sakuma Power Station began operating.The total sediment inflow volume was higher than 5.0 Mm 3 /year in 1961, 1970, and 1983, but the total annual water discharge in those years was approximately 5.5, 4.7, and

7.6 Gm 3 /year, and except for 1983 when the past maximum annual water discharge was recorded, the average value was not exceeded in 1961 and 1970. Inversely, in 1998 when the second highest annual water discharge of 7.5 Gm 3 /year was recorded, the total sediment inflow volume was low at 2 Mm 3 . In this way, the total sediment inflow volume is not necessarily large, just because the annual water discharge is large. And as shown in Figure 5, change over years is indicated by calculating the annual average inflow sediment concentration by dividing the annual sediment inflow volume by the annual water discharge. According to this, in 1961, 1970, and 1983 when the sediment inflow volume was high, the annual average inflow sediment concentration was higher than in was in the previous and following years, but the tendency for the annual average inflow sediment concentration to fall overall is conspicuous. It is, therefore, hypothesized that the sediment inflow volume at the Sakuma Reservoir will either be maintained or fall gradually in the future, as long as a phenomenon that sharply increases the inflow sediment volume does not occur.

Figure 4. Changes in annual inflow of water and sediment.

Figure 5. Changes in annual mean of sediment

concentration.

Figure 6. Correlation between annual sediment inflow

volume and annual maximum daily water discharge.

Because as shown by Figures 4 and 5, high corre

lation between the annual sediment inflow volume or

the annual average inflow sediment concentration with

the annual total water discharge cannot be counted on,

correlation analysis of the annual maximum of daily discharge, the annual maximum discharge, and the annual total of the daily average discharge equal to or above a stipulated value was performed. As shown in Figure 6, the results show the clearest correlation between the annual maximum of daily discharge and the annual sediment inflow volume. But as seen in 1999, there are years far from the regression line, so in the future, it will be necessary to carry out a detailed study of the governing flow volume of the sediment inflow volume. 4 CHARACTERISTICS OF SEDIMENT

MOVEMENT IN THE RESERVOIR 4.1 The particle size distribution of the deposited sediment As stated above, even though sedimentation countermeasures have been taken in the Sakuma Reservoir, the upstream riverbed has not fallen. To study this point, an attempt was made to clarify the state of movement of the sediment by studying the quantity of change of the particle size distribution and the lateral section of the deposited sediment. The particle size distribution of the deposited sediment was surveyed in 1979, 1980, 1981, 1983, 1988, 1992, 1995, 1997, 1998, and 1999, but the surveys up to 1995 were primarily carried out to clarify whether or not it is possible to effectively use the deposited soil as aggregate or as clay for ceramics manufacturing by sampling sediment on the surface, but there are details of the sampling locations that are not clear. However, the surveys of 1997, 1998, and 1999 were done by, according to the location, boring holes to a depth of 20 m, taking samples from the holes, and using them to measure particle size distribution by sieve analysis and by precipitation analysis in order to clarify the state of sediment deposition inside the reservoir. First, the depths involved in sediment movement were hypothesized based on the results of a sedimentation survey of the riverbed section. The results of a comparison of the lateral section shape of the same section in 1997 and 1998 that was made to obtain the deposition thickness or the eroding depth revealed that at locations where the delta shoulder had advanced, a maximum of 10 m of sediment or more was deposited, and that there are sections where encouraging sediment transport had caused scouring of about 8 m. But because the change in almost all the sections was within a range of 5 m, it was judged that the range of the sediment movement is limited to approximately 5 m from the surface, and assuming that the particle size distribution related to sediment movement can be obtained by averaging the data from the surface to the depth of 5 m, these are averaged in a case where samples are taken from multiple locations in a single section. The particle size distribution is shown at

Figure 7. Particle size distribution of sediment (1981, 83).

Figure 8. Particle size distribution of sediment

(1997, 98, 99).

representative locations for 1981 and 1983 in Figure 7

and for 1997, 1998, and 1999 in Figure 8.

Both figures show that the particle size distribu

tion generally coarsens with the distance upstream, and that the reservoir triggers classification action, but according to Figure 7, at that time, sedimentation in the range from the delta shoulder to the downstream 10 km location consisted of at least 95% silt. In Figure 8 on the other hand, the range to the 10 km location was not surveyed, so a comparison with the situation in this range is impossible. But while the fine particle near the 15 km point increases more than in it does in Figure 7, upstream from the 20 km location, the fine particle declined coarsening the material. It is hypothesized that this is a result of the movement of the fine particle from the upstream area by flushing operation that began in 1991.

4.2 Longitudinal changes in particle size distribution and critical particle size of incipient motion

To clarify the state of sediment movement inside the reservoir by flushing operation, a reservoir level of EL. 233 m and discharge of 150 m 3 /s that are the average water level and inflow volume during the period were set to calculate the traction force by a one-dimensional numerical analysis of the river course in 1981 and in 1997. Figure 9 and Figure 10 show the results of longitudinal changes in each size, 10%, 30%, 50%, 70%, 90%, and critical particle size of incipient motion. According to Figure 9, in part of the river downstream from the 30 km location in 1981 before beginning of flushing operation,

Figure 9. Longitudinal changes in each particle size and critical particle size of incipient motion (1981, 83).

sediment that was at least 90% particle size or less could be transported, and upstream from the 30 km point, sediment up to 70% could be transported, suggesting that flushing operation had adequately flushed sediment from the midstream to the upstream parts of the river. According to Figure 10 on the other hand, the range where sediment of 90% particle size or less could be transported was limited to the river up to the 25 km location, and even further upstream, it appears that sediment of about 70% particle size could not be transported. Although the effectiveness of flushing operation has declined a little from its initial level upstream under the impact of coarsening of the sediment, it can be counted on to continue to be adequately effective in the midstream part of the river. Therefore, it is assumed that although the traction force is adequate, the riverbed has not fallen upstream from the middle of the reservoir for the last few years, because such conditions have been created by the inflow of a quantity of sediment either higher than or equivalent to the quantity transported. It is also hypothesized that the actual quantity of sediment that is transported has fallen because as a result of rippling of the riverbed, the traction force that was calculated cannot effectively transport all the sediment. To clarify these points, the total quantity transported must be calculated in detail based on a sediment transport by particle size equation, but because this paper cannot discuss that question, it will be left as a challenge for the future. Turning to the second reason, it is highly likely that riverbed ripples of the lower regime were caused according to The Froude Number or the particle size. But in the case of the Sakuma Reservoir, there are

many sections where the ratio of hydraulic radius to

average particle size has reached the 10 4 order, exceed

ing the range of the existing riverbed ripple data, so a

judgement is impossible and we hope to observe and

clarify the actual way the riverbed shape was formed

as soon as possible.

A comparison of Figure 9 and Figure 10 shows

conspicuous coarsening of the sediment between the

10 km and 15 km locations, while inversely the fine

particle is higher from the 17 km to the 18 km locations than it is further upstream and downstream. In the latter part, the river flows from a slightly narrow straight part to a wider meandering part, and it is hypothesized that the fall in the flow speed deposits the fine particle and also alters the critical particle size incipient motion. Similarly, according to Figure 10, the percentage of silt and fine sand near the 22 km location rises, but this tendency is not shown by Figure 9. Nearby, a straight slightly narrow part of the river is directly linked to a meandering part that is equally narrow, so it is possible that the weir effect of the flow causes the increase of fine sediment, and it is assumed that this trend is con firmed only by extremely recent data because the flow properties now closely resemble the properties of the flow in a normal river as a result of flushing operation. It is necessary to deal with these matters by conduct ing a study with the effects of discharge during normal reservoir operation clearly separated from the action of flushing operation.

Among the surveys done in 1981 and 1983 and the surveys done in 1997, 1998, and 1999, there are only four cases where the same section was surveyed, and even in sections surveyed more than once, it is not pos sible to know if the same location was surveyed. It is,

therefore, difficult to state positively that the sediment has been coarsened. And because the number of data are limited, even in a case where multiple locations of a single section are surveyed, regardless of whether the locations are on the inside or the outside of a bend, the results are averaged and this is compared with the results of one-dimensional analysis. But it is necessary to do a detailed study of the effects of flushing oper ation, and we wish to undertake this challenge in the future.

4.3 Sediment transport of individual particle size class in the reservoir

The state of movement of sediment inside the reservoir was evaluated by particle size based on the particle size distribution and the quantity of section change of the deposited sediment in the previous part of this report.

4.3.1 Sedimentation volume of individual particle size class in the reservoir

In the Sakuma Reservoir, every year the volume of deposited sediment is measured after the runoff season, and the shape of the lateral section of reservoir and the quantity of sedimentation are reported to the Ministry of Economy, Trade, and Industry and to the Ministry of Land, Infrastructure and Transport. These section measurements are used to calculate the quantity of sediment by particle size for each section. Because in the Sakuma Reservoir, sediment is dealt with by transporting it within the reservoir and removing it from the reservoir as explained above, it is necessary to restore it to its condition before the sediment was processed by correcting the quantity removed from the reservoir and the quantity transported inside the reservoir according to the

measurement results. Therefore, the quantity transported within the reservoir and the quantity removed from the reservoir and dredging and disposal location data concerning these movements of sediment are extracted from work documents to calculate the quantity of sediment corrected for each section. But although a local quarry operator transported sediment out of the reservoir in 1981 and 1982, there were no work documents specifying the dredged locations, so it was impossible to compensate for effects. The previous paragraph also applies to the particle size distribution of the sediment used for the analysis. 4.3.2 Sediment transport of individual particle size class in the reservoir during terms of flushing operation and the other Figure 11 shows the longitudinal accumulation curve of sedimentation volume of individual classes that was obtained by accumulating the quantity of sedimentation for each particle size in each section calculated by multiplying the quantity of change of the section in 1981 and 1982 by the percentage of sediment at each particle size. Figure 12 shows the results of the same process for 1997 and 1998. Because it is assumed that except for extremely fine sediment, no sediment passes through a large dam such as the Sakuma Dam, the curves on these figures represent the quantities of sediment by particle size that have passed through each section during the same period. Because even in the case of fine sediment, it is possible to estimate the quantity that passes through if the turbidity at the dam site is measured, if the curves corresponding only to that quantity move upward in parallel, the quantity that passes through each section is shown. According to Figure 11, the accumulation curves of sediment volume of all particle sizes move upward to the right, and in 1981, the sediment flowing into the reservoir was deposited sequentially in the upstream direction. The quantity of inflow sediment with particle size less than 0.075 mm was extremely large and it was deposited in almost all parts of the reservoir, but it was conspicuous up to the 13 km location.

Figure 11. Longitudinal accumulation curve of sedimen

tation volume of individual classes, expressing their trans

ported volume (1981–82).

Figure 12. Longitudinal accumulation curve of sedimen

tation volume of individual classes, expressing their trans

ported volume (1997–98).

According to Figure 12 on the other hand, curves that fluctuate vertically match closely, indicating that there are alternating deposition and eroding zones. To take particle size of 0.85 mm or less as an exam ple, the accumulative deposition of this sediment rises abruptly near the 10 km location showing that sed imentation has advanced here, and this tendency is particular clear for the fine sediment. Upstream from that location to near the 20 km location, this quan tity falls, revealing eroding, and further upstream, after passing through a short part where sedimenta tion measures have been taken, there is almost no change in the accumulative quantity in any particle size upstream from the reservoir. This shows that in 1997, the sediment flowing into the reservoir had flowed downstream from the 25 km location without being deposited on the upstream riverbed. But the quantity that passed through clearly fell sharply from 1981. The increase in the quantity of deposition near the 10 km location is a result of the fact that most of it is fine sediment and the flushing operation had flushed out the small particle size sediment. Furthermore, the

Figure 13. Longitudinal accumulation curve of sedimentation volume of individual classes, expressing their transported volume (Dec. 2000-May 2001). Figure 14. Longitudinal accumulation curve of sedimentation volume of individual classes, expressing their transported volume (Jun. 2001-Nov. 2001). advanced sedimentation near the 22 km

location conforms with a part of the river where the traction force fell as also seen in Figure 10. In this way, a longitudinal accumulation curves of sedimentation volume by particle size class is a useful way to show the process of sedimentation inside the reservoir. And the great differences between the fluctuation of the curves in Figure 11 and Figure 12 reflects big differences in the quantity flowing in. For example while in 1981 and 1982 there were large runoffs, in 1998 and 1999, there were no large runoffs but the reservoir was operated by flushing operation. Next, the effect of sediment movement in the reservoir by flushing operation is clarified by the longitudinal accumulation curve of sedimentation volume of individual classes. The sedimentation survey in the Sakuma reservoir is carried out in November and May after flushing operation. Figure 13 shows that from November 2000 to May 2001. Figure 14 shows that from May 2001 to November 2001. It is clear that flushing operation is greatly effective to transport sedimentation. We approached same attempts in other

years, but the efficiency of flushing is invisible in some

case. This reason is supposed that intervals of around

200 m of cross section survey masked advanced dis

tance of sediment delta. So, we started to survey more

closely sediment delta by sound wave inquiry.

5 CONCLUSIONS

The process of sedimentation in the Sakuma Reservoir

was studied based on the results of past surveys. The

results have clarified the following points.

- The annual average inflow sediment concentration

in the Sakuma Reservoir is tending to fall.

- The annual sediment inflow volume at the Sakuma

Reservoir is closely correlated with the annual

maximum daily dischrge.

- A comparison of the particle size distribution of

the sediment around 1981 and around 1997 has

shown that upstream, the coarsening of the sediment

is conspicuous, revealing that the effectiveness of

flushing operation has fallen to some degree in the

upstream river.

- A comparison of the longitudinal accumulation

curves of sedimentation volume by particle size

class in 1981 ,1997, 2000 and 2001 clearly reveals

that the state of deposition of the inflow sediment

and the sedimentation inside the reservoir and state

of eroding differ sharply between the two periods,

clearly showing the effectiveness of the flushing

operation.

ABSTRACT: An experimental investigation was made to study the effects of bedload transport on super critical

flow and hydraulic jump in a rectangular channel. Experiments were performed in a stilling basin of rectangular

cross-section 500 mm wide and 3 m long. Uniform sands of

1.435, 4.05, and 5.555 mm and non-uniform sand

of 0.63 mm with different concentration were used in the experiments for various types of hydraulic jump with

Froude number ranging from 3 to 9. The results indicate that the sediment size and sediment concentration makes

no changes to the incoming super critical flow conditions and therefore, has no effect on the characteristics of

the jump (sequent depth, energy loss and length of jump). However, the incoming sediments are deposited in the

sub critical zoon (end of jump) and move downstream as bedload. The motion of the sediment is wave-like with

a mild slope at the front followed by a raised bed of nearly uniform thickness terminating into a step. This sand

wave performs a control section similar to the end sill in a stilling basin and keeps the hydraulic jump position

at the beginning of the basin. The thickness and the position of the front of this sand wave are expressed as a

function of upstream Froude number.

1 INTRODUCTION

Bed-load transport is a common occurrence in natural

and artificial streams.The transport of sediments along

rigid channels is of importance to the design and oper

ation of lined canals in irrigation practice and channels

in treatment works. In many engineering applications

with respect to sediment motion in rigid channels, bed

load is the predominant mode of transport and hence

has received the greatest attention. While the rate of

sediment particles transported by the flow is depended

on the flow characteristics; the present of sediments

can also change the structure and characteristics of the flow. Research on this interdependent relationship in both open channel and pipe flows has been well documented by Einstein (1942), Mayer-peter and Muller (1948), Bagnold (1966), Wang and Chien (1985). On the other hand, in open channel flow, the transition between supercritical and sub critical flow is characterised by a sharp rise in the free surface elevation, strong turbulence and splashing. It is an interesting phenomenon that has caught the imagination of many research workers since its first description by Leonardo da Vinci (1452–1519). The Italian engineer Bidon (1818) is credited with the first experimental investigation of this phenomenon. Since then, considerable research effort has gone into the study of this subject. Although the hydraulic jump has been investigated experimentally for nearly two centuries, little information is known of the sediment laden flow in the hydraulic jump. Turner (1973) induced a turbidity current undergoes a hydraulic jump by a change in bed slope in the contact of a canyon-fan transition. He showed that the conjugated depth of hydraulic jump in a turbidity current may be determined by: where R i is Richardson number defined by: in which y 1 and y 2 are upstream and downstream depth of flow, C is sediment concentration and U is mean velocity. Marcelo H. Garcia (1993) studied the characteristics of hydraulic jump in sediment driven bottom currents. He produced both the sediment-laden and saline fluid hydraulic jumps. He concluded that the saline and muddy hydraulic jumps have similar characteristics. A clear correlation between thickness of deposition and grain size of the sediment driving flow was observed. For similar inlet conditions, the cur

rents laden with coarser sediment generated thicker deposits. The most important effect of the change in flow regime was a marked reduction of the bed shear stress downstream of the hydraulic jump. Chanson (1997) developed a complete analogy between vertical plunging jet flows and hydraulic jumps in horizon tal channel with partially-developed inflow. His study showed that the relationship between bubble frequency and air concentration differs between hydraulic jump flow and plunging jet flow. In a plunging jet flow, the bubble frequency and air concentration are not related by a unique parabolic shape.

H. Chanson and Brattberg (2000) studied the effect of the air-water shear flow in a hydraulic jump. They concluded that with partially-developed inflow con ditions, a hydraulic jump is characterised by two air-water flow region with significantly different prop erties. In the air-water turbulent shear region, the void fraction distribution follows a solution of the diffusion equation and the bubble frequency profile exhibits a triangular shape with a maximum value. In the recirculation region, the air content increases toward 100% and the bubble frequency profile fol low a different trend which is related to a different air-water flow structure and bubble size composition.

Bergeron and Carbnneau (1999) considered the effect of sediment concentration on bed load roughness. They concluded that increasing sediment concentra tion induced a steepening of the near-bed velocity gradient that due to increase of shear stress and a cor responding increase of the roughness scale. Khullar et al (2002), on the basis of experimental study on the effect of suspended sediment on flow resistance have shown that the effect of suspended sediment on flow resistance is not the same in the both rigid and allu vial channel. They showed that in the absence of any noticeable change in bed form size the value of friction factor in alluvial channels is found to decrease with an increase in the suspended sediment concentration. In rigid boundary channels the friction factor value can decrease or increase with an increase in the value of the suspended sediment concentration.

This paper presents the results of flume experiments to investigate the experimental study of the sediment laden flow in a hydraulic jump. The results presented in this paper are expected to be useful in designing the stilling basins in the presence of sediment laden inflow.

2 EXPERIMENTAL SET UP AND PROCEDURE

Experiments were conducted in the hydraulic labo

ratory at Tehran University. Experiments were per

formed in a channel of glass sides and smooth bed, and of rectangular cross-section 500 mm wide and 9 m long. The downstream end of the channel is provided with a sediment trap and downstream tailgate to adjust the tail water depth. The supercritical inflow was initiated by a gate opening from an upstream head tank and the sediment was injected to the flow at the back of the gate. One uniform sand of 4.05 mm with different concentration was used in the experiments for various types of hydraulic jump with Froude number ranging from 3 to 9. For each Froude number, four sediment concentrations were produced. For each injection rate I, expressed in terms of mass rate, the corresponding volumetric concentration of sediment C simply is: Where Q is the water discharge and γ s is the grain specific weight taken as 2650 kg/m 3 .The experimental conditions are summarized as follows: • Uniform sediment diameters used: 1.435, 4.05, 5.555 mm • Non-uniform sediment diameters used: 0.63 mm • Froude numbers: 3, 4.5, 6, 7.8 and 9 • Sediment concentration: 0.16, 0.3, 0.4 and 0.5% 3 RESULTS For considering the effect of the sediment concentration on hydraulic jump, sediment concentration was increased in a number of experiments and the depths of flow before and after the jump was measured. In Figure 1 are shown the experimental results of the variation of y 2 /y 1 as a function of initial Froude number Fr 1 , for sediment with different size. This figure shows that the sediment laden inflow makes no changes to the ratio of the sequent depth of hydraulic jump. Effect of sediment concentration on relative energy loss is shown in Figure 2. In this figure is also shown theoretical line of relative loss. This figure also shows the sediment concentration has no change to the loss of energy. The variation of relative jump length Lj/y 1 as a function of initial Froude number Fr 1 , for different sediment concentration is shown in Figure 3. The results show that the sediment laden inflow makes no changes to the length of hydraulic jump. For considering the effect of the sediment size on hydraulic jump, sediment size was increased in a number of experiments and the characteristic of jump was measured. The result shows that the sediment size has no effect on parameter of hydraulic jump (Figs 4 to 6). As it was presented in the above figures, sediment transport, sediment size and their concentration in the range of present study in our experiments has no effects

Figure 1. Variations of conjugated depth of jump for differ

ent sediment concentration. Figure 2. Relative energy loss in a jump for different sediment concentration.

Figure 3. Length of hydraulic jump for different sediment

concentration. Figure 4. Variations of conjugated depth of jump for different sediment size. Figure 5. Relative energy loss in a jump for different sediment size. Figure 6. Length of hydraulic jump for different sediment size.

Figure 7. The position of the front of the sand dune wise

from the gate.

on the hydraulic jump characteristics. However, the

incoming sediments are deposited in the sub critical

zoon (downstream of jump) and move downstream as

bedload. The motion of sediment is wave-like with a

mild slope at the front followed by a raised bed of

nearly uniform thickness terminating into a step with

an angle equal to the submerged angle of repose of

sediment. The position of the front of this dune-wise

sand wave is almost unvarying in a certain flow and

sediment conditions but the ending step moves down

stream making a growing sand wave with a constant

speed which is related to the inflow sediment rate. The

position of the front of this dune-wise sand wave from

the gate is shown in Figure 7.

In this Figure, the length of the jump for clear water

and trend line for non-uniform sand are shown as a

dotted line and a straight line respectively. The above

figure implies that the position of the front of this dune

wise sand wave from of the gate equal to the length of the jump for three uniform sands (1.435, 4.05 and 5.555 mm). But in the non-uniform sand, sediment was finer than the other sands and transported further than the gate and movement to down stream channel like several dune.

This sand wave performs a control section similar to the end sill in a stilling basin and keeps the hydraulic jump position at the beginning of the basin. The thick ness of the front of this sand wave is functions of upstream Froude number. In Figure 8 the dimension less form of the experiment data compared with the theoretical height of the end sill. As it can be seen from the figure, there is a good agreement between the two sets of results.

The main variables that govern the thickness of the erosion wave in an open rigid boundary channel with deposited bed include hydraulic characteristics of flow such as the water depth, the flow velocity or the shear velocity and the bed slope, and the sedi ment characteristics such as grain size and initial bed

Figure 8. The thickness of the front of the sand dune wise.

Figure 9. Sand wave height as a function of specific energy.

thickness. Omid et al (2001) introduced a different non-dimensional parameter using upstream specific

energy. They showed that the sand wave height is a function of specific energy upstream of the erosion wave for sub critical flow and it determined by:

where h s is the thickness of the sand wave, d 50 is par ticle size such that 50% of particles are finer than this size by weight and E s is the specific energy upstream of the sand wave.

In this present paper, the relationship between the thickness of the sand wave and specific energy upstream the channel is studied for super critical flow and all the experimental data collapsed onto a single carve. The best formula to fit experimental data as shown in Figure 9 was found to be a simple power relationship between the relative thickness of the sand wave and non-dimensional upstream specific energy of the flow as:

In this picture the purpose formula by Omid for sub critical flow and the best trend line for all data of present paper are shown by dotted line and straight line respectively.

4 CONCLUSIONS

The effect of sediment concentration in the hydraulic jump in a rectangular stilling basin has been inves tigated experimentally for uniform sediment. The following are the conclusions:

• The results indicate that the sediment laden inflow

Can an internal hydraulic jump be inferred from the depositional record

of a turbidity current?

S. Kostic & G. Parker

National Center for Earth-surface Dynamics, St. Anthony Falls Laboratory, Minneapolis, Minnesota, USA

ABSTRACT: Turbidity currents emanating from a submarine canyon and debouching onto an associated

submarine fan often undergo an internal hydraulic jump near the canyon-fan transition. It is hypothesized here

that the sudden decline in bed shear stress due to an internal hydraulic jump leaves a clear signature in the

sediment deposit. This hypothesis is studied using the numerical model presented below. The experimental data

of Garcia (1993) on turbidity currents near a canyon-fan transition are used to verify the model. Numerical

experiments with input parameters similar to those of Garcia (1993) are designed in order to demonstrate that

under the right conditions turbidity currents mark the resulting sediment deposit in a submarine canyon-fan

system by leaving a detectible depositional signature at the location of the jump. The model is then employed to

investigate the characteristics of the depositional signature created by a generic field-scale turbidity current.

1 INTRODUCTION

Turbidity currents are a dominant driving mechanism

responsible for the genesis of submarine canyons and

associated fans. A typical canyon-fan configuration

is illustrated in Figure 1 (Pirmez, 1994). It encom

passes (a) a relatively steep-slope, narrow submarine canyon excavated by net erosive underflows and (b) a low-slope, fan-shaped submarine fan or abyssal plain placed by net depositional underflows. Submarine fans are either channelized or unchannelized. Here the case of fans traversed by distinct, well-formed channels is analyzed. The channels act to limit lateral spread of turbidity currents.

Decrease in slope in the downstream direction can cause a turbidity current to undergo an inter nal hydraulic jump near the canyon-fan transition. A hydraulic jump, internal or otherwise, is a zone of rather sharp transition from a high-velocity super critical flow upstream to a low-velocity subcritical flow downstream. In open-channel flow, a supercriti cal regime is described by the standard Froude number greater than a value near unity, while a subcritical regime corresponds to a Froude number less than a value near unity. In turbidity currents, the standard roude number is substituted by the densimetric Froude number.

Generally, supercritical flows exert a relatively high shear stress on the bed, whereas subcritical flows exert a relatively low shear stress on the bed. The sudden decline in bed shear stress due to an internal hydraulic

Figure 1. Typical configuration of a submarine canyon-fan

system. Amazon Canyon & Fan (from Pirmez, 1994). jump might be expected to leave a clear signature in the sediment deposit, e.g. turbidites, created by a turbidity current in the vicinity of a canyon-fan transition. The nature of the hydraulic jump and the resultant deposits have been the subject of speculation. Menard (1964) related the development of levees bordering deep-sea channels to the thickening of a turbidity current after a hydraulic jump.VanAndel & Komar (1969) interpreted the characteristics of sediment deposits in

Figure 2. Depositional signature left by a hydraulic jump.

The Oak Ridge Moraine, Canada (from Russell & Arnott,

2003).

enclosed basins in terms of the hypothesized occur

rence of a hydraulic jump. Mutti (1977) suggested that

turbidity currents undergoing a change in slope drop

excess sand due to a hydraulic jump, thus causing char

acteristic turbidites just downstream. Recently, Russell

& Arnott (2003) provided stratigraphic evidence of

hydraulic jump conditions in a subaqueous glaciola

custrine fan succession in the Oak Ridges Moraine,

southern Ontario, Canada (Figure 2).

Internal hydraulic jumps in sediment-driven flows

remain unobserved in the field. As for observation at

experimental scale, only a few studies are available

(Garcia, 1989, 1993; Lamb et al., 2004;Toniolo, 2003).

Garcia & Parker (1989) and Garcia (1993) induced a

hydraulic jump at a sharp change in slope, Lamb et al.

(2004) and Toniolo (2003) created a hydraulic jump

by ponding the turbidity current downstream.

The goal of the work reported here is to demonstrate how a numerical model can be employed to investigate whether a hydraulic jump can be really inferred from the depositional record. The experimental data of Garcia (1993) are used for calibration and verification of the numerical model. The model is applied to various scenarios of turbidity currents developing along a sloping bed at experimental scale. A field-scale simulation provides insight into the characteristics of a depositional signature resulting from a generic field-scale turbidity current.

2 MODEL FORMULATION

2.1 Geometric set-up

The numerical model presented herein is intended to simulate turbidity currents of constant width propagating along the bed of a canyon-fan system. The model allows for a bed of arbitrary geometry. However, in the numerical simulation at experimental and field scale shown bellow the initial bed profile is assumed to consist of an upstream portion with constant, positive slope joining continuously to a downstream portion that is horizontal. This bed configuration is illustrated in Figure 3. The sloping upstream portion represents a

Figure 3. Experimental set-up. loose surrogate for a submarine canyon, and the horizontal downstream portion is a loose surrogate for a submarine fan or abyssal plain. 2.2 Governing equations A dense bottom underflow propagating

along a canyon-fan system can be described by the following set of single-layer, layer-averaged equations in dimensionless form: where t^= tU 0 /h 0 , x^= x/h 0 , v^ s = v s /U 0 , h^= h/h 0 , U^ =U/U 0 , C^ =C/C 0 , η^= η/h 0 , t= time, x= bedattached downslope distance, h= turbidity current thickness, U = layer-averaged current velocity, C = layer-averaged concentration of suspended sediment, and η= elevation of the bed. h 0 and U 0 are respectively the current thickness and velocity at the canyon head. The formulation contains the following dimensionless parameters: Frd 0 = densimetric Froude number at the canyon head, c D = bed friction coefficient, r 0 = an order-one multiplicative constant, C 0 = suspended sediment concentration at the canyon head, e S = sediment entrainment coefficient, v^ S = fall

velocity of sediment, S i = initial bed slope, and

λ= sediment porosity.

The densimetric Froude number Frd 0 expresses the

ratio of inertial to buoyancy force at the canyon head,

and is given by

where g is gravitational acceleration, and R is the sub

merged specific gravity of the sediment (=1.65 for

quartz silt).

The entrainment of sediment into suspension by

turbidity currents is here estimated from the model

of Kostic & Parker (2003), which accommodates

different formulations for numerical simulations at

experimental and at field scale. The model is adapted

from the relations by Garcia & Parker (1993), and

Wright & Parker (in press). That is, the entrainment

coefficient e s takes the form:

where k is an adjustment coefficient, and a is a

constant, given as follows:

The adjustment of k at field scale is not a part of the

original relations, but is introduced here to account

for limits on the erodibility of the bed over which the

turbidity current runs. In addition, Z is a similarity

variable, defined as:

In the above equation u * = shear velocity due to skin

friction, Re p = particle Reynolds number, S f = friction

slope, and α 1 , α 2 , α 3 = parameters, given by: with D=median grain size of the sediment, ν= kinematic viscosity of water, and Frd = densimetric Froude number. Finally, the fall velocity v S is a function of particle Reynolds number. Here it is calculated from the relation of Dietrich (1982). The details on the dimensionless analysis can be found in Kostic & Parker (in prep.). It is useful to note from Eqs. (1)–(14) that any characteristic parameter Y of the flow field of an underflow emanating from a submarine canyon and debouching onto an associate fan can be expressed as a function of the following dimensionless parameters: In the work reported here the ratio u * /v s is replaced by the bed Shield number τ * which characterizes the degree to which the flow can mobilize the bed sediment. It is defined as 2.3 Initial and boundary conditions Initial and boundary conditions for the numerical model are discussed in detail in Kostic & Parker (in prep.). At t= 0 the dependent dimensionless variables h, U and C at all nodal points are set equal to 1. The initial bed elevation for every grid point is determined from a prescribed initial slope S i . Because of the hyperbolic nature of governing equations, the number and location of physical boundary conditions correspond to the number and location of characteristics that propagate into the flow domain (Kostic & Parker, 2003a). For the supercritical inflow boundary considered here, which corresponds to a high-velocity flow near the head of a canyon, three boundary conditions needs to be formulated, that is while the outflow BC’s take the form

where η 0 is an antecedent bed elevation as yet unmodi

fied by the turbidity current, and s denotes the position

of the turbidity current head in a deforming grid.

Once an underflow covers the prescribed length of a computational domain, no physical boundary condition is required for either supercritical or subcritical flow unless a downstream control is imposed there. This is indeed the case in the numerical simulations at experimental scale that follow. In the experiments of Garcia & Parker (1989) and Garcia (1993) the condition of a critical densimetric Froude number at the outflow boundary needs to be imposed to account for a free outfall (Figure 3).

The remaining variables are calculated from the flow domain by means of first-order extrapolation.

2.4 Numerical scheme

The governing Eqs. (1–4), together with the initial and boundary conditions, are solved numerically by the explicit ULTIMATE QUICKEST method (Leonard 1979 & 1991), which is third-order in both time and space. The scheme provides a robust, mass conservative formulation that is capable of dealing with highly advective transport and complex boundary conditions. More comprehensive consideration of the algorithm can be found in Kostic & Parker (2003a).

3 NUMERICAL SIMULATIONS AT EXPERIMENTAL SCALE

3.1 Validation of the model

The numerical model is validated using experiments by Garcia (1993) on internal hydraulic jumps in turbidity currents driven by well-sorted sediment. The experimental flume is shown in Figure 3. It was 30 cm wide and 70 cm deep. A submarine canyon was modeled by a 5 m long inclined bed with a slope of 0.08 ($\theta = 4.6^{\circ}$), followed by a 6.6 m long horizontal bed that represented the associated abyssal plain. A free outfall at the end of the horizontal region acted as a downstream control. The currents were allowed to develop until a quasisteady state continuous flow was reached. As can be seen from Table 1, the inlet current thickness was kept at 3 cm. The corresponding flow rate per unit width was set at either 25 or 33 cm^2/s, yielding inlet velocities of 8.3 and 11.0 cm/s respectively. The median grain size D of the sediment used to generate the turbidity currents was 4, 9, 30 and 65 μm. However, the underflows driven by 4-μm sediment are not of interest for the work presented here, since they were too fine to produce any noticeable deposit in the canyon-fan system during the designed run time. Inlet Reynolds numbers were always larger than 2700, ensuring turbulent conditions there. Additional input parameters include the estimated bed friction Table 1. Input parameters for the numerical model. h U D Run time

Exp. (cm) (cm/s) C x 10 3 (µm) (min) DAPER4 3.0 8.3 2.95 9 33 DAPER7 3.0 8.3 8.60 9 30 GLASSA2 3.0 8.3 3.39 30 30 GLASSA5 3.0 8.3 3.94 30 30 GLASSA7 3.0 11.0 2.66 30 30 GLASSB1 3.0 11.0 3.00 65 38 GLASSB2 3.0 11.0 6.00 65 27 GLASSB3 3.0 11.0 1.50 65 28 coefficient c D = 0.01 and the estimated sediment porosity λ= 0.5. Figures 4a, 5a and 6a demonstrate good agreement between measured and simulated streamwise variation in sediment mass deposited per unit bed area by turbidity currents driven by 9, 30 and 65 sediment respectively. Both the observations and calculations pertain to the end of each run. The best fit with experimental observations was attained with r 0 = 1 for the runs with 9 and 30µm. For the runs with 65-µm sediment the best fit was obtained with this multiplicative constant set equal to 2. These choices can be loosely justified by the sediment concentration profiles that appear to be more uniform in vertical in underflows driven by fine-grained sediment. Figures 4b, 5b and 6b show the numerical predictions of the interface elevation η+ h for turbidity currents driven by 9, 30 and 65µm respectively, while the Figures 4c, 6c and 7c illustrate how the corresponding densimetric Froude number F rd varies along the model canyon-fan system. Experimental data for the current interface and densimetric Froude number are not available. The numerical results support experimental observations by Garcia (1993), that can be summarized as follows: (a) Currents driven by 9-µm sediment are weakly depositional along the canyon and fan (Figure 4a). They reach the end of the model fan at x= 11.6 m. They are supercritical along the canyon, and subcritical on the fan, with a distinct intervening hydraulic jump (Figure 4b,c). (b) 30and 65-µm currents are strongly depositional, and create turbidites that display roughly exponential decrease in thickness with distance from the sediment source (Figure 5a, 6a). (c) 30-µm currents reach the end of model fan, while continuously decelerating and thickening after the slope break (Figure 5b). They do not show evidence of an internal hydraulic jump (Figure 5c). (d) 65-µm currents rapidly disintegrate before they reach the end of the model fan (Figure 6b,c). 0 1 2 3 4 0 8 12

hydraulic jump (c) Densimetric Froude number. According to the numerical predictions, they die out when the layer-averaged concentration of suspended sediment drops to below 0.1% of the inlet value, e.g. at the distance x= 5.38 m for run GLASSB1, x= 5.37 m for run GLASSB2 and x= 5.95 m for run GLASSB3. These flows deposit too rapidly to display an internal hydraulic jump (Figure 6c), a result confirmed by Choi & Garcia (1995).

For the work presented here the most important

observation of Garcia (1993) is that the break in 0 1 2 3 4 0 8 12 Distance from Inlet (m) S e d i m e n t D e p o s i t (g / c m 2) GLASSA2, model GLASSA5, model GLASSA7, model GLASSA2, exp. This notwithstanding, the present numerical simulations of experiments that involved an internal hydraulic jump reveal a modest but clear depositional signature associated with a drop in shear stress right after the jump. This is manifested in terms of an upstream-facing “step” or thickening of the deposit from the upstream to the downstream side of the jump. For example, in the case of runs DAPER4 and DAPER7 the

simulated deposit mass per unit bed area shows an increase of 0.0053 and 0.076 g/cm 2 respectively across zone of the jump. 0 1 2 3 4 0 4 Distance from Inlet (m)

Figure 6. Turbidity current driven by 65-μm sediment: (a)

Depositional pattern (b) Water interface with an internal hydraulic jump (c) Densimetric Froude number.

A close inspection of the experimental data of Figures 4a, 5a and 6a reveals that the measurements of run DAPER7 contains such a depositional signature as well (Figure 4a). The step is near the numerically predicted size. In the case of run DAPER4, the predicted step is sufficiently small that it would not have been clearly seen in the data (Figure 4a). There is no evidence of a depositional signature in the data for the 30and 65-μm currents, which do not undergo a jump (Figure 5a, 6a). Therefore, the data and numerical results for run DAPER7 provide the first relatively clear hint that under the right conditions a hydraulic jump might leave a depositional signature. This hint is pursued in the numerical experiments below. 0 0.5 1 0 8 12 Distance from Inlet (m) S e d i m e n t D e p o s i t (g / c m 2) C0 = 0.0007 C0 = 0.00143 C0 = 0.00295 C0 = 0.00860 C0 = 0.014 0 0.2 0.4 0.6 0 8 12 Distance from Inlet (m) W a t e r I n t e r f a c e (m) C0 = 0.0007 (Frdo = 4.50) C0 = 0.00143 (Frdo = 3.15) C0 = 0.00295 (Frdo = 2.19) C0 = 0.00860 (Frdo = 1.28) C0 = 0.014 (Frdo = 1.01) 0 0.2 0.4 0.6 0.8 1 1.2 1.4 0 8 12 Distance from Inlet (m) B e d S h i e l d S t r e s s C0 = 0.0007 C0 = 0.00143 C0 = 0.00295 C0 = 0.00860 C0 = 0.014 4 4 4 Figure 7. Numerical experiments with 9-μm sediment: (a) Depositional pattern (b) Water interface with an internal hydraulic jump (c) Bed Shield stress. 3.2 Numerical experiments at laboratory scale Having found that the numerical model can reproduce the features of turbidity currents near the experimental canyon-fan transition reported by Garcia (1993), the model is now extended to a parametric study of hydraulic jumps.The details on this study can be found in Kostic & Parker (in prep.). Numerical experiments presented here,

however, aim to demonstrate how runs using the DAPER material (9μm) can under certain conditions can leave a noticeable depositional signature. In particular, the effect of suspended sediment concentration C 0 at the canyon mouth on the formation of an internal hydraulic jump and a corresponding depositional signature is elucidated below.

The model input parameters are: h 0 = 3 cm, U 0 = 8.3 cm/s, R= 1.65, run time= 40 min. The inflow volumetric concentration of suspended sedi ment is varied in the range 0.0007≤C 0 ≤ 0.014. The lower limit is intended to simulate a dilute underflow, and the upper limit is selected to describe an under flow with an inflow densimetric Froude number close to the unity.

Figure 7a reveals that denser turbidity currents tend to deposit sediment from their very inception, and are in general more erosive in the supercritical region, and more depositional in the subcritical region. An increasing drop in shear stress associated with the jump (Figure 7c) is responsible for a successively more pronounced depositional signature (Figure 7a). In addition, turbidity currents with lower inflow buo yancy flux are slower and thicker in both their super and subcritical regions (Figure 7b), with an internal hydraulic jump that forms further downstream of the

canyon-fan break.

An increased drop in shear stress and consequently

more noticeable depositional step can be also obtained

by changing some other dimensionless parameters,

such as e.g., by increasing the bed resistance c D , or the

initial canyon slope S i (see Kostic & Parker (in prep.)).

4 MODEL APPLICATION AT FIELD SCALE

It is useful to demonstrate how the numerical model

can be employed to investigate the qualitative and

quantitative characteristics of a depositional signature

at field scale. Therefore, a generic model reach is

designed to be representative of a canyon-fan system

in the field.

Froude similarity is used to scale-up the input

parameters associated with 9μm material (DAPER)

to field dimensions. That is

where the subscript “f” denotes “field”, and the sub

script “e” denotes “experiment”. Assuming that R

is the same in the experiments and the field, (22)

results in

with the scale ratios for length and concentration

defined as Here the length scale ratio is set to 300, and concentration scale ratio to 1. The field model thus has the following input parameters: h 0 = 9 m, U 0 = 1.4 m/s, C 0 = 0.003, R= 1.65 and c D = 0.0025. The canyonfan system is assumed to be 3.48 km long. The initial bed profile of the system has a break at 1.5 km, such that the bed slope upstream and downstream of the break is 4% and 0%, respectively. The grain size of sediment is set to 20μm. No

downstream control is imposed, so as to allow turbidity currents to propagate freely. Total computation time is 60 days of continuous flow. In the field, this 60 days would be divided into a series of smaller flow durations, e.g. a few hours or days, with long dormant periods in between. It is value to note here that in the numerical simulations at field scale the adjustment coefficient k of the sediment entrainment model (see Eqs. (6-14)) must be set equal to a value smaller than the unity in order to obtain physically realistic solutions. The adjustment coefficient k may be interpreted as a limitation on the supply of sediment from the bed that is available for entrainment due to e.g. partial consolidation of the bed. In the case when k = 0, a purely depositional turbidity current is generated. If however 0.007< k ≤ 1, a turbidity current accelerates so strongly that the energy constraints of Parker et al. (1986) fail to be satisfied. The end result is a pronounced and unphysical numerical scouring along the entire canyon-fan system. Therefore, the following values of the adjustment coefficient are set in the calculation: k = 0.003, k = 0.005 and k = 0.007. Figure 8a illustrates that more erosive underflows create far more noticeable depositional signatures at the location of an internal hydraulic jump. Also, the jump is pushed further upstream from the canyon-fan break (Figure 8b). The final bed elevation is presented in Figure 8b for k = 0.005. It reveals: a) a clear depositional step associated with the hydraulic jump; b) a change in slope gradient associated with the slope break; and c) a deposit of uniform thickness in the subcritical region. 5 CONCLUSIONS Results of the numerical model reported here provide clear evidence that turbidity currents can under some circumstances leave a more or less pronounced depositional signature where they go through an internal hydraulic jump driven by declining slope. The depositional signature is created by the sudden drop in bed shear stress generated by the internal hydraulic jump. Therefore, the location of such a depositional signature defines the location of an internal hydraulic jump as well. -0.5 0.5 1.5 2.5 0 2 3 4 Distance from Inlet (km) S e d i m e n t D e p o s i t (k g / c m 2) k = 0.003 k = 0.005 k = 0.007 20 0 25 0 30 0 0 2 4 Distance from Inlet (km)

Figure 8. Numerical simulations at field scale: (a) Deposi

tional pattern (b) Current interface and final bed.

The model was successfully verified against the

experiments by Garcia (1993) on internal hydraulic

jumps in turbidity currents driven by well-sorted sed

iment. The experimental observations and numerical

predictions for Garcia’s run DAPER7 provide the first

hint that under the right conditions a hydraulic jump

might leave a depositional signature. Numerical exper

iments reveal that a depositional step becomes indeed

more noticeable than the one reproduced by the run

DAPER7 for higher values of e.g. suspended sediment

concentration C 0 at the canyon head, bed resistance

c D or initial canyon slope S i . Numerical simulations at

field scale provide insight into the characteristics of a

depositional signature resulting from a generic field

scale turbidity current. It is demonstrated that swifter

turbidity currents leave more detectible depositional

signatures.

Grain size analysis for coarse river beds using digital imagery processing

R. Weichert, M. Wickenhäuser, G.R. Bezzola & H.-E. Minor

Laboratory of Hydraulics, Hydrology and Glaciology (VAW), Swiss Federal Institute of Technology Zurich (ETH)

ABSTRACT: The present paper describes a fast, easy and inexpensive method to determine the grain size

distribution of the subsurface of coarse river beds digital imagery analyses. The proposed procedure was empir

ically derived from flume experiments performed at the Laboratory of Hydraulics, Hydrology and Glaciology

(VAW) of the Swiss Federal Institute of Technology (ETH) in Zurich and is validated with independent flume

and field data for different river types (gravel-bed rivers to torrents).

1 INTRODUCTION

Quantification of the grain size distribution of river

beds remains an issue of large importance for a wide

range of river engineering problems. The bulk sieve

analysis, customary sampling method in sand-bed

rivers, is often not practical for rivers with coarser

bed material because of the large samples required for

representativeness (Mosley & Tindale 1985, Diplas &

Fripp 1992). For gravel-bed rivers several surface

orientated sampling procedures have proven their

validity (Fehr 1986, Church et al. 1987).

Bulk sieve analyses are volumetric samples of the subsurface material. In gravel-bed rivers the bed surface is often coarser than the underlying material. Thus, to provide equivalence of the surface-orientated sampling methods to the bulk sieve analysis, several important differences with respect to the sampling procedures have to be taken into account. First it has to be distinguished, whether the samples are evaluated by weight or by number. For both, particles of each size collected are assigned to size classes, resulting in number-based or weight-based distributions of the sample. However, the number-based methods are more practical under field conditions because no material has to be removed from the field site.

Secondly, the survey of grain sizes can be carried out as areal, line transect or point sample. An areal sample contains all grains that are exposed to the flow within a selected area, whereas for the transect sampling, all particles lying beneath a line are surveyed. The point analysis is mostly applied by using a regular square grid, where all stones under the grid nodes are part of the sample or by a random walk procedure (Wolman 1954, Leopold 1970, Hey & Thorne 1983).

Kellerhals & Bray (1971) showed on the base of an idealised cube model that these fundamental differences lead to specific weighting factors which are

integrated in an appropriate conversion model. The conversion model allows to turn numberor weightbased distributions of the surface into an equivalent volumetric distribution of the subsurface: Herein p i represents the weight proportion of a fraction of the subsurface, d i is the grain size of the fraction i, n i is the number of grains within the fraction i of the surface sample and n is the total number of grains of the sample. As the cube model assumes voidless packing, and a homogenously composed mixture, it should be considered as a basis for an adequate conversion model. Consequently, there are modified models in the literature which account for more realistic assumptions with respect to porosity, and particle size and shape (Diplas & Sutherland 1988, Fraccarollo & Marion 1995). The models mentioned above do not contain an explicit armour layer, and therefore do not account for the missing finer components in the surface layer. Additionally, number-based sampling procedures are limited to coarser material (d > 8 mm: (Kellerhals & Bray 1971, Adams 1979, Fraccarollo & Marion 1995). Therefore surface-orientated sampling requires an appropriate conversion model to infer from a coarse armour layer to the grain size distribution of the subsurface. This could be done by combining partial (i.e. truncated) grading curves (Anastasi 1983). In contrast to the theoretical models, Fehr (1986) derived conversion factors on an experimental base. He performed large scale laboratory tests with coarse

bed material (d max = 0.20 m) for channel gradients

ranging up to 8%. Fehr based his analysis on well

developed armoured beds without explicit bed features

and suggested to account for the neglected finer com

ponents by adding a Fuller distribution to the converted

sample. He found conversion factors slightly smaller

than suggested by Kellerhals & Bray (1971).

Besides the described methods the application of

remote sensed procedures has attracted increasing

interest. Photographical methods represent an easy

and rapid way to obtain grain size information of the

surface layer of a river bed. However, analyses by digital imagery processing are basically adaptations to the methods described above, as the images are used to perform number-based samples (areal, tran sect or point counting) within the photograph (Adams 1979, Church et al. 1987, Rosport 1997, McEwan et al. 2000). The advantage by using the image processing is that no grains have to be removed from the river bed. This is useful in torrents, where large bed ele ments limit the applicability of the manual methods, or within flume experiments where the removal of sur face grains is made impossible by the experimental setup (e.g. Weichert et al. 2003).

The automated extraction of grain size data, rather than performing manual number-based anal yses within the image, has become more important with further advances in image processing.Automated approaches to date use imaging laser altimetry to pro duce high resolution digital elevation models (DEM) (McEwan et al. 2000) or digital photogrammetry (Butler et al. 1998, Butler et al. 2001). A combina tion of both was tested by Butler et al. (2001), but the advantage of additional information does not improve the results.

However, the most important property of any auto

matic image-based procedure is that the grain bound
aries must be strongly contrasted with other parts of
the image. Contrasts in digital photogrammetry are
based on differences in brightness and colour intensi
ties. Besides the fact that identical stones with respect
to the lithology, possess similar intensities, imbrica
tion and shadowing effects of adjacent grains blur
good contrasts. Consequently, several researchers use
a variety of edge detection and edge dilatation algo
rithms to improve the segmentation of the particles
(e.g. McEwan et al. 2000).

Grain geometry is generally characterised by its
principle axes. The aand c-axis are assigned to the
longest and shortest axis respectively. Following this,
the b-axis is defined as the perpendicular axis to the
plane spanned by the aand c-axis. Analyses of plan
view images suffer from the principle drawback that
additional bias is introduced due to imbrication of the
grains either by other grains or by shadowing effects.
Even for completely exposed grains (aand b-axis
revealed) the apparent b-axis may be less than the actual b-axis because of tilting of the grain. Therefore, the revealed axis lies somewhere in-between of the band c-axis.Thus, on average, measured axes will be smaller than actual axes and additional correction is needed (Adams 1979). Church et al. (1987) noted that the magnitude of the correction is dependent upon the magnitude and angle of imbrication, and thus is specific to the sample site studied. The determination of the b-axis from an image can be performed in two optional ways. First, it is possible to

correct the values of the grain sizes measured in the photograph (e.g. the minimum dimension perpendicular to the longest axis visible in the image) in order to improve the estimates for the true values of the b-axes. Another possibility is to fit ellipses for a fixed a-axis. The b-axis is then determined as that for which the ellipse has the same area as the actual grain (Butler et al. 2001). Depending on the camera and the photographical procedure, additional distortion may result from optically imperfect lenses, or tilted camera axis. Butler et al. (2001) examined the influence of digital image rectification. They found that the use of rectified images does not significantly improve the result. The review of existing literature shows that a number of imperfections affects the automated extraction of grain size data from digital imagery. Additionally, the survey of finer fractions is often excluded (e.g. Butler et al. 2001). As some of these deficiencies are difficult to quantify, the procedure described in the present paper is derived on an empirical base, using flume data of experiments performed at the Laboratory of Hydraulics, Hydrology and Glaciology (VAW) of the Swiss Federal Institute of Technology (ETH) in Zurich (Wickenhäuser, unpubl.). 2 METHODOLOGY The present paper outlines a procedure to extract grain size data from plan view digital imagery.The proposed method can be divided into four stages. The first stage describes the image acquisition in the field, whereas the other stages involve the image processing steps, starting from the photograph and resulting in the grain size distribution of the subsurface material. 2.1 Field work First of all, attention must be given to ensure that the sample site allows for a representative evaluation of the river bed material. Although often stated as a precondition, the consequences of a non representative sample site may be immense (see e.g. Crowder & Diplas 1997). The photographs should be taken of a dry bed section from an appropriate height (Fig. 1). The “flying

Figure 1. Vertical photograph of the river bed.

height” of the camera should be chosen in order

to provide that the image is of the correct scale with

respect to the size of grains that are of interest. For

the channel beds surveyed, the ratio of image length

to maximum grain size varied between 10 and 15.

The scale of the image can be obtained by plac

ing a measuring-tape on the gravel surface at the

sample site. The axis of the camera should be held

approximately vertical to minimise distortion effects.

Additionally, it must be provided that the ambient light

is homogeneous within the photographed area. Chang

ing light condition within the image may complicate

the detection of grain contours.

2.2 Preprocessing of the image

The purpose of image preprocessing is to create a

quasi-binary image which is suitable for the follow

ing automated extraction of grain size data. This step

can be implemented with standard photo-processing

software.

First, the photograph is transformed into a greyscale

image as shown in Figure 2. The associated histogram

points out that the image exhibits the full range of grey

levels.

Basically, the following preprocessing step is equiv

alent to a manual thresholding process. It must be

decided which grey tones are assigned to the sample Figure 2. Greyscale image. Figure 3. Quasi-binary image. and which intensity levels are excluded. The resulting image should exhibit reasonable delineations of the particles of interest (Fig. 3). This subjective thresholding process ensures that an adequate portion of the grains is part of the sample. However, as grey levels in an image of a natural deposit are often in a similar range, a perfect delineation of all grains is rather impossible. For the proposed method, this deficiency is not affecting the

results in a major way as long as enough objects are delineated reasonably. The histogram in Figure 3 shows that the preprocessed photograph is a quasibinary image with just two modes nicely separated by a valley. 2.3 Extraction of grain size data The software Image Tool 3.0 (freeware: http://ddsdx. uthscsa.edu/dig/itdesc.html) is used for the automated extraction of grain size data. As it is shown in

Figure 4. Threshold setting.

Figure 5. Recognised objects.

Figure 3 the amount of small impurities within sharply

contrasted stones is considerably large. As this would

result in a large error for the finer fractions, parti

cles smaller than a predetermined value are excluded

from the analysis. In the present study the diameter

of the smallest particle to be recognised was about

$d * min = 0.14\ d\ max$.

Thus, for a given maximum grain size, the smallest

particle that still is detected reliably can be determined.

As the programme carries out pixel-based analyses, the

length scale of the image is required to convert $d * min$

from a unit length into pixel.

As shown in Figure 4, the following manual thresh

olding process can be carried out easily, because the

image is already quasi-binary. Hence, the threshold

can be placed in the large gap between the two modes.

Once the threshold has been set, the software

scans the image and identifies objects (Fig. 5). In

the following step all recognised objects are anal

ysed. Besides other information, the programme mea

sures the longest and shortest axis of the recognised

objects. These data are used for the following conver

sion to determine the volumetric distribution of the

subsurface layer. 2.4 Conversion model The described conversion model is mainly an adaptation to the method proposed by Fehr (1986). The mean of the longest and shortest axes of the recognised objects is assumed to be a measure of the grain b-axis. These lengths are assigned to size classes resulting in a number-based frequency distribution of the surface layer. Basically, the described procedure is something in-between of a point analysis and an areal analysis, depending on the number of recognised objects. The only difference to the customary point analysis is that the random selection is made by the automated object recognition rather than by a gridbased system or a random walk procedure. With the image scale the pixel-based distances are transformed into unit lengths. Equation 1 is used to convert the number-based distribution of the surface layer into a volumetric distribution of the subsurface. For the flume experiments a weighting factor of = 0.8 gave the best results. As particles smaller than a threshold value are excluded from the analysis, the proportion of the finer material within the sample is underestimated. Thus, the sample has to be corrected and the missing finer components are replaced by a Fuller distribution in the way suggested by Fehr (1986). The theoretical values for the conversion from a number-based pointor areal-analysis into a volumetric distribution of the subsurface are = 0 and = 2, respectively. As the automated object recognition represents something in-between of these two sampling techniques, the empirically derived weighting factor of = 0.8 fits well to the theoretical values proposed by Kellerhals & Bray (1971). The flume experiments were performed to simulate steep open channels with very coarse surface layers. Consequently, the empirically derived weighting factor takes into account pronounced armouring effects. Besides the influence of different sampling procedures, additionally includes all other imperfections resulting from the digital imagery processing. Both, these imperfection and the composition of the surface-layer are dependent on the degree of armouring and thus depend on the river type and the preceding hydraulic loads. 3 CALIBRATION The proposed procedure was derived on the base of experiments performed in a 5.5 m long and 0.3 m wide

tilting flume at slopes of 7.5%, 10.0%, and 12.0% respectively (Fig. 6). A widely-graded sediment mixture was used, that corresponds to a typical grain size distribution of a torrent. The standard deviation of the grading curve was σ= (d 84 /d 16) 1/2 = 2.9.

0.6

0.8 1 0 4 8 12 16 20 24 28 32 d [mm] p [-]

Figure 7. Volumetric distribution of the subsurface obtained

by bulk sieve analysis (-) and automatic object recognition

(—) for the calibration experiments.

For each slope the flume bed was initially built up

by a uniform layer of homogeneously mixed sediment.

After the saturation of the void volume the discharge

was subsequently increased to allow for the formation

of a coarse armour layer with distinct bed features.

These bed features are commonly addressed as steps

and pools. Vertical photographs of the armour layers

were the basis for the derivation of the digital imagery

processing procedure.

Figure 7 shows the comparison between the volu

metric distribution of the subsurface obtained by a bulk

sieve analysis (-) and the average grading curve of

all experiments resulting from the automatic object

recognition (—). The error bars represent the stan

dard deviation for all analysed photographs. Thereby,

each photograph was analysed several times.The mean standard deviation averaged over all fractions is 2.3%. Thus, the mean standard deviation, basing on 30 processed images, gives a quantity for the sensitivity of the suggested image processing procedure. In addition to the natural sediment mixture, all experiments were repeated with partially coloured mixtures. For that purpose, all grain sizes of one quarter of the entire mixture were coloured.This resulted in very sharply contrasted particles, giving a good basis for the automated object recognition. Consequently, painting a specific amount of the total sediment volume represents a useful alternative under laboratory conditions. 4 RESULTS 4.1 Flume data Flume experiments with a similar grain size distribution (σ= 3.1) as for the calibration series are performed in another flume at slopes of 9.0%. The flume is 13 m long and 0.6 m wide. Starting from an unloaded and homogenously mixed sediment (0 l/s), the discharge is subsequently increased allowing for armouring (2 l/s) and the formation of steps and pools (8 l/s). As shown in Figure 8 the grading curves obtained with the automated object recognition (—) approaches the sieving curve (-) with increasing discharge. This points out that the derived weighting factor of α= 0.8 correspond to a well developed, coarse armour layer with distinct bed features, typical for steep open channels. Besides this grain size distribution typical for steep open channels, a second sediment mixture typical for gravel-bed rivers was tested. These experiments are being performed in a 28.5 m long and 3.2 m wide flume at slopes between 1.3% and 2.3%, in order to obtain a braided morphology. As the spatial variation of the bed shear stress is high in braided rivers, special attention was paid to the choice of the sample area. The bed section chosen for the survey showed significant armouring. As visible in Figure 9, the proposed method is also applicable in gravel-bed rivers, where no explicit formation of bed features could be observed. Nevertheless, the grading curve obtained by automatic object recognition lies somewhat above the distribution of the subsurface material.This observation can be attributed to the fact that the tested river-type differs from the calibration river-type and the derived conversion factor overcompensates the lack of fine material in the surface layer. 4.2 Field data In addition to the flume data, the proposed method has also been tested under field conditions. As bulk sieve

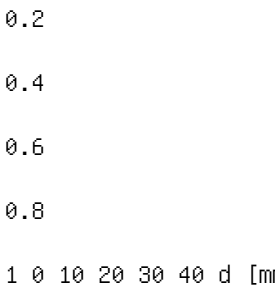

Figure 8. Volumetric distribution of the subsurface obtained by bulk sieve analysis (-) and automatic object recognition (—) for a steep open channel tested in a flume experiment for different hydraulic loadings.

analyses would have resulted in large sample quanti ties, the surface-orientated transect sampling method as suggested by Fehr (1986) was used to obtain refer ence grading curves. The validity of this method has been proven for gravel-bed rivers. However, in torrent

beds large bed elements limit the application of the

transect sampling method.

As a consequence, in a first stage the comparison

with field data is carried out for gravel-bed rivers to

ensure that the reference grading curve is determined

with sufficient accuracy. The first river tested is the

Töss River, a midland gravel-bed river, which origi

nates in the northern foothills of theAlps and meets the

Rhine River about 20 km southwest of Schaffhausen. 0.0 0.2 0.4 0.6 0.8 1.0 0 10 12 d [cm] p [-] 2 4 6 8 Figure 10. Volumetric distribution of the subsurface obtained by bulk sieve analysis (-) and automatic object recognition (—) for the Töss River, Switzerland. 0 0.2 0.4 0.6 0.8 1 0 8 12 16 d [cm] p [-] 4 Figure 11. Volumetric distribution of the subsurface obtained by bulk sieve analysis (-) and automatic object recognition (—) for the Reuss River, Switzerland. TheTöss River is characterised by relatively fine material (d max = 0.12 m). The standard deviation of the grading curve is σ= 3.0, thus armouring of the river bed is an existent phenomena (Little and Mayer 1972). Figure 10 shows that the digital imagery processing method provides a good approximation of the subsurface layer. Nevertheless, the implementation of the conversion factor derived for an armour layer that correspond to torrent beds, again leads to a somewhat finer grading curve. As shown in Figure 11 a similar result is obtained for the lower reach of the Reuss River. The Reuss River, a mountain stream, originates in the Alps near the Gotthard pass and flows towards Lake Lucerne. In the upper Reuss valley the river bed contains very large boulders. In the lower reach the channel gradients decrease and the bed material is considerably finer.

Figure 12. Volumetric distribution of the subsurface obtained by bulk sieve analysis (-) and automatic object recognition (—) for the Flaz River, Switzerland.

The sample (Fig. 11) was taken from a river bar, which contained finer and more mobile material.Thus, the present sample does not represent the coarser river bed, which shows a pronounced armour layer. Never theless, considering the comparison between the refer ence grading curve and the grading curve obtained by automated object recognition, the proposed procedure produces good results.

The last river investigated up to date is the Flaz-river in the Engadin valley, a region located in the east of Switzerland. The sample was taken from a river bar, which again was composed of more mobile material. However, the maximum grain size (d max = 0.25 m) of the sample is large.

Figure 12 shows that the approximation obtained by the digital imagery processing method is good, but again somewhat too fine.

5 CONCLUSIONS

The present paper describes a method to extract the grain size distribution of the subsurface of coarse river bed material by analysing digital imagery. The main

advantage of evaluating digital photographs is that several samples can be taken within short time.

The present paper focuses on the conversion from a surface-orientated sampling method basing on auto mated object recognition towards the grain size distri bution of the subsurface layer. The suggested proce dure was derived in flume experiments with a grain size distribution typical for steep open channels. The comparison with independent flume data shows that the proposed method gives reasonable results for torrent beds. For torrents the standard sampling pro cedures are limited in their applicability, thus the developed method may be an alternative to obtain grain

Development of discrete subaqueous bed forms

H. Friedrich, S.E. Coleman, B.W. Melville & T.M. Clunie

The University of Auckland, New Zealand

ABSTRACT: Experimental investigation of subaqueous bed forms has been undertaken and analyzed. Based

upon already-existing theories in the area of sediment bed-form initiation and development, 7 experimental runs

were carried out in a 440 mm-wide, glass-sided, 12 m-long laboratory flume. For each run, bed profiles were

measured at 30 sec intervals. The sediment in use was a fine sand with d 50 = 0.2 mm. The study is the first of

a series of studies looking at the phenomenon of submerged sediment bed-form behaviour. The main purpose

of the study was to gain information on the relations central to linkages between bed-form propagation speed,

sediment-transport rate and predictions of bed development. Relations predicting equilibrium sandform speeds

as functions of flow conditions and sediments are available in the literature, although these relations have not been

widely tested. More general relations predicting sand-form speeds as functions of flow conditions, sediments,

and bed-form magnitudes remain to be determined.

1 INTRODUCTION

1.1 Bed-form movement and sediment transport

For any sediment bed form propagating steadily with

out changing size or shape, sediment continuity con

siderations readily lead to q SH = cH, where q SH = the

volume rate of sediment transport over the crest of

the bed feature per unit width of channel, c= bedform

celerity and H= bed-form height measured crest to

subsequent trough (e.g., Coleman and Melville, 1994).

Depending on how sediment volume is measured, this

can also be expressed as q SH = cH(1-p) for equilib

rium or slowly-growing subaqueous bed forms (Nino

et al., 2002), where p is the porosity of the deposited

sediments.

A relation, such as that above, between sediment

transport and the magnitudes and speeds of prop

agating discrete bed forms (ripples and dunes) is potentially very useful. If sediment is transported as bed load in the form of bed forms, measurements or predictions of bed-form magnitudes and celerities as these waves develop, facilitate estimation of sediment transport rates for the developing bed (as well as equi librium bed-form transport rates). Such estimations increasingly underpredict transport rates as the pro portion of transport bypassing bed-form lee faces, e.g. as suspended load, increases for stronger flows. Mohrig and Smith (1996) provide a method for esti mating the bypassing fraction (up to 60%), whereby measurements or predictions of bed-form magnitudes and speeds can be used to estimate sediment-transport rates generally, and not just where sediment in motion remains cycling within individual bed forms. 1.2 Sandwave initiation theories Different theories exist about the initiation of sandwave development. Kennedy (1969) led the stability theory approach with his irrotational flow analysis. Coleman and Fenton (2000) showed, however, that the theory of irrotational flow is inadequate for sandwave generation. Coleman and Eling (2000) further showed that bed forms have their genesis in wavelets (small scale sediment waves, which are primarily a function of sediment size and not flow characteristics). Raudkivi (1983) proposes that sandwave initiation occurs through streamline oscillations within highshear and constant velocity zones within the flow profile. Other researchers, among them Nezu and Nagakawa (1993), conclude that grain entrainment and sandwave initiation are caused by the flow's coherent turbulent structure, which interacts with the bed surface. The range of analyses and conjecture reflects the current lack of understanding of the phenomena controlling sediment-wave generation, such phenomena potentially including grain movements, flow-bed instabilities and

bed-wave interactions. 2 SANDWAVES 2.1 Classification of sandwaves ASCE (1966) faced the problem of dividing sandwaves into ripples and dunes. The criteria for the distinction are still controversial, especially when a possible transition from ripples to dunes or viceversa occurs. The

Figure 1. Ripple bed forms during experimental runs con

ducted at The University of Auckland.

cause and behaviour of this transition is of great inter

est, but up to now the behaviours of, and transitions

between, these different kinds of sandwaves remain

unclear. Widely-accepted classifications of ripples and

dunes, with their associated characteristics, are funda

mental for this research and are summarized in the

next two sections. One aim of the present research is

to further investigate distinctions between ripples and

dunes as bed forms.

2.2 Ripples

According to ASCE (1966), ripples are small finesed

iment bed waves, which do not influence the water

surface (Fig. 1).

It is widely accepted that ripples are small triangu

lar sandwaves that are usually longer than 0.06 m and

shorter than 0.6 m, and are restricted to sands finer

than 0.6 mm. McLean (1990) states that ripples dis

play wavelengths of the order of 0.1–0.2 m and heights

of 0.01–0.02 m.

Furthermore, the theory was introduced that small

scale ripples may exist on an otherwise flat bed or may be superimposed on the stoss sides of larger bed forms. It remains unclear, however, what makes these superimposed bed forms ripples, and not dunes grow ing in between larger dunes, especially for sediments of d 50 > 0.6 mm.

In line with the superimposed bed forms being ripples, Raudkivi (1997) observes that rippleforming conditions can occur downstream of the reattachment point of the surface of separation for an upstream dune crest, i.e. where the bed-shear stress is low.Yalin (1992) concludes that ripples are due to the viscous structures at the bed, defining ripples as the bed forms ‘imprinted’ by the viscous flow structures (undulations) at the bed of a nevertheless turbulent flow.

2.3 Dunes

Dunes (Fig. 2) are bed waves that occupy a significant portion of the flow depth, causing the water surface to be disturbed. Figure 2. Dune bed forms during experimental runs conducted at The University of Auckland. Hydrodynamically, they affect the flow with topographic accelerations and decelerations of the flow field extending all the way to the free surface (Maddux (2002)). Dunes are normally larger and more twodimensional features when compared to ripples. On beds of coarser uniform-grains (in general it is assumed for sediment grain sizes >0.6 mm) only dunelike features develop. According to Bass (1993), no dunes form with sand finer than 0.15 mm. Dunes are generally restricted to sand-like sediment, but can occasionally also occur with coarser uniform-grained materials. Dunes are irregular sandwaves. The longitudinal

profile is roughly triangular, with a mild and slightly curved upstream surface, where as the downstream slope can be taken to be equal to the dynamic angle of repose φ of the sediment. 3 EXPERIMENTAL INVESTIGATION 3.1 Experimental arrangements Seven experiments were carried out, concentrating on sandwave development for different flows. Some of the runs reached equilibrium stages, for others recording was stopped before equilibrium. Table 1 shows an overview of the experimental runs. The experiments were conducted in a 12 m-long, 0.38 m-deep and 0.44 m-wide glass-sided openchannel flume. Water is recirculated, as well as the sediment. On the rails of the flume, a carriage carries a depth sounding probe. The carriage traveled over a distance of 4–7 m, depending on the characteristics of the runs. For the first experiments, the carriage was moved manually downstream and upstream. For the later experiments, the carriage was motorized, making more efficient use of the equipment and time. Before each run, the slope of the flume and the temperature of the water were measured and recorded.The velocity profile for each pump setting and equilibrium bed profile were also measured.

Prior to each run, the sediment bed was flattened and the depth-sounding probe was fixed on the carriage. The technique behind the depth-sounding system is based on Coleman (1997), and has since been fur ther improved at The University of Auckland. The depth-sounding system was used to record the pro files of the developing bed. According to Coleman (1997) the accuracy of bed elevation measurement is ±0.4 mm. The distance along the flume was measured using a potentiometer mounted on a 0.199 m diameter wheel running down the outside of the flume side-wall. The streamwise position was recorded at 2.45 mm distance increments, accuracy of measurement being ±1.23 mm.

For each experimental run, measurements were taken at the centreline of the flume. Therefore, only two-dimensional data evaluation can be carried out. Bed profiles were recorded initially every 30 sec for a run, with profiles in the latter stages of the experiments recorded every 5 to 15 min.

3.2 Range of experiments

As seen from Table 1, flows were chosen for the different experimental runs based on the aboveintro

duced sandwave theories, where distinctions are made

between ripples and dunes. The chosen sediment for

all the runs is a fine sand with d 50 = 0.2 mm. This sand

was chosen to ensure the development of both ripples

and dunes. Therefore, one can study the differences in

subaqueous sandwave initiation and development to

equilibrium state for the two types of bed forms.

Bed-form development started for five runs from

flat bed conditions and for two runs, the transition from

ripple to dune beds was studied.

Figure 3 shows the classification of the flows and

bed configurations according to van Rijn (1984). For

four runs (refer to Table 1) the bed forms reached

equilibrium magnitudes. Figure 3. The present flows (see Table 1 for U values) classified in terms of dimensionless flow and sediment parameters. 4 BED-FORM DATA ANALYSIS 4.1 General remarks For each run, the mean (depth-averaged) fluid velocity U, and the bed shear velocity u∗ were determined from the measured centreline flow velocity profile (see Table 1). Analysis of the different experimental runs according to Coleman (1996) indicated the bed-form results to be in line with previous research. The writers then focused on a more detailed and explicit analysis of

aspects of bed forms instead of a general and tradi

tional study.A principal goal was to gain enough infor

mation to formulate an automatic means of analyzing

the development of subaqueous sediment waves. In

the past, most of the analysis has been done with a

large manual work load and automated analyses were

often distorted because of simple determinations of wave height and length, which provide the basis for all submerged sediment wave analyses.

Therefore, this paper will focus on explicit parts of run R/D3, with special attention given to relations central to linkages between bed-form propagation speed, as a function of flow, sediment and bed-form parameters; sediment-transport rate as a function of bed-form speed and bed-form height; and the degree to which bed-form geometry can be taken to be similar. The considerations in the analyses presented here will help to provide means of automating the evaluation of the development of subaqueous sediment waves in the future and will show where there are major inconsistencies in these analyses to date.

4.2 Bed-form development of run R/D3

Run R/D3 started from flat bed conditions, with bed profiles recorded for 2 hrs. Bed profiles for the first 10 min are shown in Figure 4.

One can see from Figure 4 that the initiation of bed forms can be a sudden uniform phenomena (see bed forms 10:20:14 AM and 10:20:44 AM in Figure 5). Therefore any role of stochastic turbulence in bed from generation, as discussed in Section 1.2, must be questioned.

The bed-form unification model as proposed by Raudkivi and Witte (1990) predicts that smaller bed forms run into larger bed forms. This theory has its basis in the assumption that smaller bed forms migrate faster than larger bed forms. Therefore the larger bed forms resulting from coalescence migrate even slower. The question arises, how do new bed forms develop, because as seen from Figure 5, the number of bed forms does not change dramatically once a stable environment is established for a flow.

The speculation arises that new bed forms develop once an original large bed form gets unstable for the existing flow conditions. What then are the characteristics for bed forms to become unstable?

One parameter responsible for the breaking up of bed forms and therefore creation of new bed forms is assumed to be the rate of sediment transport. As introduced earlier, sediment transport can be defined as the product of wave propagation speed and wave height. Some inconsistencies with this assumption will be analyzed herein, the next section focusing on individual developing bed forms in terms of the two main characteristics that sediment-transport rate is dependent on:

bed-form height and bed-form speed. 1cm • 10:19:05 AM • 10:19:44 AM • 10:20:14 AM • 10:20:44 AM • 10:21:14 AM • 10:21:44 AM • 10:22:14 AM • 10:22:44 AM • 10:23:14 AM •

Mov. Avg. (Number of bed forms over 4.7 m) Figure 5. Number of identified bed forms (run R/D3) from development phase to equilibrium phase (2 hrs). 4.3 Bed-form determination regarding speeds and heights In order to make comments about bed-form propagation speed and sediment-transport rate, criteria to define individual bed forms are needed. A common approach is to determine local maxima and minima of the recorded time series of bed forms. Once this is done, the calculation of the bed-form propagation speed is the movement of the crest position of an individual sandwave over the recorded time interval. This approach neglects the aspect of changing bedform shape, as displayed in Figure 6. Changes of bed-form shape can be especially observed during the initial stages of bed-form development. As Figure 7 shows, as a sandwave migrates, the shape of the sandwave changes and therefore speeds determined by crest movement alone, can distort the assessment of true sandwave speeds. of locating local maxima/minima) can be seen in

Figure 8.

According to the writers' knowledge most studies

concentrate on location of crests/troughs through loca

tion of local maxima/minima (as indicated above), h or

use change of lee-slope steepness values to locate the

transition from the crest to the lee slope. In terms

of determining bed-form heights, both methods give

problems in analysis of the present data. Therefore a

selected length of bed forms in the developing phase

of Run R/D3 was studied in greater detail, mostly

via manual considerations. Bed-form coalescence and generation highlighted from Figure 9. were determination of bedform shape, and based on that information, calculation of bed-form heights and propagation speeds and sediment-transport rate. 4.4 Bed-form coalescing, generation and life expectancy Bed-form propagation speed is not only dependent on bed-form shape, but also the environment of the sandwaves interactions with surrounding bed forms influencing bed-form speeds. As a bed develops for a particular flow, new sandwaves can form and old sandwaves will die. This behaviour of sandwaves emerging and dying is directly related to the sediment-transport rate for the flow. For

Run R/D3, Figures 9 and 10 show the initial phase of bed development for a 2 m long section of the flume. Figure 10 highlights the emerging and dying sandwaves over the period of bed development. In Figure 10, newly generated bed forms typically arise after the merging of existing bed forms,

Figure 11. Overview of original and newly-formed sand

waves (run R/D3).

consistent with the throughpassing mechanism high

lighted by Coleman and Melville (1994) and Raudkivi

and Witte (1990).

The life expectancy of an individual sandwave dur
ing bed development has received little attention to
date. Figure 11 gives an overview for Run R/D3 of the
distribution of sandwaves, over the 10 min period stud
ied, with each sandwave being evaluated according its
origin. Figure 11 shows that after 10 min, only 20% of
the overall sandwaves were original sandwaves, these
having not been consumed in sandwave coalescence.
A relation for the life expectancy of individual sand
waves can possibly be determined as a function of
flow, slope, sediment size and water depth. In order to
determine such a relation, further analyses of different
flow environments and different sediment sizes must
be carried out.

4.5 Bed-form speed versus height and sediment transport

Figures 12 and 13 show sediment-transport-rate
related data observed in experimental run R/D3.
Because flow and sediment size did not change for
this run, the dependency of sandwave propagation
speed on sandwave height can be assessed for this run.
Once further experimental runs are carried out and
analyzed, a comparison with already existing formu
las for bed-form speed and sediment transport can be
undertaken.

Sandforms propagate downstream by sediment

being transported from their stoss sides and deposited

on their lee sides (Fig. 13). Based on laboratory

data, Coleman and Melville (1994) present a prelim

inary expression for bed-form speed as a function of

flow, sediment and bed-form parameters, that indicates

bed-form speed to decrease with increasing bed-form

height. Based principally on numerical simulations

of bed forms, Nino et al. (2002) similarly conclude
Sandwave Propagation Speed versus Sandwave Height (Run R/D3 - Initial Bed-Form Development Stage) y = 0.1843e -0.3679x 0.00 0.05 0.10 0.15 0.20 0.25 0.30 0.35 0.0 0.5 1.0 1.5 2.0 2.5 3.0 3.5 Sandwave Height [cm] S a n d w a v e P r o p a g a t i o n S p e e d [c m / s] Figure 12. Sandwave propagation speed versus sandwave height for run R/D3; 10 min period. Figure 13. Sediment transport for two individual sandwave pairs as the waves develop (run R/D3).
that bed-form speed is approximately inversely proportional to bed-form height. Prediction of bed-form speed as a function of flow, sediment and bed-form parameters needs further work however. Figure 12 shows propagation speeds of individual sandwaves versus sandwave height for Run R/D3. As predicted in the literature, sandwave propagation speed generally decreases with increasing sandwave height, although this result is certainly not clear in the data of Figure 12. Any decrease in speed with increasing height is furthermore small in comparison with other available data (e.g. Baas (1993) and Coleman and Melville (1994)). From Figure 12 it would not be expected that the relations between speed and height in the literature would be true for the present results. Clearly, the relations predicting bed-form speed as a function of bed-form and flow parameters require further work. In this regard, the concept that bed-form migration speed decreases with increasing bed-form height is central to the bed-form unification model of Raudkivi and Witte (1990). This model, based on the motions and interactions of individual bed features and building on the earlier work of Führböter (1983), provides descriptions that are consistent with physical observations of the evolution from ‘plane-bed’ conditions to equilibrium of subcritical-flow sediment waves (Coleman and Melville, 1994). Predictions of

this model will be improved, however, with improved

modeling of bedform speed as a function of flow, sediment and bed-form parameters.

Figure 13 shows why solely considering speed as a function of sandwave height can provide ambiguous results. Displayed are four sandwaves, namely two pairs of waves that were recorded 30 sec apart. The time gap between the two pairs is 4 min. One can clearly see changes in shape for the four individual bed forms. If sediment transport is taken to be dependent on the average height of two successive sandwaves and the propagation speed measured crest to crest, one comes to the result that the sandwave sediment transport of pair 1 (Fig. 13) is of higher intensity than that for pair 2. In contrast, visual inspection indicates that pair 2 transported in 30 sec more sediment load than pair 1. In this regard, the bed-form shape of pair 2 shows an obvious change in the lee-face steepness, which is not accounted for in calculation of the sediment-transport rate as a function of bed-form speed and height. It is therefore proposed that more attention should be given to the change of shape for successive sandforms. These changes should be incorporated in the calculation of sediment-transport rate. In order to do so, more analyses are necessary to show the dependence of sed

iment transport on bed-form shape. This research is continuing.

5 CONCLUSIONS

For beds developing to equilibrium, relations central to linkages between bed-form propagation, sediment transport rate and predictions of bed development (e.g. Raudkivi and Witte, 1990) have been investigated herein: principally, the product of bedform speed and bed-form height as bed-forms develop, and the relation of this product to sediment-transport rate; bed-form speed as a function of flow, sediment and bed-form parameters; and the degree to which bed-form geo metry can be taken to be similar (including whether steepness can be taken to be constant) as bed forms develop. All these considerations have been analyzed for one main flow, seen as a first major step in a 3 year project. The data and insights of the presented paper will provide the basis of further research in this area. The next step will be in terms of the last of the above mentioned considerations. In this regard, power law relations for the growth of sediment-wave lengths and heights with time for steady and changing flows (Coleman and Zhang, 2003) currently indicate that bed-form steepness is essentially invariant during bed form development, although this inference requires

confirmation from focused experimental measure

ments of developing bed forms. Further insight in the

still-debated topic of distinctions between ripples and

ABSTRACT: In order to get some insight into the poorly known dynamics of high mountain streams measure

ments of flow and sediment transport (both solute, suspended and bed load) were conducted at three different

alluvial sites along the Ürümqi He (Chinese Tian Shan). The discharge of this high mountain stream (headwaters

at 4000 m), is in part controlled by glacial melting. This first survey took place during the high flow season

in July 2001. Although of short duration it brings some useful insight into the dynamics of flow and sediment

transport by the river during the high flow season. (i) Bed load transport during peak flow can account for more

than 80% of the solid flux. (ii) Bed and solute loads together account for more than 90% of the Total load of the

river at the range front. (iii) In the glacial valley site, measurements made before and during a nearly bank-full

flood event indicate that transport of gravel seems to be

more or less a continuous process in riffle or step-pool

sections, whereas larger pools, that temporarily store the material delivered by the riffles, are flushed during a

flood event. (iv) A strong correlation exists between suspended and bed load. This suggests that movement along

the bed is necessary to unhide the smallest particles and put them into suspension.

1 INTRODUCTION

Rivers are by far the main carriers of erosion products

(Goudie, 1995). The rate at which and the mechanisms

by which a river is able to incise relief and evacuate

the eroded masses delivered from the slopes is essen

tial to our understanding of both stream morphology

and landscape evolution. It is even more crucial in

active mountain ranges where sustained tectonic uplift,

orographic precipitations and glacial melting, should

maintain significant erosion rates and enhance river

dynamics. Despite this datasets on sediment transport and morpho-dynamics of high mountain streams are sparse (Wohl, 2000). We report hereafter results from a preliminary study on the morpho-dynamics of the Ürümqi He, a high mountain stream of the northern Tian Shan (China). The river headwaters are made by retreating glaciers. The Ürümqi River initiates at 3600 m ASL from the melt of a glacier known as Glacier N ∘ 1. The river flows through two steep sections separated by a flat basin where the town of Hou Xia and the glacial station of the Chinese Academy of science are located. The river length from its headwater to the piedmont

where it enters a semi-desert environment is on order

of 60 km.

2 MORPHOLOGY OF THE ÜRÜMQI RIVER

AND ITS CATCHMENT

2.1 Sampling sites description

2.1.1 Site 1: glacial valley

The first sampling site is located in the glacial valley at an elevation of 3300 m approximately 8 km down stream of glacier number 1 which is the source of the Ürümqi River (Fig. 1). The river flows on glacial moraines though a series of cascades and flats (Fig. 1). The long distance profile of the valley is steep and grain size of surface particles is gravel-like. D 50 of the surface samples is 21.5 mm and D 90 is equal to 158 mm. Figure 1 and 7 show the study site. It is located in a confluence zone between to riffles. Upstream the river is divided into two branches flow ing around a central bar. Bed is step like with a mean slope of 4.9%. A pool is located at the confluence. The long distance averaged bed slope is steep S~ 2.5%. Most of the measurements were carried at the down stream end of the pool where the river is the widest

Figure 1. Location map of the Ürümqi He Drainage. Average monthly discharge measurements are made at a gaging station build in gorges a few kilometers south of the range front. Drainage network and slope-area relationship were extracted from the 30-arc second DEM GTOPO30. Most of the streams reported on the map north of the gaging station are not perennial. Upper left, slope area relationship for the Ürümqi He. Upper right, monthly discharge at the downstream station.

(average wetted perimeter P w varies from 9 to 12 m) and the shallowest (average hydraulic radius between R between 0.2 and 0.4 m). Some measures were taken in the pool (P w ~ 7 m, R~ 0.5 m). Some where also carried in the riffle section upstream. 2.1.2 Site 2: Hou Xia The second sampling site is located at the outlet of the upstream gorge before the town of Hou Xia (literally: after the gorge, Fig. 1).As in the case of the glacial valley, the measurement site is between two riffles or steppool sections. At the end of the upstream riffle a pool stands as in the case of site 1 although no active confluence exist at present. Bed slope averages 1.5% at the site.The wetted perimeter remained quite stable during measurement days P w between 22.5 and 23.5 m, more than twice the perimeter of the river upstream near the glaciers. Abandoned terraces can be seen in the valley, the glacial station being built on one of these. 2.1.3 Site 3: range front The third sampling site is located at the range front just outside the downstream gorge of the river. Our measurement, as for the above mentioned, is located before a riffle section where the river splits into three

main branches. The wetted perimeter was between

21 and 22 m during measurements and the hydraulic

radius between 0.5 and 0.6 m. The river is dynamic

and measurements where difficult. At the range front

the most prominent feature in the landscape is made

by large terraces standing almost 100 m above the

present day river bed. These terraces which are fill-cut

at the range front progressively turn into strath ter

races a few kilometers downstream where tertiary red

beds are seen to dip southward under a sub horizontal

dark gray gravel bed layer marking the ancient river

plain, a feature common to all the rivers of northern

Tian Shan.

2.2 Data acquisition

Discharge was measured at each site using an OTT velocimeter. 295 velocity profiles were measured cor responding to 30 complete gagings of the Ürümqi He (Fig. 2). Velocity profiles were measured regu larly across the river (between 1 and 2 m distance depending on the site). Water was sampled 26 times with a USDH 48 depth integrating sampler for suspen sions or solute load. The sampler was equipped with a 0.64 mm nozzle. Samples were filtrated to a thresh old of 0.2 microns to separate suspensions and solute load and prevent chemical reactions in the bottles after sampling. Suspensions were dried and weighted in the laboratory. Bed load was measured using a 15 cm entrance Helley-Smith sampler.The Helley-Smith was equipped with 250 microns mesh bags. Each bed load section is composed of at least 6 to 10 point measure ments regularly spaced along the section.At each point the sampler was left for 60 s (30 s during the highest flows). 95 sections were measured during this survey. Topographic measurements were conducted at site 1 and 2 using a Wild T2000 Total station equipped with a laser distance meter that permits measurements with an accuracy of less than 1 cm. Figure 2. Sample velocity profile at site 2. was established using statistical counting (Wolman, 1954). Minimum size measured was 1 mm. Solute transport in the Ürümqi river catchment has been discussed at length by Liu et al. (1995), and Williams et al. (1995), on the basis of sampling of the river at places near our sampling sites. We will therefore hereafter concentrate on the solid load. 3 VELOCITY SCALE IN MOUNTAIN STREAMS Velocity profiles were leveled regularly at each site of the Ürümqi He. Shear velocity estimates were performed by adjusting a logarithmic profile to the data according to: Where u is the velocity of the flow at depth z, u ∗ is the shear velocity, k s the bed roughness and κ= 0.4 the von Karman constant. In gravel bed rivers such as the Ürümqi He, the bed roughness usually scales with the D 90 of bed material distribution (e.g. Wilckock, 1996). Following Wilcock (1996) another estimate can then be derived using the average velocity but still assuming a logarithmic form of the velocity profile: Here U is the depth averaged velocity, and h the flow depth. The estimates were then compared (Fig. 3). The results clearly show a poor agreement for the Hou Xia site. The two other sampling sites do not Figure 3. Correlation between estimates of the shear velocity at site 2.

show a convincing correlation. If the velocity distri

bution was logarithmic throughout the flow depth as

often supposed both estimates of the shear velocity

should correlate with a 1:1 slope. As this is not the case velocity profiles can not be considered to follow a logarithmic distribution on the timescale of level ing (Wohl, 2000). The average velocity should then be preferred and considered the only relevant velocity scale at the scale of conventional sampling (60 s per measurement). Care should therefore be taken when devising transport equations with shear velocities.

4 SEDIMENT TRANSPORT

4.1 Importance of the bed load component

Numerous studies have focused on bed load trans port by mountain streams (Wohl, 2000). The reasons for this are that (1) bed load is probably an impor tant component of the total mass transport, and (2) it bears a first order control on the morphology of many mountain streams. Measurements made in the Ürümqi River attest that bed load transport is signifi cant during high flow. Daily averages of bed load show that it represents approximately 64, 20 and 45% of the total daily load at the glacial valley site, Hou Xia and at the range front respectively during the mea surement period. These values are high especially in the glacial valley and, perhaps more surprisingly, at the range front 60 km downstream of the headwaters. Only at Hou Xia is suspension the dominant mode of

transport of the solid load. One might find two expla

nations for this. The Hou Xia basin is the place where

the river profile is the flattest. Flattening of the along

stream profile of the river should therefore logically

lead to lower values of bed load transport because of

the concurrent reduction in stream power expenditure

The low value of bed load may also come from the

fact that between the glacial valley and Hou Xia, the

river cuts relatively deep into the range. There its bed

is mostly rock floured. The river, when it enters the

Hou Xia plain a few hundreds of meters before site

2, may not be a transport limited stream but a sup

ply limited river. This then could explain why the bed

load component of the solid load drops to 20%. These

results clearly show that any mass balance or sediment

budget conducted in high mountain streams should

incorporate bed load measurements.

4.2 Fractional l transport

Some samples were kept and dried in the laboratory.

Sieving was performed and the bed load was decom

posed into i-size fractions α l,Di . The coarse fractions

were then normalized to the corresponding fractions 10 0 10

Figure 4 shows the plot of these normalized fractions against grain diameter During July 19 and 20 fractional transport seems, to the first order to be independent of grain diameter. Parker et al. (1982) proposed that grains moved in proportion to their presence on the bed surface. This hypothesis was developed in order to explain transport of bed material in paved gravel Bed River and was checked against data from Oak Creek (Oregon). Parker et al. (1982) called this phenomenon equal mobility. It was then argued by others (Wilcock, 1997; Wilcock & McArdell, 1997) that equal mobility was but an endmember of partial transport. Partial transport of matter seemed to be more representative of bed load transport by rivers in which bed material does not move in large proportions. In the Ürümqi He No true pavement can be defined over large surfaces of the bed. The unstable nature of braided channels is probably the reason for this. In fact the river presents a braiding morphology at several places in the glacial valley (site 1) and everywhere both in Hou Xia (site 2) and at the Range front. Surface granulometry performed at site 2 (Hou Xia plain) shows the local variability of grain size distributions and its relationship with bed structures (Fig. 5). For example the grain size distribution in a confluence pool has a D 50 of 1 cm whereas the D 50 of a midbar nearby reaches approximately 4.5 cm. Bed material measurements in Hou Xia, on the braid plain, therefore show that grain size distribution of bed material varies according to flow structures and position on the bed. 0

Figure 6. Open circles and dark shade of gray envelope: same as Figure 4 for the Hou Xia sampling site. Dark circles and light shade of gray envelope: normalization is done with the surface granulometry of a pool.

Equal mobility is clearly achieved downstream at the Range Front where transport rates are very high (Fig. 4 profiles 19 and 20). For other days and sites sands in the range 2-4 mm seem to be over represented in the bed load compared both to there respective abundance on the bed and to other grain sizes.

Fractional transport in braided streams should take the bed surface distribution of grains depicted above into account. Indeed in Hou Xia the measurement sec tion was located after a very dynamic pool.As selective surface granulometry was performed at this site, we tested the possible influence of spatial variations in the surface granulometry. Figure 6 shows the result. Although some variability remains due most proba bly to the small number of samples, the curves (dark circles) are strongly smoothed and approach equal mobility for the fractions with sizes less than 2 cm.

The residual variability may possibly come from the subsurface (Parker et al., 1982) as it has been shown that the granulometry of the subsurface is often finer than the granulometry of the surface material. 4.3 The step/pool-pool transport unit One very interesting feature

of the Ürümqi He concerns the way bed load is transported. As the material is coarse its characteristic distance of travel is probably quite small. Does such river morphology exhibit some particular spatial scales or pattern that would be indicative of the distance of travel of the grains making up the bed? One striking pattern of the Ürümqi He in the glacial valley is the succession of steep riffles or step-pool sections that alternate with flatter pool sections (Fig. 7). During our survey of the river in the glacial valley we continuously measured bed load both in a step-pool section and after a large confluence pool (Fig. 7). Between July 11 and July 14 when we left for the second site downstream in Hou Xia, a nearly bank full flood wave passed trough the measurement section. In two days the discharge rose by an order of magnitude. Peak discharge occurred on July the 13th and reached more than 6 m 3 /s. Figure 8 shows daily averages of bed load in both step-pool and pool sections together with the average daily discharge. Our measurements indicate that bed load transport in the step-pool section is weakly dependent on discharge. The load remains high before during an after the flood. On the contrary transport in the pool is strongly discharge-dependent. Bed load rises by nearly two orders of magnitude between July 11 and July 13. This variable dependence can probably be explained by the difference in the local h/D 90 ratios. In the steppool section this ratio varies little and is on order of 1 because large boulder of diameter similar to the flow depth strongly that regulate the flow like spill gates. In the pool where the water height is always large the bottom shear stress is probably much more dependant on flow conditions and therefore variable. The mass balance between the flux transported into the pool along the step-pool section and the flux leaving the pool is approximately 2. Thus before and after the flood, bed load is transported to the pool efficiently by turbulence in the step-pool sections. Most of the mass is then stored in the pool. During the flood event the pool is flushed and sediments get delivered to the next step-pool section where they are transported at a seemingly constant rate. Bed load granulometry clearly is affected by the passage of this wave (Fig. 9). Before the flood the size of the material transported from the step-pool to the pool is largely coarser then the granulometry of the material leaving the pool. Therefore sedimentation takes place and gravels are stored in the pool, in agreement with the mass balance (Fig. 8). During the

Figure 10. Correlation between average daily suspended

and bed load along the Ürümqi He.

the scale of morphologic structures as this balance is important to understand the characteristic lengths of transport of be material and the characteristic velocities at which such structures may evolve (e.g. Wohl,

4.4 Suspended load

Suspended load was measured with the use of a USDH 48 depth integrated sampler attached to a wading rod. Between one and three samples were retrieved each day. Daily variations are insignificant with the exception of July 12 and 13 during the passage of a bank full flood wave. As suspension was sampled throughout the flow depth the concentration obtained should be representative of the true flux although depth integrated sampling may bear some uncertainties because of the very transient nature of suspended load near the bed. Sediments transported mainly consist in fine rock flour. Very few silts were sampled. Overlaps between suspended and bed load samples is therefore negligible.

There are clearly two striking features with the suspended load of the Ürümqi He. The first one is that suspended load clearly appears to be the minor mode of transport along the Ürümqi He. During our survey the water was clear except during July the 12th and the 13th when the flood wave passed through. Suspended

load accounts for at most 22% of the total load carried

by the Ürümqi in the glacial valley. It accounts for less

than 10% both in Hou Xia and at the range front.

The second important observation that can be made

is the strong correlation that seems to exist between

suspended and bed load as shown in Figure 10. Aver

ages of bed and suspended load are well correlated

through a power-law relationship. This strong correlation clearly suggests that most of the suspended sediments come from the alluvial bed and are released by movement of coarse particles, sands, gravels and cobbles. This also implies that sediment feeding from the slopes is negligible. The Ürümqi Drainage lies in an arid environment. Very few precipitations occurred during our journey. When precipitations occur the principal mode of mass transport on the slopes seems to be gravity driven flows. Wash load is clearly not a dominant process and therefore explains why such a nice correlation occurs. This certainly deserves further research for at least two reasons. Understanding such a correlation may help us achieve correct estimates of the mass fluxes transported by mountain rivers without having to measure the bed load component explicitly. The difficulty of sampling bed load in gravel bed rivers has been known for long and estimating bed load movement through the measurement of suspended load clearly is an issue in studies of erosion and sediment transport by rivers. Further more such a relationship existing between bed load and fine particles release from the bed remains unclear and badly documented whereas it may shed light on the dynamics of fine particles movement and temporary storage in gravel bed streams. Rivers like the Ürümqi He may well be ideal places to study such entrainment. 5 SUMMARY A survey was performed on three reaches of the Ürümqi He, a high mountain stream of northern Tian Shan (China). Our survey shows the close link between the morphology (step-pool to pool) and sediment transport in these step mountain rivers. Equal mobility of the grains seems to be achieved in one of the reaches. At all three sites suspended and bed load are strongly correlated. These results confirm the importance of further researches on bed load transport and the control it exerts on mountain stream morphology. Especially it is suggested that concurrent and systematic measurements of both

velocity profiles bed load fluxes and granulometry are needed in order to understand the coupled evolution of river morphology and transport dynamics. Furthermore local mass balance at the scale of morphologic structures such as step-pools and pools shows how grain sorting and temporary storage occurs in mountain streams. At lower flows sands are transported throughout the system whereas gravels only move in step-pool sections and are trapped in pools. Long term mass balance coupled with granulometry of bed material movement and hydraulic measurements should then lead to a better understanding of the timescales and lengthscales of grain movement and of the timescales of morphologic changes in mountain streams.

ABSTRACT: The present paper concerned with investigation of solving natural sediment problems at

Elbogdady reach, south Luxor staff gauge, 712.80 km U/S of Roda staff gauge on the Nile River. The main

purpose of the paper is to investigate the navigation problems in the considered river reach and to suggest the

best location for the required quay or platform. Proper solutions has been suggested and studied for sedimentation

problems. Each alternative has been evaluated from both hydrodynamics and sediment transport points of view.

The best proposal has been selected from a set of alternative proposals. A 2-D numerical model (SED-2) has

been applied for simulating the sediment transport along the river reach.

1 INTRODUCTION

Planning of harbors covers the collection, process

ing and using of the natural choice of location and

orientation of major port components such as access

channels, breakwaters, basins, quays and specialized berths. It covers also, the choice of type of structures for preliminary engineering and cost estimates as well as design criteria for the different structures. The conditions affecting the quays planning may be climatic conditions; winds, temperature, rainfall and Humidity. Oceanographic conditions; waves, tides, currents and Sediment transport may have an important effect on the quays planning.Topographic, hydrographic conditions and soil conditions effect on the quay location.The following properties of the navigation channel through navigable streams should be investigated carefully while the design procedure.

- Channel location and orientation,
- Channel width and side slopes,
- Channel minimum water depth, and

Characteristics of the channel bends. The subjects of sediment transport and flow in alluvial streams are gaining it importance with the increasing utilization of water resources. Considerable research had been done in sediment transportation and the problems related alluvial streams in the past four decades by hydraulic engineers, geologists and researchers from other disciplines such as fluid mechanics. The knowledge of the distribution of sediment in the vertical is eventually used to compute the total suspended load carried by the stream. Observations in laboratory flumes and natural streams have shown that the concentration of suspended load in the vertical direction decreases with increase in distance from

the bed. The sediment transported past a strip of unit width and thickness will be (c * u dz) c and u are the local sediment concentration and the local velocity respectively. The method of integrating (c * u) over the depth had been proposed by Einstein H.A. 1942.Also, Bagnold R.A. 1966 introduced an energy balance concept and related. The suspended load transport to the work done by the fluid. Many authors had studied the simulation of sediment transport with various techniques. A number of attempts have been introduced including the laboratory investigations, the field studies and the numerical models. The numeric attempts have been surveyed. Paintal A.S. 1971 investigated a stochastic model of bed load transport Lung W.S. & O'Conner D.J. 1982 modified a 2-D mass transport equation in estuaries. Lin P. & Shen H.W. 1984 developed a 2-D model by characteristic method. Characteristic method was applied to analyze the two-dimensional unsteady flow

over a bed of fine sediment. Cole P. & Miles G.V.

1983 developed a 2-D model of mud transport. The

model studied the transportation of well-mixed cohe

sive sediments in estuaries and coastal waters.Van Rijn

L.C. 1986 investigated the mathematical modeling of

suspended sediment in non-uniform flows. Galappatt

G. and Vreugdenhil C.B. 1986 introduced a depth

integrated model for the suspended sediment transport.

Schoellhamer D.H. 1988 investigated a two dimen

sional Lagrangian simulation of suspended sediment.

Pacheco R. & Ceballos 1989 introduced an analytical

solution to enable the prediction of the sediment trans

port.Wang K.H. & Hu H. 1998 built a two-dimensional

mathematical model for calculating suspended sedi

ment transport in open channels. Ahmed Z. et al. 1999

studied a finite difference solution method as a tool for

solving the equation of longitudinal dispersion of con

servative pollutants in open channels. Verbanck M.A.

et al. 2002 applied the classical Rouse-Schmidt proce

dure to compute the vertical distribution of suspended

solids concentrations in open-channel flows.

2 NAVIGATION PROBLEMS

In order to develop more than more water transport

facilities, river channels must be improved so that they

are suitable for navigation. Several rivers in Europe

such as the Danube, the Volga, and the Rhine and such

rivers as the Mississippi in U.S.A. and the Yangtze in

China have been developed and regulated for inland

navigation. Inland navigation is also practised on some

of the Indian rivers in the eastern part of the coun

try. This improvement for navigation is effected by

one or more of the following processes: canalization,

regulation by river training works, providing lateral 0 100 200 300 400 500 600 700 800 900 1000 1100 1200 1300 1400 1500 1600 1700 1800 1900 2000 2100 2200 2300 2400 2500 2600 2700

Figure 1. Topographic map of the studied reach at Elbogdady area 1993. canals with locks, dredging to deepen the critical sections, and providing storage reservoirs to supplement minimum flow and increase the water depth. Application of these methods requires a deep insight into river hydraulics. The sedimentation problems in the Nile River become more severe after the construction of the Aswan High Dam because of the sediment free flow has the ability to convey sediment from either the river bed or banks causing a bed degradation and bank erosion. The following section introduces some of previous works in sediment transport branch and some of sedimentation problem, which happen over long reaches at the Nile River. Gasser M.M. 1988 introduced report on the best alignment of the two approach channels of the new navigation look at NagaHammadi. Gasser M.M. 1988 introduced final report on study of navigation problems existing on the Nile River at Selwa-Bahary. Ahmed M.A. & Ahmed M. 1997 introduced report on study of scouring problem which existing on the east bank of Nile River at Rashid branch at El-Wardan km. 34.000. 3 DESCRIPTION OF THE PROBLEM Elbogdady reach is located south Luxor staff gauge, 712.80 km U/S of Roda staff gauge. This area has been studied by the Nile Research Institute (NRI), ElMottasem M. & Zaki A. 1994. The main target of this investigation was to precise the efficiency of the reach as a quay for cargoes and floated hotels. The safest path of the navigation should be detected as shown in Figure 1. Hydrological data were collected about maximum and minimum discharges through the studied reach. Also, it has included the study of maximum

and minimum water levels of the Nile River at the stud

ied reach from 1970 to 1993. The collected data are as

follows in Table 1.

4 APPLIED MODELS

The 2-D hydrodynamic model (HYD-2) by Elfiky

M.M. et al. 1997 used for simulating the flow field,

it was based on the solution of the Reynolds form

of Navier-Stokes equations for turbulent flow. The

governing equations of (HYD-2) used for simulat

ing the flow field, are the momentum equations in x

and y directions in addition to the continuity equation,

reading as:

The sediment behavior has been simulated using the

2-D sediment transport model (SED-2) Elfiky M.M.

et al. 2002 which simulates the sediment transport

behavior in rivers. The movement of the suspended

sediment in alluvial streams can be governed by the

mass balance equation of sediment. Integrating the

3-D convection-diffusion equation of the suspended

sediment in vertical direction, yielding

Table 1. The hydrological collected data.

The collected data	In flood case	In emergency closure case	In winter case
Total discharge	245 mm 3 / day	605 mm 3 / day	65 mm 3 / day
Water level	(73.58)	(75.77)	(69.06)

Water slope for Nile River in this reach is assumed to be

equals about 4 cm/km. in which $\bar{u}$ and $\bar{v}$ are the depth-averaged velocity components in x and y directions, respectively, g is the gravitational acceleration, z s is the elevation of water surface above reference plane, h is the flow depth, ρ is the water density, τ b is the bottom shear stress, F is the external deriving force, ε f is the horizontal fluid diffusion coefficient, $\bar{c}$ is the depth averaged sediment concentration, c ∗ is the sediment carrying capacity, ε s is sediment horizontal diffusion

coefficient, α is the ratio of sediment concentration near the bed to the averaged concentration. 5 REACH INVESTIGATION 5.1 Hydrographic studies The hydrographic survey was done for Elbogdady river reach on 1993 through 18 lateral cross-sections from Km. 710.280 to Km. 712.220, as shown in Figure 1. It can be noticed that the top width of water surface varies between 891 m at Sec. (1) to 581 m at Sec. (18) for the flood season, while it varies between 798 m at Sec. (1) to 466 m at Sec. (18) for winter season. The river cross-section width tends to increase toward the north direction. It can be noticed easily the proposed navigation path, which was suggested by the (NRI). Also, the bed topography of this river reach has been investigated using the old surveys carried out between 1970 to 1993 to predict the history of the bed variations within this area. Figure 2 shows the bed topography of Elbogdady river reach carried out on 1982. Comparing between contour map 1982 and the recent one 1993, it has been found that the river west side between Sec. (12) to Sec. (18) has subjected to a great scouring process. While, the west side has subjected to a silting process between Sec. (1) to Sec. (12). In the east side, no variance can be noticed on the bed levels between Sec. (1) to Sec. (12). As a result of the above notation, (NRI) reported that the best location of the quay may be located at the east side between Sec. (6) to Sec. (12). 5.2 Hydrodynamic simulation The considered river reach has been schematized in a uniform rectangular mesh with ∂x= 20.0 m and ∂y= 20.0 m.The reach was investigated at first, using the 2-D hydrodynamic model (HYD-2) for two flow cases; case of minimum passing discharge and the flood case. The water slope was adjusted to be about 4.2 cm/km for the first case, while it was 4.0 cm/km for the second one. Moreover, a variation in the bed levels, within 0.01 m may be taken place, to simulate the velocities in the field. Velocities in lateral and longitudinal directions and discharge distribution were investigated. It was very important to satisfy 0 100 200 300 400 500 600 700 800 900 1000 1100 1200 1300 1400 1500 1600 1700 1800 1900 2000 2100 2200 2300 2400 2500 2600 2700

the hydrodynamic model calibration before using its

velocity computations in the developed model solving

the convection-diffusion equation in two dimensions.

Figures 3,4 show the comparison between the velocity

field measurements and the HYD-2 model outputs at

Sec. Sec (6) and Sec (12), respectively. It can be clearly

seen that, there are acceptable agreements between

the hydrodynamic model (HYD-2) results and the

field measurements. Now, the best site of the quay

should be studied and the safest path of the navigation

thought Elbogdady reach should be investigated with

the help of the developed model SED-2 in addition to

the HYD-2 model outputs. 0.00 0.20 0.40 0.60 0.80 0 50 100 150 200 250 300 350 400 450 500 550 Distance from east bank (m) D e p t h A v e r . V e l . (m / s e c .) Comparison between prototype and model for Sec (12). 6 PROPOSED SOLUTIONS The optimal scientific solution for the problem has depended on the investigation of the problem reasons. In addition, it has investigated the problem effects on the Nile River morphology and the necessary steps for the problem elimination. Proper solutions may be suggested and easily studied for the present problem to define the optimum proposal. All proposals, which have been suggested for the navigation path has been, introduced as shown in Figure 5. It can be noticed easily that the first proposal was suggested by the (NRI). There are some dredging areas as shown in the other proposal. These dredging areas were suggested with

Figure 5. The proposed navigation paths at the studied reach for all proposals.

Figure 6. The stream distribution at the studied reach.

bed level (66.00) achieving the necessary conditions

for a navigation path.

The suggestion of the two proposals is mainly

depend on the stream distribution as shown in Fig

ure 6. The suggestion depends also on the following

consideration. The orientation should normally be per

pendicular to the deepest contour lines to reduce the

dredging materials and dredging costs as well. More

over, the channel must be straight, if possible and the

S-curve orientation is should be carefully designed.

The prevailing wind direction must be taken into con

sideration while planning procedure to reduce the wave

forces acting on the sailing ships. The minimum width

for a straight navigable channel may be ranged as 3

to 4 times of the maximum vessel width for one lane

traffic, and 5 to 6 times of the average vessel width for

two-lane traffic. For the side slopes of the navigable

channels, the type of deposits, forming the channel

bed materials, plays the important role for selection

the appropriate and stable side slope. 7 COMPARISON BETWEEN PROPOSALS Comparison between the proposals depends on the investigating of the historical bed topography, the sediment process, and the cost. The navigation path should be pass through the deepest points in the studied reach. Investigating the 1993 bed topography, it can be noticed that the deepest point in the studied reach in the east side is located between Sec. (6) to Sec. (8) with bed level (64.53) and the minimum water depth reads 4.97 m. In addition, the deepest point at the west side has been found between Sec. (16) and Sec. (18) with bed level (63.91) and the minimum water depth reads 5.57 m. Achieving the necessary conditions for a navigation path, it is better to suggest the navigation path following the thalwage line which bind between the deepest area along the considered river reach, these consideration support both of the first and third proposals more than the second proposals.

Figure 9. Comparison between the sediment processes at centerline of the navigation paths for the two proposals.

A main decision to accept the suggested navigation path depends on the investigation of the sediment pro cess, which supports the first suggestion as shown in Figures 7,8.

It can be noticed easily in the second proposal for

navigation path, there are many locations of scour

and silting processes. It can not be acceptable at all,

because it may be very danger with respect to the

navigation process. But, it can be noticed in the first proposed navigation path for the two extreme flow cases that there are some locations, which may be subjected to scour process and very little zones subjected to silting process. The sedimentation process at the centerline of the two proposed navigation paths has been shown in Figure 9. It can be noticed that the second proposal should be subjected for the more active sedimentation rates. This notation supports the first proposal. Also, the 63.5 64.0 64.5 65.0 65.5 66.0 66.5 67.0 0 200 400 600 800 1000 1200 1400 1600 1800 2000 2200 2400 2600 Distance from East Bank (m)

updated bed along the two proposed navigation paths for 30-days has been detected as seen in Figures 10, 11. The figures define the bed variation along the two proposed navigation paths during 30-day. It clears that the first suggested navigation path should be subjected to scour process only along its centerline and the silting process may not accrue along the suggested navigation path. But, the second navigation path should be subjected for critical sedimentation processes specially starting from Km. 700.

The cost may play an important role in determine the best proposal. The volume of dredging materials and the length of the navigation path may be the important factors, which determine the cost for each proposal. Finally, the comparison between the alternative proposals may be summarized as shown as in Figure 12. The comparison cleared that, the first proposal is the more acceptable one than the other.

Finally, the suggested navigation path for the first

proposal may be safe from the hydraulic point of

view in addition to the historical bed topography

investigations.

8 QUAY SITE INVESTIGATION

The sediment behavior has been simulated using the

2-D models (SED-2) for the two flow cases at LWL

and HWL. Also, the river bed topography surveyed

on 1982 and 1993 were considered while simulation.

The safest location of the quay should be investigated through the studied reach taking into consideration the following factors: - The orientation should be parallel to and beside the suggested navigation path with enough area, - The orientation should be parallel to and beside the high way traffic, and - The silting process should not be accepted as possible. Generally, the quay site should be located at stable zone. Achieving the above conditions for a quay site, the site location shown in Figure 13 has been proposed. Figure 7 shows the sediment behavior for the studied reach at LWL considering the map 1993. It can be noticed that the studied reach has subjected to scour and silting processes, especially at the west bank. It is clear also that the east bank has subjected to little sediment behavior. Also, the sediment behavior has been studied considering the HWL flow case for the map 1993, as shown in Figure 8. It can be noticed that the suggested quay location is not subject to scour or silting process. As shown in Figure 9, the zone (A) clears the sediment process at the recommended location of the quay. It can be noticed that the sediment process at this location is very small. Also, comparing between the bed variation for the recent contour map 1993 and the predicted on for 30-days at Km. (1800) as shown in Figure 14, it has been found that the river west side has subjected for silting process. But, the east side at the recommended location of the quay, the bed may be subjected for sediment 2600 2650 2700 2750 2800 2850 2900 2950 3000 3050

firms the above notes also, and

- The proposed site dimensions satisfy the navigation

requirements.

9 CONCLUSION

In this paper, The Nile reach at Elbogdady area south Luxor staff gauge has been restudied.The investigation of the reach has cleared that, the reach is suitable for the navigation processes. Proper solution has been sug gested. Finally, the first proposal has been supported as the most optimal proposal. Also, the best location of the quay has been studied. It can be noticed eas ily the best location of the quay is at the east side of the reach. The investigation has been done by the 2-D sediment transport model (SED-2), which can predict the locations of scouring and silting zones along the considered river reach.

ACKNOWLEDGMENT

A computational distributed gravel budget for the lower

Fraser River,

British Columbia

S. Li & R.G. Millar

Dept. of Civil Engineering, University of British Columbia, Vancouver, B.C., Canada

ABSTRACT: A depth-averaged 2D model is used to compute a distributed sediment budget for a gravel

bed reach of lower Fraser River. The model couples the hydrodynamics and bedload transport of multiple size

fractions, and computes bed level changes on a curvilinear grid. Bedload transport, surface coarsening, spatial

variation in the size distribution, and morphologic change are calculated, for five steady discharges. For each

discharge, longitudinal variation in bedload transporting capacity is determined by integrating transporting

capacity across the channel at each 50 m section, defining zones of aggradation and degradation. A bedload

transport rating curve is developed at the boundary of each zone, and the mean annual bedload transport across

each boundary is obtained. The distributed sediment budget is determined. This yields average annual rates of

gravel aggradation and degradation volumes for each zone. The computed sediment budget agrees well with

results based on high quality field measurements of gravel transport.

1 INTRODUCTION

The Fraser River is a major river of British Columbia,

Canada, that rises in the Rocky Mountains and flows

generally SW into the Strait of Georgia at Vancouver,

B.C.The so-called “Gravel Reach” is located along the

Fraser Valley between Laidlaw and Sumas Mountain

(Fig. 1a). The Gravel Reach consists of an anabranch
ing network of gravel-bed channels, which are sep
arated by relatively stable vegetated islands and less
stable gravel bars. The Gravel Reach is located on
a confined alluvial fan, which has developed down
stream of the town of Hope where the Fraser emerges
from a steep canyon through the mountains.The reduc
tion in channel gradient downstream of Hope results in
deposition of the gravel load, which causes long-term
aggradation of the channel bed. There is an abrupt
termination of the Gravel Reach at Sumas Mountain
(Fig. 1a). Downstream of this point the Fraser is a
tidally-influenced sand-bed river.

The morphology of the Gravel Reach is a conse
quence of the gravel deposition, and it provides excep
tionally rich and diverse instream habitat. There are
also substantial management issues related to flood
ing, riverbank erosion and gravel extraction. Flood
protection is provided principally by a system of dykes
that were constructed several decades ago. A recent
revision of the design flood profile (UMA 2000) has
found that in places the dykes do not currently provide
adequate protection for the design flood. This is due in
part to bed aggradation as a consequence of gravel
deposition. Annual gravel extraction is recommended as one
management option to maintain the flood profile and the
integrity of the flood protection system (Church et al.

2001). Effective gravel management including removal requires a distributed sediment budget that includes estimates of the gravel inflow to the reach, the longitudinal variation in gravel transport rates, and locations of aggrading and degrading zones. Previous work includes gravel transport measurements conducted by Water Survey of Canada near Agassiz (Fig. 2), and longer term morphological estimates of gravel deposition based on repeated bathymetric surveys of the Gravel Reach in 1952, 1984, 1999 and a recentlyconducted survey in 2003 (McLean and Church 1999; Church et al. 2001). In this paper we present the first results obtained by applying a 2D morphological model to the Gravel Reach in order to obtain a distributed sediment budget. We have modified MIKE21C, a curvilinear hydrodynamic-river morphology model developed by DHI Water and Environment (DHI 1999). Modifications are necessary as the original model formulation was developed for sand-bed rivers and does not adequately describe important features of gravel transport and gravel bank stability and erosion. We modify the bedload transport algorithm and use the surfacebased transport model developed by Parker (1990). The remaining sections of this paper describe the Agassiz

Figure 1. Map of the Lower Fraser area (a), showing river kilometres upstream from Sand Heads (from Church et al. 2001).

The gravel reach is between about 95 and 150 km. The area of this study is between Mission and Agassiz (b), covered by a

curvilinear grid of 79 rows× 800 columns (plotted every 4th row and 8th column). Typical grid spacing in the alongand

cross-channel direction is 50 and 25 m, respectively. The most refined cells are located in the main channel and special care

in terms of flow splitting is taken for sub-areas with multiple channels. 0 5000 10000 15000 20000 25000 0 5000 10000 15000

from this study for the same location (km 44). data used, outline the model theory, and present the preliminary results. 2 DATA We obtained data of bathymetry, discharge and sediment for model input, verification and sediment budget evaluation. The bathymetry data were collected in 1999. A digital elevation model (DEM) developed from this survey by Mr. Darren Ham provides an approximate 25× 25 m coverage over the entire reach. Initial grain size distributions of the bed material are derived from field measurements of sediment transport (McLean and Church 1999). A flow duration curve and histogram was developed from discharge data measured at Hope (1912–1997) and is used in the sediment budget calculations. Inflows at

the Harrison River were obtained from a hydrologic

study conducted by UMA (2001).

3 MODEL

Here we provide a brief outline of the modified model.

The surface-based gravel bedload algorithm of Parker

(1990) is used because it explicitly accounts for devel

opment of surface coarsening, and hiding and exposure of different grain sizes on the bed surface. The sub surface sediment mixture is divided into eight grain size intervals. Mike 21C solves vertically-integrated 2D equations of continuity and momentum conser vation (St. Venant equations) to yield velocity field and free surface elevation, from which local bed shear stress is determined. Helical flows, which arise from curving streamlines in a river, around an island or a middle-channel bar and produce flow-direction devi ations from the depth-averaged velocity vector, are also computed using schemes suggested by Engelund (1974) and Struiksma et al. (1985). The effects of heli cal flows on near-bed flow and bed shear stress can be substantial.

Sub-grid motions not explicitly resolved are param eterized through an eddy-viscosity coefficient. It is determined using the scheme by Smagorinsky (1963), which relates the coefficient to the local flow deforma tion and spatial resolutions. Its value is adjusted solely to maintain numerical stability. The model was imple mented on an orthogonal curvilinear grid, covering the Lower Fraser between Mission and Agassiz (Fig. 1b). This curvilinear grid not only realistically resolves riverbanks, islands and gravel bars, but also allows the

flexibility of using higher resolutions in dynamically more important regions like the main channel.

On the established grid, the flow field and free surface elevation at each grid point are predicted as functions of imposed upstream (discharge) and down stream (water level) conditions, bottom friction and eddy viscosity. The net sediment flux in or out each local cell is evaluated, and bed level changes are com puted using the sediment continuity equation (Exner equation).

Bedload transport simulations were carried out on a sub-grid downstream from Agassiz to the downstream limit of gravel transport (Fig. 1b). There is no estab lished rating curve at the downstream boundary, and therefore the hydrodynamic model is extended down stream to the gauging station at Mission where a rating curve has been developed. We conducted five simula tions with steady discharges at Agassiz: 6000, 8000, 10,000, 12,000 and 14,000 m 3 /s. The discharge of 5000 m 3 /s represents the approximate threshold below which there is negligible gravel transport at Agassiz (Church et al. 2001). Each simulation was run for 48 hours of model time, which takes about 15 hours of CPU (real) time. 0 5000 10000 15000 20000 25000 25 30 35 40 45 14000 12000 10000 8000 6000 G r a v e l t r a n s p o r t r a t e (t o n s / d a y) Distance upstream of Mission (km) Figure 3. Longitudinal variation in total

cross section gravel bedload transport rates for discharges ranging from 6000 to 14,000 m 3 /s. Data has been smoothed by averaging with five adjacent cross sections in both the upstream and downstream directions. 4 RESULTS Calibration of the model was performed by comparing computed water level with data from eight gauging stations located along the gravel reach, which are from the HYDAT database (Water Survey of Canada). Calibration was achieved by adjusting distributed bottom friction coefficient (Strickler number or 1/n).The computed water levels at the gauge locations match the data with differences less than 0.15 m. For each cell bedload transport rates generally increase to a maximum shortly after the beginning of simulation, and then decrease with time as the bed surface coarsens. An approximate steady state for all size fractions is reached after a period of time (generally 18 hours or more of model time), which represents a condition of equilibrium transport in which all size fractions display near equal mobility (Parker 1990). Examination of the surface grain size distribution along the reach shows that the bed surface coarsens in regions of high flow. Transport rates are integrated across the channel to provide sectional totals. Longitudinal variation in the sectional total transport rates shows considerable spatial variation (Fig. 3), even after smoothing. Raw model output from Mike 21C has been smoothed by averaging transport rates over five cross-sections immediately upstream and downstream. The smoothing is necessary to make the output appear less noisy, and to define boundaries between aggrading and

annual aggradation volume (Table 1) divided by the zone

length times a nominal active channel width of 500 m.

degrading zones. Boundaries are identified as peaks

or troughs that delineate changes in the longitudi

nal transport gradient. Positive downstream gradients

indicate increasing downstream bedload transporting

capacity and zones of degradation, whereas negative

downstream gradients reflect decreasing capacity and

characterise zones of aggradation.

A gravel bedload rating curve is developed from

the model-derived transport rates at each boundary by

fitting an equation of the form: where G b = transport rate (tons/day); Q= discharge (m 3 /s); the value 5000 (m 3 /s) is the threshold discharge below which little gravel transport occurs (Fig. 2); and coefficients a and b are empirically derived.This rating curve is then integrated with the flow duration histogram to provide an estimate of the average annual transport capacity: where G bT = average annual load (tons/year); G bi = transport rate (tons/day) from the rating curve (1) corresponding to Q i from the flow duration histogram; p i = the proportion of the time the flow is within the range represented by Q i (where 'p i = 1); and 365.25 is the conversion factor for the number of days in one year. Calculated annual gravel loads across the upper boundary of each zone are given in Table 1. Average annual aggradation (degradation) volumes for each zone are derived from conservation of mass assuming a bulk density of 1.65 tons/m 3 : where I = inflow volume at upstream boundary (m 3 /year); O= outflow volume at downstream boundary (m 3 /year); and ΔS = change in gravel storage volume (m 3 /year) (Table 1). Finally, the nominal aggradation rate (m/year) for each zone is determined assuming a nominal active channel width of 500 m (Fig. 4). 5 DISCUSSION AND CONCLUSIONS This analysis represents the first attempt at computing a distributed gravel budget for the Fraser River Gravel Reach using a hydrodynamic model. The results appear to compare favourably with previous estimates derived from field measurements. Although there

is tremendous scatter, the computed rating curve for Agassiz-Rosedale Bridge (km 44) plots more or less about the middle of the measured gravel transport data collected by Water Survey of Canada at the same location (Fig. 2). Based on this rating curve our analysis returns an average annual gravel load passing the Agassiz-Rosedale Bridge of 340,000 tons/year (206,000 m 3 /year), which compares very well-perhaps fortuitously-with the estimate from Church et al. (2001, p. 65) of between 170,000- 230,000 m 3 /year. None of these values include the sand component. The current gravel budget analysis is based on the 1999 bathymetric survey, and provides a snapshot of the equilibrium gravel transporting capacity at the time of the survey. It is not possible to directly compare

these results with the previous work of Church et al.

(2001) who defined aggrading and degrading cells

based on overlays of the 1952, 1984 and 1999 surveys.

The Church et al. (2001) results represent averages

over the 47-year period. A better test would be to

compare our computed gravel budget with locations

and rates of aggradation/degradation for the period

between 1999 and the recent 2003 survey.These results

are not yet available.

Provided further testing supports the analysis pre

sented in this paper, then the computed gravel budget

provides useful information for gravel management

and development of gravel removal targets within the

Fraser River Gravel Reach. Zones of active aggra

dation are well defined and can be ranked in terms

of aggradation rate. Zone boundaries can be used as

boundary conditions to define smaller model sub

domains that are more amenable to intensive model

simulation that includes bed elevation changes, and

bank erosion and retreat.

The influence of drainage network formation and characteristics on a

catchment's sediment yield

E. Lykoudi

National Technical University of Athens, Athens, Greece

D. Zarris

Department of Water Resources, School of Civil Engineering, National Technical

University of Athens, Athens, Greece

ABSTRACT: The influence of certain geomorphologic parameters, such as the bifurcation ratio, on a catch

ment's sediment yield is rarely reported in the literature in contrast to the catchment area, which is assumed as a

predominant morphological parameter for quantifying catchment sediment yields. In this paper, the influence of

the catchment bifurcation ratio on the sediment yield is examined. Specifically, the mean weighted bifurcation

ratio is proposed so as to give more weight to the first order streams of the overall drainage pattern in the context

of sediment productivity and delivery. Mean annual sediment yields from four adjacent catchments in Western

Greece have been estimated. It is shown that in catchments with higher bifurcation ratios there is an increase

in sediment yield estimates, which is mainly accounted for the neo-tectonic activity and the geomorphologic

processes in the area.

1 INTRODUCTION

1.1 Global sediment yield estimates

At present, sediment yield estimations are achieved

mainly from simple empirical models that relate mean

annual sediment yield (S Y in t/km 2) to catchment prop

erties, including drainage area, topography, climate

and vegetation characteristics (e.g., Flaxman, 1972,

Jansen & Painter 1974, Dendy & Bolton 1976, Walling

1983). In some cases, catchment area (A in km 2) seems

to be the only explanatory variable used to predict sed

iment yield (Dendy & Bolton 1976, Higgit & Lu 1996,

Webb & Griffiths 2001,Verstraeten et al. 2003). Catch

ment sediment yield usually decreases with basin

scale, mainly because sediment sinks, such as flood

plains, will generally increase, assuming the concept

of source-transport-deposition continuum as the ideal

fluvial system (Schumm 1977). However, there is a

significant variability of sediment yield with catch

ment area. For two catchments with the same area but

contrasting climates and geomorphologic regimes will

likely exhibit completely different sediment yields.

Indeed, Parker & Osterkamp (1995) compiled mean

annual sediment discharges from 24 gauged rivers

in the United States. Drainage areas ranged from

1.6× 10 3 to 1.8× 10 6 km 2 . Mean annual sediment yields ranged from less than 5 to more than 1480 t/km 2 . Linear and non-linear regression analyses of mean annual sediment yields with drainage area indicate no statistical significant relationships. Furthermore, Avendano Salas et al. (1997) presented a dataset of sediment yield values from 60 catchments based on reservoir sedimentation rates throughout Spain. The relation between S Y and A for the 60 catchments is: That means that the drainage area explains only the 17% of the observed variability of the sediment yield estimates, even within the same region. On the contrary, Dendy and Bolton (1976) presented data from sediment deposits in reservoirs for 800 catchments throughout the USA. There was a statistically significant relation between mean annual sediment yields and drainage areas of the form of the equation (reprinted from Lane et al. 1997): Additionally, data from 37 catchments in northern Arizona show a remarkably good correlation with catchment area (Webb & Griffiths 2001). Sediment

discharge (Q S in t/yr) exhibits a power function with

catchment area of the form:

Lu et al. 2003 reported that from 248 sediment dis

charge measurement sites within the Upper Yangtze

catchment in China, sediment yield exhibits a fairly

good correlation with subcatchment drainage area in

the form of the equation:

Moulder and Syvitski (1996) showed that Q S is strongly correlated to catchment area and the maximum catchment elevation (H max) as:

It is likely that the increasing trend of sediment discharge with maximum elevation is a surrogate of tectonic activity. Milliman and Syvitski (1992) concluded that the strong correlation between sediment and topographic relief may not indicate that the second is the cause of the first, but rather that both are caused by another factor less susceptible to numerical modeling, namely tectonism. Furthermore, rivers that drain active edges of continental margins (e.g., western South and North America) or collision margins (e.g., southern Europe and southern Asia) are generally much smaller, but collectively they transport similar amounts of sediment as do large passive margin rivers.

Someone might have to consider the random or systematic errors that are associated with such estimates used in the regression equations described above. For instance, if a catchment sediment yield is derived from reservoir sedimentation rates, this estimation is subject to quite a lot of parameters that can induce significant errors, depending on the extend of the reservoir and the available instrumentation. More specifically,

errors can be accounted during the hydrographic sur

vey of the reservoir (e.g., GPS selected availability,

varied velocity of hydrographic vessel) and during the

post-processing of the hydrographic data (e.g., inaccu

rate Digital Terrain Models (DTMs) for old reservoirs

before the dam impoundment, obscure definition of

mud–water interface). Moreover, significant errors are

connected with estimation of deposits' density, espe

cially if it is not possible to collect undisturbed samples

from the reservoir's invert. Moreover, the same applies

to sediment yield estimates from sediment discharge

rating curves, especially as a design practice in Greece.

Simultaneous measurements of river discharge and sediment discharge are mainly conducted only in lowflow periods, thus any extrapolation for wash loads at the time of low frequency – high magnitude flood flows will generally give misleading results. Conclusively, it is noted that there is not a "universal expression" between sediment yield and catchment area, not only because there are different types of catchment geology, hydrology and topography but also because regional tectonics and geomorphology play an important role on the sediment availability within the catchment. 1.2 Catchment bifurcation ratio and sediment delivery ratio Horton (1945) stated that the decrease in number and increase in lengths of streams with centripetal order is approximately geometric and hypothesized that the increase in mean subcatchment area is also geometric. These statistical relations are known as the "Horton's laws" of stream numbers, lengths and areas. Their respective series ratios are designated as the bifurcation, length and area ratios. The bifurcation ratio (R B) between successive stream orders, according to Strahler's (1964) classification, is then defined as: where N U = number of streams with order U . The mean bifurcation ratio is the average value of the corresponding ones for the successive stream orders. Typical values of bifurcation ratios between 2 and 4 are typical for most natural fluvial systems.The

ideal number of streams for a basin of a given order, according to Horton (1945), is then as follows: The symbol K is defined as the order of the main trunk stream. It is supposed that, while calculating the mean bifurcation ratio, the streams of higher order have the same weight with the streams of the first and second order. This is obviously not representative; especially from sediment yield oriented considerations. It could be more appropriate to assign more specific weight to the first order streams (according to the proportion of the number of these streams against the total number of streams) than to the streams of the highest order. This could be rational, since the first order streams are pointing towards the sediment source areas of the specific catchment and contribute more to sediment availability.We then use the mean weighted bifurcation

ratio (R B,W), which is determined as:

The mean weighted bifurcation ratio is not intended

to replace the mean bifurcation ratio in Equation 7; this

will certainly give wrong results. This ratio intends to

give a first estimation on the degree of the catchment's

maturity or, in other words, how much the specific

catchment has developed all its streams of any order

depending on its geomorphologic state.

Bifurcation ratio is by no means involved in any

empirical (statistical) regression relations with sed

iment yield in international literature, according to

the authors' knowledge. It is included, however, in

statistical relations with catchment sediment delivery

ratio, DR, (i.e. the proportion of eroded sediment that

finally reaches the catchment's outlet). Roehl (1962)

using sediment yield data from 15 catchments from the

Southeast USA and source erosion estimates derived

from the Universal Soil Loss Equation (USLE), stated that (reprinted from McCuen 1998, p. 795):

where L=watershed length; and R=watershed relief (or the elevation difference), all in English units and DR expressed as a percentage. The concept of delivery ratio might be valuable in conceptualizing sediment yield processes but is highly uncertain in its applica tion. Indeed, source erosion is at least as difficult to be computed (usually with the USLE) as the sediment yield itself.

It is evident from Equation 9 that the delivery ratio is a decreasing function of bifurcation ratio. It is supposed that higher bifurcation ratios are likely to reveal elongated catchments with long, thin drainage networks that forces sediment to deposit within the stream network, especially if moderate magnitude flood events are prevailing and/or the vegetation cover is dense.

The objective of this paper is to show that, according to our sediment yield data for four adjacent catch ments in Western Greece, sediment yield and delivery is generally an increasing function of bifurcation ratio, in contrast to Roehl's (1962) findings. We argue that (a) the mean weighted bifurcation ratio is the most appropriative indication of catchment bifurcation in

terms of sediment yield, because it gives more weight

to the first order streams that, in turn, point towards the

sediment source areas, and (b) local geomorphologic

regime and tectonic activity (e.g., orogenic uplift), that

support higher bifurcation ratios, together with the high intensity of storms and runoff events are the driving forces for higher sediment production rates, thus for higher sediment yields. 2 RESEARCH FRAMEWORK 2.1 Study area Four adjacent catchments in western Greece are selected for analysis. Acheloos River, Agrafiotis River and Megdovas River are discharging at Kremasta reservoir, whereas Evinos R. is discharging at the Patraikos Gulf (see Figure 1). Kremasta dam was built at exactly the confluence of Agrafiotis and Megdovas Rivers with the main stem river (Acheloos R.) and was firstly operated at 1965. Sediment yield estimates for the three rivers discharging at Kremasta Reservoir were computed as reservoir sedimentation rates after a comprehensive hydrographic survey (Zarris et al. 2002). The DTMs before the dam impoundment (1964) and the period of hydrographic survey (1998–99) have been subtracted to produce the volume Figure 1. Map of the selected catchments with drainage network (only shown 3rd, 4th, 5th and 6th order streams).

of deposited sediments. The density of the sediments

was estimated by the extraction and laboratory analysis

of two sedimentary cores from the reservoir’s invert.

These rivers are discharging separately in the reservoir

so as their sediment yield could be estimated inde

pendently. Trikeriotis River, actually a subcatchment

of Megdovas R, while presented in Figure 1, is com

puted together with Megdovas R. as one catchment,

since their sediment deposits in the reservoir could not

be computed independently. Mean annual sediment

yield of the Evinos R. at Poros Riganiou measuring

discharge station was computed by means of apply
ing the ordinary suspended sediment discharge rating
curves to the available sample of mean daily discharges
(Nalbantis 1990).

The source erosion of the three basins discharging
at the Kremasta reservoir was estimated by applying
the USLE on a GIS platform. The sediment delivery
ratios were then estimated for all but the Evinos R.
catchment.

Mean annual inflow at the Kremasta reservoir is
76.6 m 3 /s, a significant portion of which belongs to
Acheloos River itself (49.9 m 3 /s). The mean annual
discharge of Evinos River at Poros Riganiou measur
ing site is estimated as 24.75 m 3 /s. Poros Riganiou is
located upstream of the river’s delta in the Patraikos
Gulf, but the catchment can be considered as an ideal
conceptual system of erosion–transport–deposition
continuum. All streams are perennial but are subject
to severe floods because of the intense storms that are
enhanced by the orographic uplifting of the Pindos
mountain range.All streams are sixth order catchments
(according to Strahler’s classification system) except
Agrafiotis R., which is a fourth order catchment, due
to its relative small area.

Table 1 presents the sediment yields and delivery

ratios estimated for the catchments under considera

tion. The results generally follow the trend of higher

sediment yields and delivery ratios with decreas

ing catchment areas, except the sediment yield from

Acheloos catchment. Particularly, Agrafiotis R. sedi

ment yield is in the same order of magnitude even with

the majority of Japanese rivers (Oguchi et al. 2001),

which are famous for their pronounced sediment

yields. Table 1. Characteristic elements of selected catchments. Mean Mean weighted Area S Y Bifurcation bifurcation Catchment (km 2) (t/km 2) DR ratio ratio Acheloos R. 1733 1184.6 0.17 4.20 4.94 Agrafiotis R. 320 2034.8 0.42 5.62 5.86 Megdovas R. 1239 489.4 0.22 3.89 4.75 Evinos R. 884 734 - 3.86 5.27 Applying the Equation 9 to the data of Table 1, delivery ratios are calculated equal to 0.13, 0.12 and 0.24 for the Acheloos R., Agrafiotis R. and Megdovas R. catchments respectively. It is shown that Roehl's equation not only gives misleading results for these basins (except for Megdovas R.) but also changes completely the order of the basins with higher delivery ratios. Indeed,Agrafiotis R., which exhibits the highest delivery ratio, according to our estimates from the Kremasta reservoir sedimentation rates, seems to have the least corresponding value according to Roehl's equation. The authors are unaware of any similar work by other researchers on that issue and this paper is dedicated to give some insight on the possible correlation of bifurcation ratio with sediment yield and delivery ratio. 2.2 Geology of the study area The geologic structure of the catchments under consideration has directly affected the formation of the drainage network and the morphology of the relief.The geologic setting of the study area is covered by formations of the "Gavrovo" and the "Pindos" geotectonic zones, which belong to the external "Hellenides", as well as post-alpine formations, ophiolites and igneous rocks. More specifically, the Acheloos River catchment is mainly formed by flysch and thickly bedded limestone of the "Gavrovo" zone, and alternations of the flysch with thinly bedded limestone, irestone and clastic sediments of the "Pindos" zone, which are intensely folded. The catchments of the rest of the rivers under consideration are consisted

of the intensely folded formations of the “Pindos” zone. More specifically, an extended part of the northeastern part of the Evinos catchment is formed only by the “Pindos” flysch with depth on excess of 1000 m. Figure 2 presents a synoptic view of the geologic formations of the region. 2.3 Regional tectonics The “Gavrovo” zone is characterized by a gentle tectonism, with synclines and anticlines, of which the axes follow a NW-SE direction as well as faults with a NW-SE and NE-SW direction. The “Pindos” zone is characterized as a gigantic tectonic cover, heavily

Figure 2. Geo-tectonic map of the study area.

cracked. This tectonism is demonstrated with micro

plications with axial direction NW-SE, thrusts of the

same direction as well as faults, which are contem

porary of the alpine structures following the same

directions or more recent following a W-E direction.

Generally, the “Pindos” zone has been under

gone intensified tectonic strain due to the consider

able movement of the “Pindos” formations over the

“Gavrovo” zone. Particularly, over the thrusting front

(where the whole of the Agrafiotis R. and the eastern

part of the Acheloos R. catchments are situated), the

tectonic stress is pronounced.

The main faults and thrusts are presented synopti

cally in Figure 2.

3 DISCUSSION

We consider, like Milliman and Syvitski (1992), that

the topographic/tectonic character of a river catchment

plays an important role in determining its sediment

yield and that catchment area plays only a supplemen

tary role. For instance, both Japan and New Zealand are characterized by high-relief mountains on active margins, coupled by tropical cyclones, which are assumed as the driving forces for the world's highest recorded sediment yields under natural conditions. 3.1 Mean bifurcation ratio and mean weighted bifurcation ratio Bifurcation ratios are normally assigning the values between 2 and 4, whereas 4 should be suggested as the "ideal" value of a catchment's bifurcation (Leopold & Langbein 1962, Costa-Cabral & Burges 1997). Yang (1971) measured 14 basins in the maturity stage in the middle-western USA. The bifurcation ratio of those basins ranges from 3.29 to 4.79, with a mean value of 4.05, which is nearly equal to 4.0. Other researchers (e.g., Eyles 1968, Gustafson 1973) reported less bifurcation ratio values for areas such as Germany (3.98), Australia (3.45) and Israel (3.75). The catchments of Northern Europe and North America were formed in a much older geologic period; therefore their catchments and rivers are stable, so that channel streams consisted mainly of the most probable networks in which the bifurcation ratio is close to a value of 4.0. As noted in Table 1, the mean bifurcation ratios of the examined catchments are quite high, higher than the average value of most catchments in other countries with less tectonic activity. The Agrafiotis R. bifurcation ratio value is even higher than the corresponding value observed even in Japanese catchments. For instance, Shimano (1992) measured the morphometric parameters of 180 catchments all over Japan. The values of bifurcation ratios range from 3.2 and 5.4 while most of them range between 3.6 and 4.8. Agrafiotis R. also exhibits a quite significant sediment yield and sediment delivery ratio, which is one of the highest values ever reported in the literature, particularly for the European region. There are two basic elements, which are important to be carefully noticed. Firstly, there is a deficit of the first order streams for all the catchments between the observed number of these streams and the supposed number according to the first Horton's law. The arithmetic values are given in Table 2. Secondly, another interesting point comes from the comparison between the mean bifurcation ratio and the mean weighted one (from Table 1). It is evident that for the Agrafiotis R. the difference between these values is almost infinitesimal, while the same differences for the other catchments are significant. It is implied, however, that these observations are in some way interconnected. Agrafiotis R., which exhibits the highest bifurcation ratio, has the lowest deficit of the first order streams. In pure numbers, it needs only 5 first order streams in order to reach the ideal state, as described by Horton's

scaling law. At the same time, the difference

Table 2. Comparison between observed first order streams against simulated ones as resulted from Horton (1945).

Basin	Simulated first order streams	Observed first order streams (from Horton, 1945)	% Deficit
Acheloos R.	1195	1308	9.45
Agrafiotis R.	172	177	3.20
Megdovas R.	840	888	5.70
Evinos R.	817	854	4.48

between the mean and the weighted mean bifurcation ratio is very small.We argue that these observations are closely related to the high sediment yield of this particular basin. Since Agrafiotis R. has developed almost the total number of the first order streams that it could be possible to develop, then, giving more weight to the first order streams, does not considerably increase the mean weighted bifurcation ratio of the catchment.This is also explained by the high bifurcation between the first and second order streams (4.53) for that particular catchment. It could be concluded that this catchment reaches the state of full maturity; it has developed almost the whole of its drainage network and finally exhibits high sediment yield values.

On the other side, the other catchments need a considerable number of first order streams to reach the ideal state of maturity. Acheloos R. needs 113 first

order streams, Megdovas R. 48 streams and Evinos R. 37 streams. For these catchments, the mean weighted ratio gives more substantial differences compared with the simple mean ratio. Based on the local geotectonic regime, the fate of these catchments is to further develop their drainage basins so as to reach the maturity that Agrafiotis R. has already reached. Therefore the sediment yields of these catchments will further increase, especially the Acheloos R. catchment, which has the most considerable hysteresis in terms of its drainage network formation, but it already exhibits a quite impressive sediment yield, constituting a possible exception to the general approved relation of increasing area – decreasing sediment yield.

3.2 Interrelations of geomorphologic and tectonic elements with sediment yields

TheAgrafiotis R. catchment is situated over the thrusting front of the “Pindos” cover; therefore its formations are heavily cracked. Additionally, all the river catchments are being undergone neo-tectonic movements, particularly orogenic uplift, which is characteristic of their geologic age. Agrafiotis R. catchment is already in an early mature state while the rest of the catchments are in a younger state. Orogenic movements are also responsible for the high sediment yields, because the equilibrium between the excess available sediment (from rock weathering) and the transport downstream should be

reached at all times. Channel incision through tectonic forcing is evident which keeps the catchment in a mature state, while constantly rejuvenated. Channel incision adds more first order streams in the drainage system, increasing the order of the whole catchment and re-arranging the overall drainage network; thus finally conveying new sediment source areas to the catchment outlet. Moreover, the uplift creates steeper stream slopes that, in turn, develop higher stream power of the flow, especially in large infrequent floods, which are typical in Mediterranean environments. Indeed, Snyder et al. (2003) stated that, comparing basins from high uplift zones (uplift rates around 4 mm/yr) to the ones in the low uplift zones (uplift rates approximately 0.5 mm/yr), streams in high uplift zones are about twice as steep for a given drainage area, therefore exhibit an increase of the catchment response to rainfall and sediment. Significant stream power values in V-shaped streams can easily transport sediment downstream (as wash load), increasing sediment delivery to the catchment's outlet. These processes of orogenic uplifting and increasing sediment yield are seem to be probably everlasting leading to continuously changing catchments and drainage patterns. 4 CONCLUSIONS This paper has introduced the bifurcation ratio concept in the context of sediment yield and delivery ratio processes of a catchment in order to draw useful interconnections between these geomorphologic parameters. Primarily, it was shown that the Roehl's (1962) equation, that assumed the sediment delivery ratio as a decreasing function of the bifurcation ratio does not hold, at least for the four adjacent catchments in Western Greece. On the contrary, it was shown that it is, in fact, an increasing function of the bifurcation ratio and was assumed that the regional neo-tectonic activity coupled with the state of maturity that these basins exhibit, are the influential factors for the relatively high sediment yield. It was shown that, for active tectonic areas, the increase of the bifurcation ratio entails greater sediment yields because there are more first order streams encouraging the conveyance of detached sediments to reach the drainage network.Additionally, the axial erosion in V-shaped, first order, streams with high stream power-low frequency flood peaks, transports the wash load further downstream, so as the residence times of the sediments within the catchment will be relatively low. This of course is a prerequisite for higher catchment sediment yields.

Finally, it was proposed that the mean weighted

bifurcation ratio is a better indicator for qualitatively

describing the drainage pattern in terms of sediment production, availability and transport. For catchments, that have fully developed their drainage patterns, according to Horton, the difference between the mean and the mean weighted bifurcation ratio is insignifi cant. On the contrary, for young catchments, which are still developing their drainage forms, the difference is significant because there is also a considerable deficit of the first order basins relative to the ideal value for the perfect fluvial system.

The observations of this paper, especially the con tradicting results with Roehl's equation, could give a motive to the geomorphologists, engineers and other earth scientists to cast their shadows over the real influ ence of the geomorphologic pattern of the catchment (e.g., drainage network formation, tectonic activity) over the long-term evolution of sediment yield. It is important to notice that there are no equations with global applicability but any approach will be tailored and specified for any particular catchment or region with homogenous geomorphologic characteristics.

Flow structure and bedload distribution at alluvial diversions

Arjan de Heer & Erik Mosselman

Delft University of Technology & WL/Delft Hydraulics, Delft, The Netherlands

ABSTRACT: Bulle (1926) carried out well-documented experiments on the bedload distribution at alluvial

diversions. We re-analyzed his results by simulating the experiments numerically using Delft3D. The bifur

cation angles and the roundnesses of the angles in the

upstream walls of the channel entrances are found to have a strong effect on flow structure and the division of bedload transport rates over the bifurcated channels. Hence they are key ingredients for the nodal point relations that are used to specify the sediment transport distribution at bifurcations in one-dimensional river models. Other key ingredients are found to be the division of discharges over the bifurcated channels, the widths and average depths of water flowing to the left channel and water flowing to the right channel, the widths of the channel entrances and sediment mobility.

1 INTRODUCTION

Bifurcations play a central role in a multitude of problems in river engineering and fluvial sedimentology. They are part of the elementary confluence-diffluence unit in braided rivers. They affect the stability of rivers on alluvial fans and in deltas. They determine the required maintenance in irrigation canals that take off from rivers as well as in secondary channels that are created for the ecological rehabilitation of floodplains. Finally, they are a key element in developing bend cut offs and avulsions, the latter being important not only in river engineering but also in alluvial stratigraphy for oil reservoir exploration. It is therefore surprising that the fluvial processes in bifurcations have not been studied as much as those in confluences, especially when realizing that the 1-D hydraulic and morpho

logical modelling of confluences is straightforward.

The 1-D modelling of bifurcations is more problem

atic, because it requires additional input in the form

of a nodal point relation that specifies how sediment

transport rates are divided over the two branches of the

bifurcation.

Flokstra (1985) and Wang et al. (1995) demonstrate

that the morphological development of the bifurcated

channels depends sensitively on the parameters of the

nodal point relation. Certain parameter ranges produce

a behaviour in which one of the channels is closed

inevitably by sedimentation, whereas other parameter

ranges produce a behaviour which tends to a stable

equilibrium in which both channels remain open. Nodal point relations are an issue if bedload transport is dominant. Situations with mainly suspended load do not pose great difficulties. The sediment transport rates of vertically homogeneous suspensions are divided simply in proportion to the discharges through the bifurcated channels. Suspensions with vertical concentration gradients can be approximated by analytical concentration profiles. Integration over the vertical leads to depth-averaged concentrations as a function of local flow depth and flow strength at the entrances of the bifurcated channels. Multiplication by discharge yields the sediment transports into the bifurcated channels (Slingerland & Smith, 1998). For bedload-dominated rivers, however, nodal point relations are usually purely empirical. A first step away is the physically-based approach of Bolla Pittaluga et al. (2001, 2003). Our study shows, however, that their approach still leaves room for improvement. We focus this paper on alluvial diversions as a special case of alluvial bifurcations. In alluvial diversions, the main channel has the same direction upstream and downstream of the bifurcation, so that only one of the bifurcated channels has a non-zero bifurcation angle. Bulle (1926) carried out

well-documented experiments on the bedload distribution at alluvial diversions. We re-analyzed his results by simulating the experiments numerically using Delft3D. The analysis shows that bifurcation angles strongly affect the division of sediment transport rates over the bifurcated channels. Nodal point relations should hence account for this effect.

2 DATA AND METHOD

2.1 Bulle's (1926) experiments

Bulle's experimental set-up consisted of a 0.2 m wide main flume and a 0.2 m wide diversion flume, taking off from the main flume under various angles. Here we consider only the experiments with an angle of 30 ∘ . The discharge was 5 l/s. The tailgates were set in such a way that, initially, this discharge was divided equally over the two branches. Experiments were carried out on a fixed bed without sediments, a fixed bed partly covered with sediment and a fully alluvial mobile bed. The sediments consisted of sands with sizes up to 1.2 mm, mainly transported as bedload. Bulle did not report more details on the grain size distribution. Bulle found that the diversion produced a curved flow pattern that induced a helical motion with out ward flow near the water surface and inward flow near the bed. In this way, a disproportionate amount of the bedload was transported into the diversion channel, cf. Figure 1. This has become known as the 'Bulle effect' among river engineers. Furthermore, Bulle found that

the flow separated at the entrance of the diversion

Figure 1. Disproportionate amount of bedload into diver

sion channel (Bulle, 1926).

Figure 2. Flow pattern with eddies in diversion channel and

main channel (Bulle, 1926). channel, producing an eddy along the outer wall. A smaller eddy occurred on the opposite side along the outer wall of the main channel, cf. Figure 2. During the experiments with sediment, the discharge through the diversion channel initially decreased due to sedimentation (after 45 minutes, Figure 3), but later increased back to the original value (after 75 minutes, Figure 4). The size of the eddy could be reduced by making the angle in the upstream wall of the channel entrance rounder. Figure 3. Sediment cover after 45 minutes (Bulle, 1926). Figure 4. Sediment cover after 75 minutes (Bulle, 1926).

The Bulle effect and the generation of eddies rep

resent two distinct mechanisms by which bifurcation

angles affect the division of sediment transport rates

over the bifurcated channels.

2.2 Numerical model

Bulle’s experimental set-up was schematized in the

Delft3D modelling system. Figure 5 shows a detail

of the computational grid around the bifurcation. The

numerical schematization was mirrored with respect

to the real configuration to facilitate De Heer’s (2003)

comparison with similar experiments by Riad (1961),

not reported here. We made three-dimensional com

putations of the flow and two-dimensional depth

averaged computations of sediment transport. Here

we focus only on the flow computations. The Chézy

coefficient for hydraulic roughness was 36 m 1/2 /s.

3 RESULTS

Figure 6 shows the computed flow pattern. The

model reproduces eddies in the main channel and the

Figure 5. Computational grid around bifurcation.

Figure 6. Computed pattern of depth-averaged flow

velocities. diversion channel. However, the computed eddy in the main channel is too large and the computed eddy in the diversion channel too small. We find that these results can be influenced by grid resolution, eddy viscosities and wall friction. The main cause of the disagreement seems to be, however, that the numerical grid implies too round an angle in the upstream wall of the channel entrance. This complies with Bulle's experimental finding that the size of the eddy in the diversion channel can be reduced by making this angle rounder. The problem is that a sharper angle in the numerical grid would increase the truncation errors in the discretized equations due to deviations from grid smoothness and grid orthogonality. 4 DISCUSSION 4.1 Importance of bifurcation angle It has been common knowledge since long that channels with a large bifurcation angle tend to experience sedimentation. In the nineteenth century, research in present-day India, Pakistan and Bangladesh was at the frontier of river engineering. Many of the design rules in the handbooks of Joglekar (1956, 1971) and Varma et al. (1989) stem from that period. These handbooks recognize the importance of bifurcation angles in, for instance, their guideline that the alignments of pilot channels for artificial bend cut-offs should be made at a curvature flatter than the dominant curvature of the river itself. Klaassen et al. (1993) and Mosselman et al. (1995) find empirically that larger bifurcation angles increase the probability of channel abandonment in the braided Brahmaputra-Jamuna river. Traditionally, this importance of bifurcation angles is explained from the Bulle effect. However, the generation of eddies appears to be important as well. That places various earlier empirical findings and engineering design rules in a new light. The typical sedimentation pattern at the entrance of alluvial diversions as shown in Figure 7 may result as much from the trapping of sediments in an eddy as from flow divergence and the Bulle effect. In the eighteenth century, works to stabilize the Rhine bifurcation at Pannerden ("Pannerdense

Kop") sedimentation Figure 7. Typical sedimentation pattern at entrance of an alluvial diversion.

by trial and error have been the cradle of Rijkswater staat, the executive body of the Ministry of Transport and PublicWorks in the Netherlands (van deVen, 1976, 1979). The solution finally arrived at was a slender flow divider between two bifurcating channels with negligible bifurcation angles. Recent two-dimensional morphological computations of the Pannerdense Kop by Sloff et al. (2003) demonstrate that the large width to-depth ratios of the Rhine branches make the Bulle effect of minor importance. Apparently, the failures of earlier solutions with larger bifurcation angles must be ascribed to sedimentation in areas of flow separation. Another example is the prescription by Joglekar (1956, 1971) andVarma et al. (1989) that the entrances of pilot channels for artificial bend cut-offs should be made bellmouth. The rationale might be that the resulting wider entrance section prevents eddies from squeezing the flow-conveying part into a narrow zone with a large bifurcation angle.

4.2 Nodal point relations in 1-D models

The division of bedload transport over the branches of a bifurcation depends on conditions in the branches, conditions in the local area immediately upstream of the bifurcation and conditions upstream of this local

area. These three types of conditions are discussed subsequently below.

4.2.1 Conditions in the branches

The conditions in the branches can be divided into downstream water level controls, cross-sections along the branches, hydraulic roughnesses along the branches and eddies close to the bifurcation. The water level controls, cross-sections and hydraulic roughnesses manifest themselves in the division of discharges at the bifurcation. Generally this division can be computed by a 1-D model without further difficulties, applying a backwater calculation for each branch and a water surface closure condition. This part of the conditions in the branches is therefore represented sufficiently by the division of discharges. Joglekar's (1956, 1971) cut-off ratio and the analytical expressions of Klaassen et al. (1989) and Jagers (2003) for the conditions in the branches are covered in this way.

The eddies depend to a large extent on the bifur cation angles and the roundness of the angles in the upstream walls of the channel entrances. It is worth noting that eddies may even affect the division of dis charges when one of them squeezes the entrance of a branch so much, that it becomes an obstacle with a local drop of the water level.

4.2.2 Conditions in local area immediately upstream of the bifurcation

The conditions in the local area immediately upstream

of the bifurcation can be subdivided into parameters characterizing the local primary flow field, parameters characterizing the local secondary flow field, parameters characterizing the local bed topography and parameters characterizing local sediment mobility. The primary flow field is defined as the flow field that has the same depth-averaged flow velocities as the full flow field but equiform flow velocity distributions over the vertical. The secondary flow field is defined as the difference between the full flow field and the primary flow field. It vanishes when averaged over depth. In the primary flow field, a vertical separation plane can be identified between a body of water flowing to the left branch and a body of water flowing to the right branch. Neglecting spatial variations in hydraulic roughness, the shape of the separation plane depends mainly on the division of discharges, the widths and average depths of the water bodies on either side of the separation plane and the widths of the entrances of the branches. These parameters determine also the cross-sectionally averaged flow velocities in each water body and hence, depending on sediment mobility, the primary supply of sediment to each branch of the bifurcation. A secondary sediment supply arises because sediments can pass the separation plane of the primary flow by helical water motion and by gravity pull along transversely sloping beds. The helical flow is a form of local secondary flow that depends on the curvature of the horizontal projection of the vertical separation plane. This curvature follows from the shape of the separation plane and hence from the same parameters, mentioned above, that determine this shape. The gravity pull depends on local sediment mobility and the local transverse bed slope. The latter might be represented by the difference between the flow depths in the two water bodies divided by half of the local width. Summarizing, the conditions immediately upstream of the bifurcation seem to be represented sufficiently by the division of discharges, the widths and average depths of the water bodies on either side of the separation plane, the widths of the entrances of the branches and local sediment mobility. The laboratory experiments of Federici (2003) confirm the importance of sediment mobility. Wang et al. (1995) have shown that the stability of bifurcations depends also on the nonlinearity of the sediment transport formula for the relevant range of flows and hence on sediment mobility. 4.2.3 Conditions

upstream of the local area The upstream conditions are responsible for asymmetries in the transverse distributions of flow velocities, sediment transports and bed topography immediately upstream of the bifurcation. Laboratory experiments by Federici (2003) and two-dimensional computations of the Pannerdense Kop by Sloff et al. (2003) confirm

that those asymmetries are important factors. The

degree of asymmetry can be represented by the local

transverse bed slope, which also figures among the

conditions in the local area immediately upstream

of the bifurcation. The transverse bed slope can be

defined as the difference between the flow depths in

the two water bodies on either side of the separation

plane divided by half of the local width.

4.2.4 Towards a physically-based relation

The key ingredients identified can be seen as building

blocks for a physically-based nodal point relation. The

transverse bed slope has been included in the nodal

point relation of Bolla Pittaluga et al. (2001, 2003),

who find that the associated transverse exchange of

sediment produces invariably stable bifurcations with

both branches open, unless the Shields parameter falls

under its critical value for incipient motion. How

ever, their nodal point relation does not account for

the effects of upstream asymmetries, local curvature

induced secondary flows or local eddies, that are

represented empirically by the parameters of the nodal

point relation of Flokstra (1985) and Wang et al. (1995). Figure 7 shows that the sedimentation induced by a bifurcation angle tends to increase this angle. This destabilizing effect is opposite to Bolla Pittaluga's stabilizing effect that the sedimentation induced by a transverse bed slope tends to decrease this slope. We therefore expect that further refinement of the analysis of Bolla Pittaluga et al. by including more effects will reveal that a downstream branch may be closed in conditions above the critical Shields value as well.

A generic physically-based nodal point relation might once be found for river bifurcations with fixed banks. If banks erode, however, bifurcation angles and other parameters of local geometry change. This implies changes in the nodal point relation that can never be predicted using a 1-D model alone. One dimensional morphological computations of bifurcating river systems can hence be meaningful in a limited number of situations only. In many cases, 2-D or 3-D models will remain a necessity.

5 CONCLUSIONS

Bulle's (1926) experiments reveal two mechanisms by which bifurcation angles affect the division of sediment transport rates over the bifurcated channels. First, flow curvature produces the 'Bulle effect' by which

a disproportionately high amount of bedload enters the channel with the largest bifurcation angle. Second, flow separation produces eddies that affect the division of flows and trap sediments. The eddies are larger in channels with larger bifurcation angles and also larger

Three dimensional modeling of sediment transport in a channel bend

N. Ruether & N.R.B. Olsen

Department of Hydraulic and Environmental Engineering, The Norwegian University of Science and

Technology, Trondheim, Norway

ABSTRACT: A three dimensional numerical model is introduced which is able to calculate the sediment

transport rate and the according bed changes over time in river bends. The model was tested against data from laboratory experiments. Several detailed studies of the lateral bed load movement on side slopes were investigated to find the appropriate formulas describing the physical phenomena of sediment transport in alluvial channel bends. Considering a stability analysis of a sediment particle on a side slope, and introducing an appropriate algorithm which takes the characteristic movement of sediments in river bends into account, the calculated velocities as well as the bed level changes over time showed a good agreement with the measurements.

1 INTRODUCTION

Sediment transport in river bends is of highest interest in the field of sedimentation engineering. The lateral bed load transport and corresponding lateral migration of rivers is one of the major unknown herein. Many research studies have been carried out to investigate particle movement on side slopes in channel bends.

The flow in river bends is dominated by transverse secondary currents. The sediments are eroded by the accelerated flow at the outer part of the bend and trans ported by the secondary currents to the inner part. Here they tend to deposit due to the reduced velocity and shear stress, forming a so called point bar. Addition ally, bed load particles tend to move down slope in response to gravity. This force is acting contrary to the force from the secondary currents, and keeps the river

bed in an equilibrium condition.

2 BED LOAD TRANSPORT IN RIVER BENDS

Sediment transport in river bends is mainly influenced by the complex flow structure. To understand morpho dynamics in river bends and consequently to derive formulas for sediment transport on side slopes, a num ber of researchers (van Bendegom 1947; Engelund 1974; Kikkawa et al. 1976; Ikeda et al. 1982 a, b; Olesen 1987; Kovacs & Parker 1994) has done investi gations in this field.The main results are the following.

The sediment particle on a side slope has a lower crit ical shear stress compared to those on the flat bed.

Furthermore it is observed that the sediment particle being transported on a transversal slope is not following the direction of the near bed velocity as it would on a flat bed. To reproduce the sediment transport in channel bends, it was necessary to find reasonable models from the literature. Investigations on an incipient motion criteria of particles on side slopes leads to a formula calculating a factor K (Eq. 1) which is reducing the critical shear stress of sediments resulting in an effective shear stress for particles on side slopes (Brookes 1963). The factor K is a function of the sediments' friction angle of repose, the transversal slope and the direction of the near bed velocity. where δ= angle between the stream line and the direction of the near bed flow velocity;α= transversal slope of the channel bed;□= slope parameter similar to the sediments friction angle of repose. The characteristic mechanism how the sediments are transported in channel bends is described by an equation derived by Engelund (1981). It is a further development of a formula by Engelund (1974) which was based on a static consideration of the forces acting on a grain on side slopes. The improvements are done by introducing a modified shields parameter which is

Figure 1. Velocity and sediment directions on a sloping bed

in a channel bend.

derived empirically considering the skin frictino of the

sediments. The equation reads

where = angle between the sediment transport

direction and the main flow direction; ∂h/dn=

tan (α)= transversal slope of the channel bed;

′ = shields parameter related to the skin friction;

′ = shields parameter; ρ W = density of water; ρ S =

density of sediments; d 50 = sediments size where 50%

is smaller. τ b = bed shear stress.

The model leads to an angle of the sediment trans

port related to the direction of the near bed velocity,

being a function of both the transversal slope ∂h/∂n

and the shields parameter related to the skin friction

′ . At the initial stage of the scour and deposition pro

cess in a channel bend, where the bed is still flat, a bed

load particle will move along the same direction as the

flow at the bed which is skewed inward due to the effect

of the secondary flow. However, as the deformation of

the bed develops, the path of the particles does not

longer follow the direction of the flow at the bed due

to the effect of gravity. Dependent on the side slope

of the bed geometry the bed load is transported more

in the direction of the outer part of the channel bend.

This mechanism is illustrated in Figure 1, explaining

the process described previously and the terminology

of the parameters used in the model of Engelund. 3 THREE DIMENSIONAL SIMULATION OF SEDIMENT TRANSPORT The numerical model which is used in the present study is called SSIIM and is developed by Olsen (2002). It solves the Reynolds-averaged Navier-Stokes equations in three dimensions to compute the water flow using the finite volume approach (Olsen 2003) as discretization method.The k-ε turbulence closure scheme (Rodi 1980) computed the stress term and the SIMPLE method (Patankar 1980) the pressure term. The suspended sediment transport was calculated by solving the transient convection-diffusion equation for sediment concentration. The diffusion coefficent was set equal to the eddy viscosity taken from the k-ε model. To define the boundary conditions for the suspended sediment concentration, van Rijn's (1984b) formula was applied to the cells closed to the bed. Additionally, the bed load transport was calculated using the bed load formula by van Rijn (1984a). The bed level changes were then calculated by solving the continuity equation in order to predict the vertical changes in the bed morphology over time. The direction of the transported material is then equal to the direction of the velocity at the bed. This might be sufficient in cases where no steep gradients in the bed evolution occur and the river course stays mainly straight. In contrast to this, sediment transport in river bends is a complex phenomenon and demands a more advanced model for sediment transport. From literature it is known that the direction of the transported material differs from the direction of the flow velocity near the bed. Therefore a new algorithm is implemented. It follows equation 3 and gives the transported sediments a certain direction, which is mainly depending on the transversal slope of the bed. Further on, a new incipient motion criterion for particles on side slopes is used. The results are compared with those of the default sediment algorithm, in order to see the sensitivity of this process. 4 RESULTS Kawai and Julien (1996) observed the bed level changes in a 90 ∘ bended flume under uniform flow condition. The resulting bed level changes of the physical model study are illustrated in Figure 2. In the 0.2 m wide channel an almost uniform bed material with a mean diameter of d s = 0.6 mm is used to form the initially flat bed with a longitudinal slope of 1/300. Both the water and the sediment discharge were kept constant to a value of Q = 4.0 l/s and Q B = 0.00144 l/s.The observed bed scour at the outer bank has a maximum depth of 0.11 m and is located near the bend angle α; = 60 ∘ . At bend angles of 10 ∘ <α< 40 ∘ , a point bar was formed near the inner bank. During

the whole

numerical simulation.

study time of 200 hours no bed forms were observed

(Julien 2003).

Figure 3 illustrates the contour map of the bed level

changes of the numerical calculations after the full

simulation time.The bed changes were calculated with

the default sediment transport algorithm. Herein, the

sediment transport direction is in accordance with the

direction of the near bed flow velocity. Considering

Figure 3 one can see that the maximum values of

the calculated bed changes are matching the measured

ones from the physical model. However the locations Figure 4. Contour map of the bed level changes from the numerical simulation considering the difference in directions of bed velocity and sediment transport and a modified motion criteria for particles on side slopes. of the maxima in bed changes are shifted towards the downstream direction of about 10 ∘ . The maximum scour and the minimum water depth are at a bend angle of about 70 ∘ and 40 ∘ , respectively. More over the plane dimensions of the point bar deposit at the inner side of the bend are too small compared to the measured values. These deviations could be interpreted as an over estimation of the sediment transport in longitudinal direction. Most likely this is due to the fact that the lateral sediment transport in this simulation was too small. Figure 4 shows the contour map of the bed level changes with the zero reference to the initial flat bed, with the modified bed load transport algorithm according to the model after Engelund (Eq. 3). Looking at the bed changes one can see that these results are much closer to the measurements than that without the enhanced sediment

transport algorithm. In this case, both the range of the bed elevation and the location of the maximum values are matching the results from the physical model. The plane dimensions of the scour and deposition are also fitting better the observed values. In the Figures 5a and b, the vectors of the sediment transport direction are illustrated. One can see that in the beginning of the calculation (Fig. 5a) where the bed is still flat, the vectors are slightly skewed towards the inner part of the bend following exactly the direction of the flow. This fact proves that the model is able to predict the secondary flow in channel bends. With the development over time, illustrated in Figure 5b, the bed starts to deform and direction of the sediments to deviate from the direction of the

(a) (b)

Figure 5. Direction of the sediment transport situated at the

entrance of the bend during flow calculation: (a) on a flat bed

and (b) on a transversal sloped bed. (Flow is from down left

to up right).

flow. At the end of the simulation time and the fully

developed bed topography, the vectors are pointing

mostly to outer part of the bend, in the direction of

the transversal slope.

5 CONCLUSION

A three dimensional model is presented which is

capable to calculate the flow field and the sediment

transport in a channel bend of 90 ∘ . The model uses

formulas based on a stability analysis for sediment

particle on a side slope, and introduces an appropri

ate algorithm which takes the characteristic movement

of sediments in river bends into account. The calcu

lated velocities as well as the bed level changes over

time showed good agreement to measurements from a

physical model study.

Chigasaki Research Institute, J-POWER (Electric Power Development Co., Ltd.), Chigasaki, Japan

ABSTRACT: In most reservoirs incisive channels are formed within the widening depositional area (the delta).

Understanding this phenomenon is important for the development of an efficient sedimentation control strategy

that uses these natural erosion processes to remove the deposits. Laboratory experiments in a wide rectangular

flume with an initially flat alluvial bed showed that the location of the channel is determined by the initial flow

pattern, and by the upand down-stream conditions that control this pattern. In these experiments the channel

formed along the left bank although the outflow was positioned on the right bank. Two to three major horizontal

eddies developed which force the flow field to support the observed curved channel. This particular behavior

could also be reproduced by a two-dimensional (depth-averaged) morphological model of the experiment using

the Delft3D modeling system. The simulations indicate that the observed asymmetry in channel position, and

sudden switches in channel location can be explained by the sensitivity of this flow pattern to geometry and

boundary conditions. Following this verification of the model-approach, a case-study has been carried out for

Senbiri reservoir in the Hokkaido region in Japan which shows the characteristic channel pattern as observed in

the flume experiment. Two-dimensional simulations indicate that time-dependent control of outflow gates and

modification of bend pattern in upstream river reach can be applied to increase erosion of the deposits.

1 INTRODUCTION

Reservoirs for hydropower, storage or flood con

trol, positioned in an alluvial river are subject to

sediment deposition in which sediment deposits are

non-uniformly distributed over the reservoir area. Sed

iments that are transported by the river settle within the

active storage of the reservoir, forming an advancing

delta of coarse sediments at the head of the reservoir,

and forming a more uniform bottom-set bed of fine

sediments in the deeper parts of the reservoir (e.g.,

Graf, 1983, Sloff, 1997). These deposits reduce the

capacity and lifetime of the reservoir. To fight these

losses and support sustainable management of reser

voir capacity, it is necessary to understand and predict

the relevant phenomena. Mathematical modeling tech

niques, especially twoand three-dimensional models,

are considered to have most potential for this purpose,

as the relevant processes and their interactions can be quantified properly.

One of the phenomena in reservoirs that is not well investigated and theoretically explained is the formation of incisive channels in the depositional area (delta) of the reservoir. It is most pronounced in reservoirs with a seasonal fluctuating water level (as in most hydropower, flood-control and water-supply reservoirs), or in reservoir that are operated with regular water-level draw-down to flush sediments from the delta (e.g., Fan and Morris, 1992). In many reservoirs these channels can be found, e.g. see figure 1, as they are a common feature of deltaic deposition in wide reservoirs. Nevertheless a full understanding of the development of these incisive channels is required to enable successful sediment-management strategies. Modeling of the channels may help to forecast deposition patterns, and to improve flushing operations using the erosive channel flow. Reliable theory regarding both the dynamic dimensions (width and depth) of these channels, and the varying location of such a channel is not yet available. The lack of knowledge regarding these phenomena initiated a study to channel formation, applied to sedimentation and channel formation in a small

Figure 1. Photograph of a channel (see arrows) in the delta top-set bed in Lake Mead (USGS, aerial photograph 1994).

reservoir in Japan. This reservoir is characterized by a pronounced channel formed on the far left side of the reservoir, with a large depositional area next to it on the right (J-POWER, unpublished).

The concerning Senbiri Reservoir, with a relatively small storage capacity, is located in the Toshibetsu River (tributary of theTockachi River) in the Hokkaido area, and has a quite large catchment area. Therefore, during floods, much water and sediment is flushed

through the reservoir. Nevertheless the deposits are gradually growing, and clogging up the conveyance.

It was found that, despite of the location of dam outlets on the far right side, the channel remained at the left side, such that at the right side a quiescent deposition area is maintained.A similar behavior was for instance reported in flume experiments of flushing operations by Schälchli (1987).

The study aims at investigating the causes of this observed behavior, and find measures to initiate the erosion of deposits from the right side by redirecting the eroding flow during high discharges. Therefore this study has been focused mainly on the loca tion of the channel (rather than its depth and width) and comprises both experiments in a wide labora tory flume, and two-dimensional mathematical mod eling using the Delft3D modeling system (WL |Delft Hydraulics, 2003). These modeling approaches allow for a representation of the spatial variations in flow and morphology that are supposed to determine channel development. Application of the numerical modeling approach to prototype conditions of Senbiri reservoir has been worked out afterwards to verify the findings, and for proposing site-specific measures. Figure 2. Topographic map of Senbiri reservoir (Hokkaido, Japan) with arrows indicating the location of the channel within the reservoir. In chapter 2 the processes are introduced that

cause the formation of channels in reservoirs. The modeling activities and results of wide flume modeling are presented in chapter 3 and 4, while the case study with prototype simulations in Senbiri reservoir is discussed in chapter 5. The results are discussed in chapter 6. 2 MORPHOLOGICAL PROCESSES The channels in reservoirs that are relevant in relation with this study, are those which develop by an interaction of deltaic deposition during periods of relatively high pool levels, and erosion during periods of low pool levels and/or high discharges (flushing). The processes that shape and position the channel are complex and highly dependent on the flow and sediment-transport conditions. 2.1 Channel formation during deposition The morphological evolution in the backwater reach is of a deltaic type, in which in a narrow reservoir the flow and sediment spread evenly across the pool, while in a wide reservoir the flow enters the pool much as a jet (Vanoni, 1977). Below the jet-flow a submerged ridge develops which subtends a submerged channel which will be built up to the surface and will extend farther into the reservoir, e.g. see figure 1 (ridge development into SE-direction). Fine sediment are carried and deposited to both sides of the channel, by reverse eddies that are generated by the jet flow. A process of building up of channel deposits followed

Figure 3. Back cutting of a channel caused by meander cut

offs in the Powder River, USA by Gay et al. (1998). Flow

direction is from top to bottom.

by avulsions leads to an unstable process in which

even multiple distributary channels may develop. Nev

ertheless, in situations with periodic floods or with

significant draw-down of water levels usually a single

main channel can be found.

2.2 Channel formation during erosion

The specific channel-erosion processes in reservoirs

are controlled primarily by the upstream and down

stream conditions, i.e. discharge and sediment supply

from upstream, and water level and outflow down

stream. For this study two types of channel-erosion processes in reservoirs can be mentioned:

• retrogressive erosion i.e. head ward (upstream) back-cutting into the deposits, see figure 4. These are the processes that occur during draw-down of the downstream water levels (using the bottom outlets). The phenomena can be compared to morphologi cal processes due to meander cut-offs, for instance shown in figure 3. The main flow tends to be con centrated in the channel. The channel dimensions are not only determined by transport of particles, but also by erosion of the banks through geotech nical processes such as sliding of the banks after undercutting.

• degradation, growing in downstream direction and caused by highly erosive inflows at the upstream inflow boundary, see figure 4. This situation is less common, and caused by an upstream deficit of sediment (e.g., caused by an upstream dam).

2.3 Channel location

Flow patterns that are brought about by the river and reservoir geometry (bathymetry), are assumed to con trol the location of the channel. As soon as conditions give rise to channel formation, the prevailing flow pat tern is determining the onset of course of the channel.

Often the jet-like inflow from the river is directed by

the river-channel upstream and the large supporting

horizontal eddy(s) next to this jet in the reservoir.After

the channel is formed its location is rather stable, and
Retrogressive erosion 0 0 1000 2000 3000 4000 Distance from dam (m) C h a n g e o f b e d l e v e l D A M flow Degradation 0 0 1000 2000 3000 4000 Distance from dam (m) C h a n g e o f B e d l e v e l D A M flow Figure 4. Erosion processes in a reservoir (1D modeling results). Upper figure: retrogressive erosion induced by downstream water level drawdown; Lower figure: degradation induced by reduced sediment inflow from upstream. difficult to shift as its depth enforces the flow pattern to follow the channel path. Since the initial flow pattern and initiation processes of channel formation are sensitive to the conditions, the location of the channel is difficult to predict. In Senbiri reservoir in Japan the channel is formed by a combination of deposition by riverine sediments, and erosion by water-level draw-down during floods. Laboratory experiments, and mathematical model simulations show in the following sections how the flow patterns determine the channel location. 3 WIDE FLUME EXPERIMENTS 3.1 Laboratory experiments Laboratory experiments were set up to examine the phenomena of channel formation as observed in Senbiri reservoir. The experiments were carried out in a wide morphological flume at J-POWER, Chigasaki

Figure 5. Wide morphological flume at hydraulic labora

tory of J-POWER, Chigasaki R&D Centre (flow direction in

this picture is from left to right).

Figure 6. Thickness of sediment layer (top view) at the

end of flume experiment B-b-1c (arrows indicate inflow and

outflow).

R&D Center in Japan, as shown in figure 3. The model

section of the flume is 2 m wide and 7 m long. To

reproduce schematically the observed channel devel

opment, a relatively wide and shallow flow field was generated on a slightly sloping sediment layer (slope 1/600). The flow enters the model at the upstream side through a narrow (40 cm wide) culvert in the middle of the flume, while the outflow was forced through a narrow opening on the right-hand side of the lower boundary. A discharge of 0.025 m 3 /s was imposed (without sediment), resulting in a flow depth of about 0.15 m.

By the clear-water inflow a channel is eroded in the sediment layer (by means of degradation). Since the sediment layer was initially only five centimeters thick, the fixed bottom of the flume was exposed after erosion. Similar to the observations in Senbiri reser voir, the channel did not develop along the shortest path from inflow to outflow gate, but developed toward the outer left side (opposite of the outflow location). Figures 6, 7 and 8 show the final configuration of the channel after experiment B-b-1c.

One of the proposed measures in Senbiri reservoir for changing the course of the channel, is the par tial closure of the existing channel through a sediment dike. To test the effectivity of this measure an exper iment was carried out starting from the end-situation of the experiment above. In figure 9 is shown how a

small dam was created from bed-material, to partially close the original channel. Sediment for the dam was taken from the right-hand side (dotted line indicates original bank line). Figure 7. Photograph, looking downstream, of eroded channel (dashed arrows) at end of flume experiment B-b-1c (after 72 h). Figure 8. Photograph, looking upstream, of eroded channel (dashed arrows) at end of flume experiment B-b-1c (after 72 h). Figure 9. Initial situation for experiment B-b-3c (looking downstream) with position of a small dam to partially close the original channel.

Figure 10. Photograph, looking upstream, of eroded channel and flow pattern (dashed arrows) during flume experiment B-b-3c after about 4 hours.

Figure 11. Photograph, looking upstream, of eroded channel (dashed arrows) at end of flume experiment B-b-3c (after 72 h).

Figure 12. Thickness of sediment layer at the end of flume experiment B-b-3c.

In figure 10 the situation is shown after about 4 hours. Due to the small dam the flow is forced towards the right side of the flume, and starts to erode through the deposits. Eroded sediments are transported down stream forming a wide advancing front over which the flow fans out. Due to the fanning out of the flow it losses its transporting capacity and causes the front to built up to form an underwater-ridge (see figure 10). After about 4.5 hours the main flow suddenly switches back to left side, and starts to erode the small dam. The flow pattern completely reverses, and again a bed topography similar to the end-situation of the previous experiment

(B-b-c1) is obtained at the end. The end state of the experiment is shown in figures 11 and 12. Analyzing these experiments it is assumed that after 4.5 hours a state developed, due to bed topography (and bed-form roughness), in which the flow-gradient to the left overgrows the gradient towards the right. The phenomena observed in this last experiment Bb-3c show some analogy to the stability of channel bifurcations (e.g., Sloff et al., 2003), in which the left and right channel are the branches downstream of the bifurcation. The system may maintain a state of an unstable 'quasi-equilibrium' in which only one branch is open. After some period of morphological evolution the system can reach a point in which a transfer to a new state occurs, in which the other branch is open. From theoretical analyses of Wang et al. (1995) it is known that this transition can occur very suddenly. On basis of mathematical model results the observed phenomena are further analyzed and explained. These analyses are presented in the following chapter. 4 MATHEMATICAL MODELING 4.1 Delft3D modeling system As shown in the previous sections the spatial variations in morphology require an accurate description of the flow patterns within the reservoir. Therefore, to study the channel formation in reservoirs a two-dimensional or three-dimensional mathematical model is most appropriate. For this reason simulations of the flume experiments and of the Senbiri reservoir were carried out using the Delft3D modeling system. To be able to unraffle and analyze the models it is decided to select an approach which includes a simulation of only the most processes which are assumed to drive the channel formation: • Depth-average shallow water equations are solved with a constant eddy viscosity for horizontal turbulence effects. These horizontal turbulence effects are very relevant for simulating the flow pattern (jets and eddies), and enter the momentum equations for 2D flow by the Reynold's stresses F ξ and F η (m/s 2). These forces are expressed by the following Laplace operator for turbulent momentum flux:

with ν 11 is a constant eddy viscosity (m 2 /s), G ξξ

and G ηη are coefficients to transform curvi-linear

to rectangular co-ordinates (m 2), u and v are flow

velocities (m/s) in ξand η-direction of the curvi

linear grid (reducing to xand y-direction on a

rectangular grid). Near closed boundaries a more

complex form is used to account for the shear stresses along these boundaries.

- The bed sediment is assumed to be of a uniform grain size, and the sediment transport rate can be based on total-transport formula. For this purpose a 2D form of the Ashida and Michiue (Egashira et al., 1997) formula is applied, which is expressed by:

In which D m is the mean diameter (m), K c is a correction factor due to the influence of bed slope, γ is a calibration factor, τ_{*cm0} is the non dimensional critical stress, and τ_{*mf} is the actual non-dimensional Shields value computed on the depth-averaged velocity and the mean grain size.

- The effect of relevant 3D processes such as helical flow in a bend (following from curvature of the flow field by a parameterized model), and the effect of gravity on sediment on a sloping bed, are reproduced by correction of the sediment-transport direction as follows (additional to the effect of coefficient K c which affects the transport magnitude):

with α is the near-bed flow direction (corrected for helical flow), β is the direction of sediment transport, $\partial z_b / \partial \xi$ and $\partial z_b / \partial \eta$ is the bed level slope, and $f(\tau_{*mf}, \xi)$ is a function dependent on the ratio τ_{*cm0} / τ_{*mf}, on bed slope components, and some

other flow and sediment related quantities.

• For simulations of the flume experiments a

sediment-layer on top of a fixed concrete bed is

modeled. Therefore the underlying concrete bed is

modeled as a non-erodible layer. The used model

ing concept for non-erodible is that of Struiksma

(1999).

Since during morphologically relevant conditions

the bed is assumed to be submerged over the entire

domain, the morphological processes are dominated

by scouring and accretion of sediment, also for the

steep slopes at the submerged channel banks. Typical

geotechnical bank-erosion phenomena (e.g., sliding

of banks) seem therefore not relevant for the channel

location in the flume, and are therefore not included

in the model. Figure 13. Stationary flow field computed for the observed initial flume conditions (plane bed, constant discharge), and plotted on the numerical grid. To further reduce the complexity of the system, specific processes, such as sediment sorting and convection-diffusion effects of suspended-sediment concentrations are not included for the moment (although these effects can be simulated with the modeling system). 4.2 Delft3D simulations for the laboratory experiments The flume experiments were repeated using Delft3D in order to study whether the relevant processes can be reproduced mathematically, and what features (e.g., varying roughness, non-erodible layers) are controlling the phenomena. The model was represented by a simple rectangular grid with grid spacing of about 20 cm in flow direction and 10 cm in transverse direction. A Chézy value of 60 m 1/2 /s was used for bed-roughness, and a roughness height of 0.05 mm was used for wall roughness. A median grain size D 50 of 0.26 mm was used to represent the bed sediment. And it was assumed that if the sediment layer

on the bed becomes less than 2 cm, the influence of the fixed concrete bed enters the transport computation as the troughs of bed forms are assumed to reach the concrete.As the simulations were only mend for qualitative comparison, little effort was spend to calibration. In figure 13 the simulated stationary flow field is shown that is computed starting from an initial condition of stagnant water with a plane bed. The flow pattern was found to agree with the observations, showing a channel positioned on the left, supported by a large stable eddy on the right hand side, and a small eddy left of the flume entrance. Nevertheless it was also found that this simulated pattern can switch to a reverse pattern with the channel positioned on the right side, and the eddy on the left side. This could be achieved by changing the initial state, or the local geometry. The sensitivity to these conditions is quite strong. The morphological simulation shows that the initial flow pattern with a jet-type concentrated flow channel, drives the incision of the main channel on the left side. Comparison of simulated results in figures 14 and 15 with the observations in figures 6, 7 and 8 show that there is a striking agreement, despite of the difference after 5 hours 59 minutes 0 0.002 0.005 0.015 0.025 0.045 0.065 0.085

in layer-thickness (due to underestimation of initial

sediment-layer thickness in the computation).

Also the experiment B-b-3c has been simulated, in

which the final state of experiment B-b-1c is modified as shown in figure 16.

As a consequence of this initial topography simulation shows that the main flow is directed towards the right side due to the obstruction of the left hand channel, which corresponds to the observations. Sediment-transport and erosion is therefore mainly occurring on the right-hand side, see figure 17.

The observed sudden switch from channel erosion on the right, to channel erosion on the left side (after 4.5 hours) could not be reproduced automatically by the simulation (the flow pattern remained stable). Most likely some small erosion of the small dam and formation of the ridge (see figure 10) are not fully reproduced by the model. This might be a matter of further calibration. Nevertheless, by stopping the simulation, after 24 hours 0 0.002 0.005 0.015 0.025 0.045 0.065 0.085 Figure 18. Thickness of sediment layer above concrete flume bed simulated after 24 hours. generating a new flow pattern with the main flow along the left bank, and restarting the simulation with this flow field, the observed continuation of channel development could be reproduced (see figure 18). It is concluded from these simulations that notably the small changes in geometry affect the flow pattern in such a way that the main channel can switch from ‘equilibrium states’ with a left or a right position of the channel. Nevertheless, it is not disproved that in this set-up with an asymmetric position of the outflow gate, the channel tends to develop towards the opposite side (taking the longest path). Knowing now that the modeling system can be used to reproduce the observed morphological behavior, a model was set-up for Senbiri reservoir. In the following chapter the results are presented, and show what this means in a prototype situation. 5 CASE STUDY: SENBIRI MODEL In chapter 1 the Senbiri reservoir has been introduced. It is

supposed that the morphology of the reservoir is predominantly determined during floods. Main flow is concentrated along the left bank, despite the location of the outflow gates at the right bank (figure 2). On basis of annual sediment balance data of the measured reservoir volume it was found that net sedimentation occurs in years with lower peak discharges, and net erosion occurs in years with high peak discharges (i.e., 1992 and 1998). The reservoir and part of the upstream Toshibetsu river was schematized in the Delft3D modeling system, using a curvi-linear numerical grid (about 170× 18 grid points).The model is shown in figure 19. The length of the model is about 5 km, and the grid size is about 20 to 50 m in longitudinal direction, and 15 to 40 m in transverse direction. The dam is the lower boundary of the model, by which the gates are modeled as open water-level boundaries. Furthermore, the model uses a constant Manning roughness coefficient of 0.035 m 1/3 /s, and a grain size varying from D 50 = 10 mm in upstream reach to 1 mm at the dam. Sediment transport is computed again using the 2D form of the Ashida and Michiue equation, multiplied with a factor of 2 after (rough) calibration and a dimensionless critical shear stress (τ ∗ crit) of 0.05. 77 77.5 78 78.5 79 79.5 80 80.5 81 81.5 82 distance (m)

Figure 20. Initial bed topography in reservoir reach.

Several simulations were carried out with different

boundary conditions:

• Simulations based on a constant discharge ranging

from 200 to 800 m 3 /s imposed at the upper bound

ary. These discharges are characteristic average

values of observed flood discharges.

• Simulations based on a varying discharge, using a

hydrograph that represents the peak discharges dur

ing the years 1994–2000 (up to almost 1000 m 3 /s).

In all simulations the channel was found to per

sistently develop along the left bank, as shown in

figures 20 and 21. Only during very high discharges

the channel was able to break through the sand bar

Figure 21. Final bed topography in reservoir reach. on the right side to form a temporary cut-off channel (bend cut-off). These events explain the observed erosion during high discharges in 1992 and 1998. Nevertheless, these cut-off events can only occur when water levels at the dam are not completely draw down, because then the flow becomes concentrated in the existing deep channel on the left. The flow field that causes the channel to be oriented to the left may also be influenced by the position of river banks and the onset of a bend towards the left just upstream of the widening part of the reservoir. It might be considered to design upstream measures to modify the channel direction, e.g. modify the meander pattern in such a way (by bank displacement) that the channel is forced to flow to the right instead of to the left. Furthermore it is possible to use floating surface vanes (anchored to the banks) during floods to force the upper sediment-free water towards the right to erode the deposits, and allow the lower sediment-laden water to flow to the left, towards the deep channel. The simulations also confirmed the important role of boundary conditions in sedimentation and erosion. The computations show that the type and schematization of the upper boundary determines the supply of sediment to the model. At the same time the operation of the gates during the floods has a significant impact on erosion and sedimentation processes within the reservoir area. Any disagreement between modeled and actual sediment inand out-flow affects the sediment balance. 6 DISCUSSION Laboratory experiments and numerical simulations for a wide flume show that channel formation in reservoirs is particularly controlled by the flow pattern. It is therefore highly dependent on the boundary conditions, the initial flow conditions and the geometry (and changes in time). Due to the sensitivity of the

flow pattern to these conditions it is difficult to pre

dict the exact location of the channel. On the other hand, the sensitivity of flow patterns creates opportunities to redirect the channel direction by means of small interventions in the flow field (e.g., operation of water-levels at gates, or constructions that redirect the flow within the reservoir).

Although the simulations show that a 2D depth averaged model can be used to reproduce the observed features in laboratory in field, it is believed that further improvement of the modeling technique can lead to more reliable predictions. For a better approximation of the eddies and jets it is recommended to use a more detailed model for horizontal turbulence. For instance techniques such as HLES (horizontal large eddy simulation) or even fully 3D approaches can be considered. Furthermore, the sediment-transport model can be extended with multiple size fractions (e.g., Sloff et al., 2003) and convection-diffusion processes for suspended sediment. For application to prototype conditions these sediment-transport processes are quite relevant for reservoir morphology (e.g., to distinguish between development of coarse delta deposits and fine bottom set bed). Verification of the models for laboratory experiments with retrogressive erosion and graded-sediment feeding (instead of

the presently performed degradation experiment) are

thought to be necessary for validation as well.

To effectively apply the channel incision processes

for removing deposits, the location of the channel

can be changed by modifications of the flow pattern.

Before a channel is formed these interventions can

be much smaller than after its formation, because the

channel attracts the main flow, and stabilizes the flow

pattern.

The present study has not yielded new information

regarding the dimensions of channels. For flushing

sediments it is considered relevant to know the chan

Measuring the flow structures that initiate stone movement

Bas Hofland & Robert Booij

Environmental Fluid Mechanics Section, Faculty of Civil Engineering and Geosciences, Delft University of

Technology, Delft, The Netherlands

ABSTRACT: This paper deals with the entrainment of coarse material from a streambed under a uniform

turbulent flow with low-mobility transport. The flow field during the actual entrainment of a single stone was

measured using the PIV technique. In order to determine the flow structures responsible for this entrainment

the flow field was conditionally averaged over many entrainment events. The resulting flow fields show that

two flow structures are responsible for the entrainment: the first is a large-scale sweep ($u' > 0$, $v' < 0$), causing

increased quasi-steady forces, the second is an embedded small-scale structure with vertical velocity fluctua

tions, $\sigma(v')$, causing turbulence wall pressure fluctuations (TWP). The increased $\sigma(v')$ is often associated with

a single spanwise vortex or a small hairpin-vortex packet. The structures can be present simultaneously in the

instantaneous flow fields. It is hypothesised that the vertical fluctuations initiate the motion of the stone and the

sweep moves the stone further over its pivot point. This hypothesis is supported by the fact that the intensities of

the structures are negatively correlated: if one of the structures is more intense, the other does not have to be as

intense. Some intense sweep events show no significant small-scale structure.

1 INTRODUCTION

Bed protections near hydraulic structures are often

composed of several layers consisting of loose granu

lar material (riprap). Especially for non-uniform flow,

the existing equations for stability of stones in the top

layer have limited validity. The transport rate of stones

under design conditions is low, with a Shields factor

near the “critical” value of 0.055. Low-mobility trans

port is also important for gravel bed rivers (Andrews &

Smith, 1992). The present measurements are therefore

aimed at low-mobility transport. This complicates the

measurements, as the movement of the stones becomes

a rare event, caused by the fluctuating forces created

by the turbulence in the flow.

An elaborate measurement set-up was used to cap

ture the flow and pressure field at the moment of

entrainment of a stone from a granular bed. The mea

surements can aid the understanding of damage to

granular bed protections and entrainment of sedi

ments from river beds. This paper focuses on the deter

mination of the flow structures that cause entrainment.

2 EXPERIMENTAL SET-UP

The experiments focussed on the movement of a sin

gle stone, the target stone. This makes it possible to

average the flow field at the moment of entrainment. A flume of 20 m long and 0.495 m wide was used. The bed material had a nominal diameter, d n50 , of 17.8 mm (d n50 = 3 √ V 50 , where V 50 is the median stone volume).The flow conditions that can be generated are not sufficient to move the stones. Therefore the target stone was copied with epoxy resin having a density, ρ s , of 1300 kg/m 3 . It had a d n of 1.86 mm and a Curry shape factor of 0.62. The position of the target stone and various sensors in the granular bed is depicted in Figure 1. An inductive sensor was used to see if the stone was touching the bed. As the main mode of movement is pivoting (Carling et al. 1992; and our own observations), it was possible to place the stone

Figure 1. Measured longitudinal sections of the granular bed near the target stone indicating positions of pressure sensors (©: upward/lift,□: forward/drag, off-centre) and motion sensor (□). on a hinge in such a way that the motion is the same as

in the prototype situation. Further, the motion of the

stone was obstructed by a little bar after pivoting over

roughly 40 degrees.When the stone reaches the bar, the

hydrodynamic force on the stone has increased. There fore the stone remains pushed against the bar until it falls back with the passage of a negative fluctuation. In cases where the stone was allowed to rotate further, it did not fall back, which means that it would have moved from its position without the bar present.

2.1 Flow parameters

The Reynolds number was 10 5 , based on the water depth h of 0.159 m and the mean bulk velocity U of 0.64 m/s. The turbulence was considered fully devel oped with the rough bed spanning a length of 66 h upstream to 28 h downstream of the target stone. The width/depth ratio of about 3 implies the presence of some secondary flow. The shear velocity u ∗ was deter mined from the water level slope at 0.062 m/s, giving a Shields factor of = u 2 ∗ /(ρ s /ρ−1)gd n50 = 0.073, and a Particle Reynolds number of u ∗ d n50 /v= 1.2 · 10 3 . The Shields factor is higher than expected. The low movement frequency of the stone (0.11 min −1) was expected at a lower . It could be that because of the low stone density the added mass is relatively more important, increasing the critical Shields factor. Because the hinge was placed about 1.5 mm higher than the original point of rotation, the resistance of the stone against pivoting could also have been slightly

higher than assumed.

In this paper x and y are the streamwise and upward coordinates respectively and u and v the corresponding velocity components. The time average of u is denoted as u, the fluctuating part (u – u) as u ′ , and a spatial average over area a is <u> a .

2.2 Equipment

A LaVision PIV system (hardware and software) was used to measure streamwise vertical 2-D velocity fields in the centre of the flume above the target stone. The dedicated Kodak ES1.0 camera (1K× 1K pixels) and 50 mJ double-pulsed New-Wave YAG laser have a maximum double-frame sampling frequency of up to 15 Hz. The time interval between two images in a pair was 2 ms. The flow was seeded with hollow glass spheres of 10µm diameter.

The distance between light sheet optics and the mea suring area was set to about 1.5 m in order to keep the divergence angle of the sheet width limited.

The rail on which the optics were mounted was placed in line with the flume (Fig. 2). The laser sheet was guided towards the measuring area using two coated mirrors where it was about 1.5 mm thick and 150 mm wide. It entered the water surface undistorted through a streamlined window. In order to diminish the

Figure 2. PIV set-up with laser (top left), sheet optics, mirrors, window on water surface and camera (bottom right). bed reflections of the light sheet, the stones under the light sheet were painted fluorescent red and an optical filter was placed in front of the camera. The velocities were determined using a multipass cross-correlation method with discrete window offset, using window sizes of two times 32× 32 pixels and one time 16× 16 pixels with a 50% overlap. This gave a vector spacing ∆x of 1.2 mm. The final results were checked using a median filter (with the possibility to select the second correlation peak), an absolute vector range, and a minimum ratio of the height of the correlation peak to the highest noise peak of 1.1. The Kolmogorov length scale was not resolved. Therefore the small-scale turbulence (wavelengths smaller than 2.4 mm) will cause noise in the determination of the velocity vectors. Still typically 95% of the vectors were validated. The unresolved fluctuations will not lead to significant forces on the stone and are therefore not of interest. Miniature, low-range, piezo-resistive pressure transducers (Honeywell, 24pcefaxx) were used to capture the pressure fluctuations near the target stone. 2.3 Timing We discern two modes of motion of the target stone, rocking and moving. The stone was assumed to have moved (i.e. lifted out of its pocket) if it had reached the obstructing bar. The fact that the stone is sometimes pushed against the bar shows up in the histogram of durations of stone motions in Figure 3. If the stone is pushed against the bar it takes much longer for it to fall down again.This gives the small second maximum around ∆T up = 10 s. The target stone was assumed to have moved when the duration of detachment exceeded the time between the two maxima in the histogram (dashed line). Otherwise the mode of movement was regarded as rocking. The threshold of one second was not strictly dividing both modes of movement, so for determination of the real movements, visual inspection of the recordings was necessary.

Figure 3. Histogram of the durations that the target stone is

detached from the bed.

The stone moved on average once every 526 s, while

the PIV apparatus had a limited storage capacity (1

GB of RAM). Therefore the PIV and pressure mea

surements were only saved when the stone was not

in contact with the bed for at least 1 s and was thus regarded to have moved. The recordings were made continuously and stored in a ring buffer, so measure ments could still be saved from before to after the entrainment. As the stone fell back to its original posi tion eventually, a new recording started automatically when the prior data were saved and the stone was back in its original position. In principle the time between the detachment of the stone and the first consecutive PIV recording was measured very accurately, which would increase the precision of determination of the position of flow structures that lead to movement of the stone. Due to instrumentation problems, however, we were not able to use this information.

3 PHYSICAL CONCEPTS

In previous work the origin of pressure fluctuations was examined (Hofland, subm. a, b). However, the displacement of a stone does not only depend on the magnitude of the pressure fluctuations, but also on their location and duration. Therefore the actual move ment of a stone was used as a trigger to distinguish the velocity fields leading to stone entrainment.

It could be that several types of flow structure are responsible for the entrainment of stones and that they vary in size. We will use some of the knowl

edge obtained in the previous research to find the flow structure(s) that cause(s) the movement of the stone.

We previously identified two force-generating mechanisms. Therefore we will first divide the flow fields for all events into two classes, corresponding to these mechanisms. These are:

- Quasi-steady force fluctuations, caused by large scale sweeps ($u' > 0$, $v' < 0$).

- Small-scale turbulence wall pressure fluctuations (TWP), caused by small-scale wall normal fluctuations (v') and vortices. These two classes should be recognisable in the flow field and can help to distinguish between different flow structures that cause entrainment. Next we will describe how we can distinguish them. 3.1 Quasi-steady forces Most stability formulae that incorporate turbulent fluctuations regard the streamwise velocity near the bed (or u∗). This is based on the fact that the steady drag and lift force vary according to $|u|u$ and u^2 So a fluctuation of u will lead to quasi-steady fluctuating forces.To quantify the influence of this force generating mechanism we will average the instantaneous u-velocity in the PIV recordings over a relatively large area A above the stone, yielding $\langle u \rangle_A$, and regard the values of $F_A \propto |\langle u \rangle_A| \langle u \rangle_A$ and its fluctuations. 3.2 Turbulence wall pressures A turbulent flow over a bed creates wall pressure fluctuations (TWP) on this bed, even if it is smooth. These pressures are not created by the streamline curvature that is caused by the obstruction of the flow by the stone itself (which is the case for the quasi-steady forces), but are due to the turbulence in the flow. These pressures can also lead to net forces on bed material (Hofland, subm. b). The origin of turbulent wall pressure fluctuations (TWP) can be small-scale vortices. As only TWP with a length scale of the order of the stone diameter d will give significant forces on a stone, a vortex at 0.5–2 d above the target stone will induce a large (lift) force. The force vector rotates clockwise from a lift to a drag direction as the vortex passes. This lift-drag combination could be efficient in starting the

entrainment. To identify the presence of this force-generating mechanism we will regard the instantaneous standard deviation of v in area B near the target stone, σ(v) B . This value becomes large when a vortex is present, and is not very sensitive to the exact position of the vortex. Not only vortices, but a wall normal fluctuation of any kind is linked to TWP as a Reynolds decomposition of the Euler equation shows that pressure gradients are caused by the term: Due to the 2-D measurements, vortices with axes parallel to the measuring plane cannot be identified as such. 4 DATA PROCESSING 4.1 Splicing In order to regard the large-scale flow structure a hybrid technique was used to merge a sequential

series of PIV recordings, which will be called splic

ing here, after the technique used for joining pieces of

rope by interweaving strands.

To this end first the correlation of the upstream part

of the outer u ′ field of the first image and an equally

sized downstream part of the outer u ′ field of the sec

ond image was determined as a function of the overlap

length.The overlap at which this function was maximal

was taken as the (instantaneous) value of the convec

tion velocity of the total flow structure. Subsequently

a new flow field is created by averaging the velocities

of the overlapping part of the two images, and adding

the remaining parts on both sides. This total image is

now used as the first image and the third image from

the series as the second. This process is repeated for all

recordings during the measurement of a single event.

The resulting image can be seen both as a spatial

image or as a temporal image with a direction opposite

to the spatial image.

The process is similar to transforming a point mea
surement into a spatial measurement based on Taylor's
hypothesis. Differences are that: the vertical structure
is instantaneously measured, each velocity value is
averaged over a few measurements. (Here the average
is based on roughly three vector fields as the structure
moves about 1/3 of the whole field per recording).
And the convection velocity is determined for every
image.

4.2 Inspection of vector plots

It can be difficult to distinguish the structural fea
tures of an instantaneous turbulent flow field when
large gradients are present in a flow or when the flow
structures have a wide range of scales. Both these com
plicating factors are present in the wall flow that is
being examined here. Therefore the flow field is often
decomposed in various spatial or temporal scales.
Adrian et al. (2000b) give an overview of several possi
bilities. All techniques give different output, and many
are dependent on (arbitrary) parameters.

Even for the 33 cases of stone movement using
only a few different methods to regard the flow field
will yield too much information to handle. For conve
nience we inspected the instantaneous plots first using

a Reynolds' decomposition, because only one image

results from this decomposition. For closer inspection

we used the Galilean transform (subtracting a bulk

velocity from all vectors) and plots of the swirling

strength, λ. The latter is a measure of the intensity

of the local rotation in a flow field. It is capable

of pinpointing separate vortices accurately. We use a

definition where it is positive with a vortex present:

where ω is vorticity and γ is the strain rate. 5 RESULTS
5.1 Mean flow From the PIV measurements the profiles of the mean (u) and rms [σ(u)] velocity can be determined. They are depicted in Figure 4. The relative depth h/k s (k s is equivalent sand roughness height) is rather low. Therefore the rms profile does not overlap the semiempirical profile of Nezu & Nagakawa (1993). Near the bed it does coincide with the measurements by Wang et al. (1993). The spatial fluctuations of the flow from the horizontal mean are depicted in Figure 5. It can be seen that the flow follows the bed elements, with some 3-D influences. At y= 15 mm the direct influence of the bed on the mean flow is considered to be small. 5.2 Classification According to §3, we expect that the indicators F ′ A and/or σ(v) B will have high values if the respective Figure 4. Measured profiles of σ(u) (∘) and u (□). The fitted log-law and the Nezu & Nagakawa (1993) rms profile are represented by the solid lines. The dashed line is the data by Wang et al. (1993) for σ(u) with h/k s = 2.7 · u∗ differed from the one determined from the water surface slope. Figure 5. Spatial fluctuations of mean flow. The horizontally-averaged < u> H , is subtracted from u.

quasi-steady forces (sweeps events) or the TWP are

important. Therefore we plotted the combination of

these indicators for all flow fields just before move

ment of the stone. Several sizes for the averaging areas

A and B were tried, and the ones that caused the most

pronounced distinction of extreme values of F ′ A and

σ(v) B were chosen. The final extents of the areas are depicted in Figure 6. Area B turned out to be larger than area A. This was unexpected, as the quasi-steady flow structure was expected to be larger.

Figure 7 depicts the combinations of F ′ A and σ(v) B for the flow fields just before movement and for a measurement with a fixed stone.

It is clear that the values of the indicators for the flow fields just before movement are among the maximum values of the long measurement. This confirms that the force generating mechanisms corresponding to the indicators both play a role in the entrainment process.

The values of F ′ A and σ(v) B , belonging to the flow fields before entrainment are negatively correlated. No

Figure 6. Areas used for averaging. The target stone is located at (x, y)= (0, 0).

Figure 7. Classification of events. F ′ A (|<u> A |<u> A) and

σ(v) B indicate quasi-steady and TWP forces respectively. Dots are the values of a 10 min./0.5 Hz measurement with a fixed stone. The circles are the values just before stone movement. The dashed lines distinguish the sweep and TWP

events. clear groups of data points appear, but we will call values of large F ′ A sweep events, and with large σ(v) B TWP events. The dashed lines indicate the arbitrary limits of this classification. We distinguish 14 TWP, 13 sweep and 6 transitional events. F ′ A is positive for almost all events, so the longitudinal velocity is

increased during entrainment. This has been shown previously by Nelson et al. (1995). 5.3 Pressures The measured pressures, conditionally averaged over all stone movements are depicted in Figure 8. The pressure on the lift sensor (located on top of a stone) upstream of the target stone decreases when the target stone moves. It is reasonable to conclude that the target stone experiences lift as well. The pressure under the target stone decreases slightly just before movement. This is probably because the flow through the pore under the target stone increases due to the increased u in the outer flow. When the stone begins to move the pressure increases. This is explained by the increasing exposure of the stone, which leads to a stagnation pressure under the target stone. The drag pressure sensor (on the upstream side of a stone) 40 mm besides the target stone shows an increased drag around the moment of movement. This is clearly due to the quasi-steady mechanism: an increased longitudinal velocity increases the stagnation pressure upstream of the stone. The differences between the sweep and TWP events are not very large. A difference is that the lift upstream of the target stone starts to increase earlier for the TWP events. A second difference is that the magnitude of the drag pressure is higher for the sweep events, which agrees with the larger u|u| for which they were selected. Figure 8. Conditionally averaged pressures near target stone during entrainment at t= 0 for sweep (thin line) and TWP (thick line) events. Top: lift sensor upstream of target stone (L 1 , Fig. 1). Middle: sensor under target stone (L 2 , Fig. 1). Bottom: drag sensor next to target stone (D 1 , Fig. 1).

5.4 Conditional averages

Before inspecting the instantaneous flow fields, we

will inspect the smoother conditionally averaged flow

fields. If a certain structure appears we can check after

wards whether the structures present in these fields can

be recognised in the instantaneous fields as well.

The conditionally averaged sequences of sweep

events (Fig. 9) shows a large-scale (≈4 h in stream

wise direction) area of increased longitudinal velocity.

The largest part of this area has a downward directed

vertical velocity, which indicates that it is indeed a sweep (this was not sure yet, as the sweeps were clas sified based on u only). In this large-scale sweep a small-scale patch of fluid moving upwards is embed ded just upstream of the stone (after first movement), and a small-scale patch of downward moving fluid is embedded just downstream of the stone (before first movement).

The shape and size of the wedge-shape sweep is similar to that identified by Buffin-Bélanger et al. (2000) from measurements in a gravel bed river. The shape can be slightly different due to the fact that we plotted u ′ instead of u ′ /σ(u). Their largest struc tures had a duration, T , of more than 5 s, which is about TU /h≈ 5 h. So the size of the present structure is similar.

The conditionally averaged sequence of TWP events (Fig. 10) shows a similar flow structure as the sweep event. Only the large-scale patch with increased u ′ is smaller and has lower velocities. Conversely, the small-scale patches with upand down-ward motions are more intense. The number of high λ values for this case around the position of the stone is both higher than for the sweep case and for other positions in the conditionally averagedTWP field.The increased num

ber of high λ values (vortices) becomes more clear if

we average the number of points of the lower plot at

every longitudinal location, see Figure 11. The sweep

events did not exhibit as clear an increase of high

λ values around the place/time of movement. u c t

Figure 9. Spliced and conditionally averaged recording for

sweep events. Stone moves at x= 0. Upper plot: u ′ , middle

plot: v ′ , bottom plot: smoothed λ. 5.5 Small-scale instantaneous flow structure We will now investigate the small-scale flow structures with intense v fluctuations around the first movement of the target stone in more detail. The large-scale increased value of uwas indeed visible for most sweep events. However, inside this large-scale structure u is often locally decreased just before movement. Many TWP-events had a decreased flow velocity just above the stone as well. A decreased u corresponds to a clockwise-rotating span-wise vortex. Not all sweep events exhibited a small-scale structure. As only vortices at a distance of about the stone size can create considerable forces, only part of the entire flow field was inspected.We saw that 12/14 of theTWP events and 9/13 of the sweep events had intense spanwise vortices near the stone (upstream of the stone on the image before movement and downstream of the stone on the image after movement). Around the point with high λ a rotational flow field is indeed visible if the proper convection velocity is subtracted. One flow structure that can be discerned is a single vortex rotating in the clockwise direction. This can be responsible for lifting the stone, as it causes u c t Figure 10. Spliced and conditionally averaged recording for TWP events. Stone moves at x= 0. Upper plot: u ′ , middle plot: v ′ , bottom plot: smoothed λ. Figure 11. Average number of points where λ> 200 m 2 s −2 during TWP events determined from spliced and conditionally averaged recording. The λ field was smoothed with a filter with a width of 20x.

a low-pressure area under its core. This is sometimes

accompanied by an ejection (an increased upward flow

upstream of and below the vortex), which is an indi

cation that it is part of a horseshoe/hairpin vortex: the induced velocity of the hairpin legs causes the ejection. The two structures together are called a hairpin vortex signature (HVS; Adrian, 2000a). In Figure 12 an example of such a vortex is depicted. Similar flow fields were found at 4/13 of the TWP events and 2/14 of the sweep events, the centre of the vortex typically 20–30 mm above the top of the stone. The value of λ has several maxima, but a "noisy" image can be expected in such a turbulent flow. Upstream of the large vortex six smaller ones are present, arranged as indicated by the dashed line.

Another small-scale flow structure that can be discerned is a hairpin vortex packet (HVP: a series of broad horseshoe/hairpin vortices, with the heads aligned at an angle with respect to the bed, that cover an area of almost uniform low-momentum (Adrian et al., 2000a). A clear HVP was visible at 5/13 of the sweep events and 3/13 of the TWP events. In the HVP the velocity is retarded and directed upward (relative to the ambient large-scale flow, not to the mean flow). An example is depicted on Figure 13. This area has a decreased velocity. The HVP is embedded in a large scale sweep ($u' > 0$, $v' < 0$). The increased u follows after the ejection has (slightly) lifted the stone from

the ground.

A few velocity fields without a clear cause of

entrainment do show a small vortex of low intensity target stone

Figure 12. Detail of typical instantaneous flow field with single vortex just before movement of the target stone. u-0.65U .

(event 5). Shading: λ> 350/1400/2800 m 2 s -2 . that rotates anti-clockwise. This flow structure could be very efficient in dislodging the stone, as it creates an increased quasi-steady drag and TWP-lift simultaneously. 5.6 Large-scale spliced flow structure Not all large-scale spliced flow fields have been checked as of now. We only took the same events as presented above in detail. The sweep event in Figure 14 (same as in Figure 13) resembles the conditional average of Figure 9 remarkably. The small-scale upward velocity at x= 0, which was seen to belong to a HVP. The length of the sweep is about 4 h, equal to the length in the conditional average. The gradients and the maximum value of u are larger in the instantaneous event, which is due to the fact that it was not smoothed by an averaging procedure. The TWP event in Figure 15 (same as in Figure 12) does have the clear v fluctuation at the moment of entrainment. This is followed by a smaller sweep event. The two structures are not as clearly overlapping as with the sweep event. Over the length of the spliced plot there seem to be three HVPs, one of which includes the strong vortex that moves the stone at x= 0 (Fig. 13).These HVPs are indicated in Figure 15 by the inclined dashed lines.At these lines there is a transition from an ejection to a sweep region, and there are many vortices (increased λ) present. The angles of the lines are about 18 ∘ , 16 ∘ and 22 ∘ , which is on the high side of the range 10 ∘ -20 ∘ as provided by Tomkins (2001). HVS HVS HVS HVS Sweep target stone

middle plot: v ′ , bottom plot: λ (smoothed). 6 DISCUSSION
The combination of a large-scale sweep and a smallscale ejection is optimal for moving material from a bed. A sweep causes an increased drag and lift force due to the enlarged longitudinal velocity. However, the corresponding negative v ′ decreases the lift. For the first movement of the stone, the lift force is often important as the vertical exposed area of the stone is still small and the torque created by the drag force is not very large yet. Therefore an increased lift force of short duration is necessary to dislodge the stone. Once it is slightly raised, the drag force alone is capable of moving the stone further over its point of rotation. Adding a convected small-scale ejection to a sweep can result in an outward interaction (u ′ > 0, v ′ > 0), as depicted in Figure 16. The large-scale sweep has a longer duration than the ejection, so the resulting force vector fluctuates as indicated by the curved arrow.This makes that the force direction follows the angle of repose – which moves in consequence of the moving stone – such that the torque remains large for a longer time. Which kind of structure will eventually move the stone depends on the shape and position of the stone. The shape of the target stone is typical for bed protection. It has sharp edges, and a normal shape factor. Its smallest axis points upwards. This means that the area on which a lift force can act is usually larger than the vertically exposed area that determines the drag force. u v large-scale sweep embedded smallscale ejection resulting outward interaction

Figure 16. Illustration of a sweep and a convected ejection

near a stone create an outward interaction.

When starting an experiment with low mobility

transport, the transport is seen to gradually decrease,

until it reaches a steady state, caused by the rear

rangement of the top particles most susceptible to

movement (water-working). The orientation of the top

particles often becomes imbricated. The quasi-steady drag force is less effective on these stones. The present stone position is therefore probably illustrative for a water-worked bed. We are quite confident that the mechanisms as described in this paper are important for low-mobility transport on a water-worked bed. In addition, the lower the protrusion or the higher the angle of repose, the more important the TWP events become. Measurements with other stones and sur rounding geometries have been done and will be used to check the universality of the present geometry. In trial experiments we observed that a slight change in position drastically changed the stability of the stone. Moreover we saw that a stone often slightly changes its orientation in its pocket without moving (rocking). These two facts support the hypothesis that a stone moves very slowly to a more unstable position after which it will finally move. Furthermore, as two kinds of structure are necessary at the same time to move a stone, the chance that this occurs is smaller than the chance of the occurrence of one. Both mech anisms introduce a long time scale in the entrainment process, and can explain the measurements of Paintal (1971), who measured transport at Shields factors as low as 0.02.

7 CONCLUSIONS

The conclusions derived here apply to a single stone

with its specific position, shape, size, and density.

Still the results can be illustrative for the entrainment

Experimental modeling of rapidly varying flows on wet bed and

in presence of submersible obstacles

F. Aureli, A. Maranzoni & P. Mignosa

Dipartimento di Ingegneria Civile, dell'Ambiente, del Territorio & Architettura, Parma, Italy

ABSTRACT: The results of two experimental tests concerning rapidly varying flows, originated by the sudden

removal of a gate, are described. In the first the flow expands on a flat plane initially wet for few seconds,

then reflects against solid walls. In the second a submersible obstacle is placed in the flat area in order to

simulate an abrupt change in the topography. By adding a colouring agent to the water it was possible to obtain

a solution with colour intensity increasing together with water thickness. Quantitative information about water

depth distribution in the domain was obtained back lighting the Plexiglas bottom of the experimental facility

and taking photographs of the area of interest. The tones of the images acquired were converted into water

depths by means of transformation functions derived from a preliminary calibration. The test conditions were

then simulated with a 2D numerical finite volumes model presented here briefly.

1 INTRODUCTION

Rapidly varying flows such as those resulting from

the sudden collapse of a dam are, apart from the

first moments, strongly affected by the topography

of the region subject to flooding. Valley contractions,

irregular bed slopes and obstacles present in the flow

field are key factors that can induce the formation of

hydraulic jumps, shocks, wave reflections and other

sudden changes in the flow behaviour. In modeling

this kind of flows, usually accomplished by solving

numerically the 2D shallow water equations, the terms related to resistance and topographical influence are synthesized in the so-called source terms. However the capabilities of the numerical schemes are often veri fied comparing computed results only with analytical solutions in which the source terms are equal to zero. Since for truly 2D unsteady flows analytical solutions are not available – even for simple geometries and in the absence of the source terms of the equations – it is worthwhile to validate numerical models by com parison with experimental results too (Bechteler et al. 1992, Bellos et al. 1992, Fraccarollo & Toro 1995, Brufau & Garcia-Navarro 2000, CADAM 2000, Soares Frazão et al. 2001).

The paper presents the results of a laboratory inves tigation having the aim to acquire experimental data of rapidly varying free surface flows induced by the sud den removal of a sluice gate. Two experimental tests are presented here. In the first the flow expands on a flat plane initially wet for few seconds, then reflects against solid walls. In the second an obstacle was placed in the flat area in order to simulate an abrupt change in the topography; the obstacle was chosen thin enough so that it can be submerged by the water but in the meantime enough thick to influence significantly the overall phenomenon. Amongst the available experimental methods to measure water depths, a colorimetric technique applied to the images acquired with a high resolution digital camera was favoured (Braschi et al. 1994). This choice allows to obtain information in the whole area of interest, highlighting the main flow field characteristics, such as shocks and

hydraulic jumps, without introducing any disturbance in the flow field. The results of the experimental investigation were then compared with the numerical results obtained by means of a 2D finite volume numerical code, realised by the authors themselves, whose main features are described here briefly and explained in depth in another paper presented at this Conference (Aureli et al. 2004). 2 EXPERIMENTAL FACILITY AND TEST CONDITIONS The experimental facility (Figs. 1a, b), set up at the hydraulic laboratory of Parma University, consists of a rectangular tank with a flat bottom made by transparent Plexiglas. The tank is divided by a wall into two portions: the smaller having the function of reservoir 2 5 105

and the bigger subject to the flooding consequent to the

sudden removal of a gate, placed in the middle portion

of the dividing wall. The aluminium gate is seated in

a trapezoidal groove for seal reasons and is moved by

a pneumatic piston which ensures that the total stroke

(0.20 m) is released in about 8/100 s. 95 10 5 25 1 0 . 5 9 5 2 7 ° Figure 2. Shape and dimensions (in cm) of the obstacle. In order to reproduce in a schematic way the effects of an abrupt change in the bottom topography on the flow field, one of the tests was performed placing asymmetrically an obstacle in the floodable area. Likewise the flat bottom, the obstacle itself was realized in a block of Plexiglas so as to be as much transparent as possible. The location and dimensions of the obstacle (Fig. 2) are such that it can be completely submerged by the water flowing from the reservoir after the release of the gate, but in the meantime to significantly influence the overall phenomenon. At the aim of acquiring water depths in the flooded area via colorimetric techniques, this part of the tank was back lighted with cold fluorescent lamps placed in such a way to obtain a luminance as uniform as

possible over the entire investigation area. Colorimetric information were obtained adding to the water a fixed quantity of a coloring agent (methylene blue) and taking photographs of the back lighted floodable area by means of a reflex digital camera (Canon EOS 10D). The camera is equipped with a 22.7× 15.1 mm CMOS sensor and is capable to acquire 9 frames at about 3 Hz with the maximum resolution of 3072× 2048 pixels; afterwards the filling of the buffer allows to acquire only one frame every 1.8 seconds about. The camera was placed on a tribrach in order to put the optical axis as normal as possible with respect to the bottom of the facility and aligned with the center of the floodable area. To time exactly each picture a 0.01 s resolution digital timer was set in a lateral portion of the frame, triggered by the movement of the gate. The experimental investigation was completed by point measurements of water depth time series accomplished by means of a piezoelectric ultrasonic distance meter. The gauge was located close to the longitudinal wall (x= 1.627 m, y= 0.022 m in the coordinate system of Figure 1b), to be out from the perspective projection of the back lighted bottom. In the following the results of two laboratory tests are reported, whose main characteristics are

Table 1. Main features of the experimental tests.

Test No.	Initial upstream water level (m)	Initial downstr. water level (m)	Obstacle
1	0.15	0.01	Absent
2	0.15	0.00	Present

summarized in Table 1. In the first, due to the presence of an initially wet floodable area, a shock is expected to move downstream and, after few seconds, to reflect against the solid walls of the experimental facility. In the second test the floodable area is initially dry, but the presence of the obstacle induces a complex flow field with the formation of hydraulic jumps and reflec tions. The aim of the experimentation is to track this

two dimensional structures and to reproduce them with the mathematical model.

3 MEASURING TECHNIQUE AND CALIBRATION

The adding of a fixed quantity of colouring agent (methylene blue) to the water permits to obtain a solution whose color intensity, increasing with water thickness, can be translated in quantitative information about water depth distribution in the flow field. This technique allows to obtain water depth information in the whole area of interest avoiding in the meantime any kind of disturbances in the flow (Braschi et al. 1994). The acquired RAW images were firstly converted in TIFF format (8 bit per channel), avoiding any artifact eventually introduced by compression algorithms or sharpness filtering, and then the three RGB layers were merged in 8 bit grey space. Figure 3 shows an example of the photograph taken at t= 4.77 s during the Test 2. Before each test a spatial calibration was performed taking several photographs of the back lighted area submerged with an increasing thickness (from 1 to 15 cm) of water, previously colored, at rest condition. This calibration procedure allows to account for every local disturb that could be caused by a not perfect uni formity of the lighting field, by the light absorption of the Plexiglas block of the obstacle (if present), by the

optics vignetting and by all the other external chances.

From the calibration images it was possible to derive

for each pixel a transformation function between grey

tones, ranging from 0 to 255, and water depths (from

0 to 15 cm) and then to estimate indirectly the water

depth. The colouring agent concentration (12.5 g/m 3)

and exposure parameters, of course fixed for all the

calibration and test photographs, were chosen in such

a way to cover a range of grey tones as wide as possible.

Figure 4 shows three examples of the transforma

tion functions grey scale – water depth for a central

pixel, for a pixel on the edge of the back lighted area
Figure 3. Picture taken during Test 2 at t= 4.77 s. 0 50 100 150 200 250 grayscale 0 2 4 6 8 10 12 14 16 h (c m) central edge obstacle Figure 4. Examples of transformation functions grey scale-water depth for a central pixel, for a pixel on the edge of the back lighted area and for a pixel belonging to the obstacle (Test 2). and for a pixel belonging to the obstacle. From the graph it can be observed that for thin water depths the precision of the conversion is high (about 55-60 grey tones between 0 and 1 cm), whereas for thick layers of water the precision decreases significantly (about 6 grey tones in the range 13-15 cm). The repeatability error, that is the differences in the grey value for the same pixel in different shots taken at the same conditions, is typically of one or, at most, two grey tones. Then the percentage error in the water depth estimation is almost constant and of about 2%. Other sources of errors are due to anomalous light reflections against the walls and to the entrapment of air bubbles in the water.To get out of the first source, all the walls and the gate itself were internally blackened. For the second source of errors, no general solution was found. Small air bubbles do not affect very much the images indeed, since the pixel dimension (7.4µm) corresponds to about 1 mm in the real field and then all the smaller irregularities are masked; the bigger bubbles, on the other hand, give rise to anomalous reflections which darken the contours sometimes – but sometimes not – below the minimum

grey values

recorded during the calibration procedure. Since dur

ing the test execution water depth values higher than

the initial one in the reservoir (15 cm) were not

expected, it was decided to not extrapolate the trans

formation function but to discard these data instead.

A post processing routine was set up in order to

calibrate the camera and to transform the central pro

jection of each image in a real orthophotograph.

Firstly the inner calibration of the camera and of the

lenses was performed, once and for all, by means of a

commercial package (PhotoModeler Pro 4.0, 2000).

From the calibration the exact focal length (c), the

principal point coordinates (ξ 0 , η 0) and the radial (k 1 ,

k 2) and decentering (p 1 , p 2) lens distortion parameters

were derived. To any pixel of the sensor surface, being

FC, ξ, η (Fig. 5) the system of image coordinates, the

following compensation was applied:

where the radial distortion components are:

with:

whereas those for decentering distortion read:

z z 0 P(x,y,z) x y x 0 y 0 ξ P'(ξ,η) PP(ξ 0 ,η 0) FC O(x 0 ,y 0 ,z 0) c η

Figure 5. Relation between image and object coordinates

(Kraus 1997). Then the six parameters of the outer

orientation, which define the position and attitude of the camera in the object coordinate system (x 0 , y 0 , z 0 and the angles of rotation ω, φ, κ on the primary, secondary and tertiary axis), were derived using three control points with known image and object coordinates. The reconstruction of the orthogonal projection of the water depth field on the object coordinate system, known the water depth z for each pixel and the outer orientation of the camera, was based on the collinearity equations: where the parameters r ij (i, j= 1, 2, 3) are the elements of a spatial rotation matrix which describes the attitude in space of the photograph relative to the object coordinate system xyz (Kraus 1997). Finally, the scatter data obtained in the object coordinate system were interpolated on a Cartesian grid with ∂z=∂y= 5 mm perfectly superimposable to that adopted in the mathematical model. The interpolation was based on the following inverse distance relation: where N are the scatter data searched in a circle with 1 cm radius around the grid point, each of them characterised by the water depth z i at distance d i from the grid point. Anyhow, the high number of scatter points make the interpolation procedure substantially unimportant. The acquiring and correction procedure, although not free from inaccuracies, allows nevertheless a comprehensive reconstruction of the phenomenon and of its characteristics. 4 NUMERICAL SIMULATION The adopted numerical code is based on a finitevolumes discretization of the 2D shallow water equations written in integral form: where A represents the area of the integration cell, C the cell boundary, n is the outward unit vector normal to C and t is the time; U= (h, uh, vh) T is the vector

of the conserved variables (water depth and specific

discharge in x and y directions); H= (F, G) is the ten

sor of fluxes, being F= (uh, u 2 h+ 0.5gh 2 , uvh) T and

G= (vh, uvh, v 2 h+ 0.5gh 2) T , with g acceleration due

Figure 6. Numerical results for Test 2 at the time t= 4.77 s:

a) contour map of water depths (m), b) vector map of velocity

field c) contour map of velocity norm (m/s), d) contour map

of Froude numbers with line at Fr= 1 drawn. to gravity; S= (0, gh(S 0x − S fx), gh(S 0y − S fy)) T is the source

term,where S 0x , S 0y , S fx and S fy are, respectively, the bottom and frictional slopes along the x and y axis. The Manning equation is used to compute the friction terms: in which n is the Manning roughness coefficient. The adopted numerical method for the solution of the homogeneous part of (7) belongs to the class of MUSCL-Hancock centred slope limiter schemes, known in literature under the acronym SLIC (Slope LImiter Centred) (Toro 1997, Toro 2001); it is explicit, shock capturing, high resolution,TVD, of second order of accuracy both in time and space and it is based on the unsplit formula: In (9) U n i,j represents the vector of the integral averages of the conserved variables over the element (i, j) at time t= t n , ∆t is the time step, ∆x and ∆y are the mesh sizes, f and g are the intercell numerical fluxes in x and y directions, respectively. Numerical fluxes are based on the FORCE (FirstORder Centred) (Toro 1997, Toro 2001) method. The source term S is treated with a splitting technique (Toro 1997, Toro 2001). A more detailed description of the numerical scheme can be found in a related paper presented at this Conference (Aureli et al. 2004). The computational domain was described by means of a Cartesian cell - centred discretization with square cells of 5× 5 mm. The computational time step ∆t was controlled via the CFL stability criterion, with Courant Number Cr= 0.95. Reflective, free-slip conditions were imposed on the solid boundaries. The Manning coefficient for the Plexiglas bottom was set at 0.007 s m -1/3 . As an example, the complete numerical results for Test 2 at t= 4.77 s are shown in Figure 6. 5 COMPARISON BETWEEN EXPERIMENTAL AND NUMERICAL RESULTS Figures 7 to 14 show snapshots of experimental and computed water depths in the floodable area at different times for the two tests presented here. The areas on the borders of the orthophotographs, where not enough information was available to interpolate a reasonable water depth value, were blacked. They of course increase with the water depth. The

Figure 16. Comparison between experimental and numeri

cal water level time series (Test 2).

At t= 4.77 s, on the other hand, the experimen

tal water depth flow field becomes again very well

reproduced by the numerical model.

Figures 15 and 16 show the water depth time

series derived from the ultrasonic transducer, from the

orthophotographs and from the numerical model at the

location reported in the graphs (cfr. Fig. 1b).

In Test 1 (Fig. 15) the comparison between the

results obtained by means of the two experimental

techniques is fairly good. The computed results match

well the experimental ones too, especially before

the second shock at t≈ 3.5 s. The results for Test 2

(Fig. 16) are less satisfactory. The computed water

depths show a less peaked value at t≈ 1.2 s with

respect to those derived with both the experimental

techniques; also, the time location of the first shock

is slightly anticipated. In the intermediate times, how

ever, the values deduced by the orthophotographs and

those computed fit fairly. It must be stressed that the

comparison is made at a very bad location, close to

the solid wall, in order to avoid the presence of the

transducer body on the acquired images.

ABSTRACT: An investigation of dam-break flow with dry and wet beds downstream has been undertaken. An

image analysis system based on tracer particles was used in the laboratory to record the instantaneous velocity

variations in the area of interest in the downstream channel and visualise the flow structure. The experimental

measurements of the flow velocity downstream dry and wet-bed were obtained. Higher values of velocity

were obtained for the dry-bed case than for the case with downstream water depths. Measurements from the

experimental study were used for comparison with analytical solutions, which demonstrates a good agreement

with experimental results.

1 INTRODUCTION

Dam-break flows have been studied for a long time, but

the flooding caused by the dam rupture only received focused attention during the Second World War due to bombing. These failures and the associated dam age have emphasised the importance of evaluating the safety of existing dams for design and planning purposes.

Predictive mathematical model investigations of the effect of dam-break floods have been carried out by several researchers several decades and some impor tant results have been obtained, see for example Su & Barnes (1970), Fread (1977) and Bellos & Sakkas (1987). Since field data for this flow is very difficult to obtain, it is necessary to collect experimental data to verify the mathematical models. Several experimental investigations of dam-break flow have been reported in the last four decades, see Derssler (1954), Miller & Tschantz (1972), Bell et al. (1992) and Lauber & Hager (1998 & 1999).

With the improvement made in computer technol ogy, computational models of flows in dam failures are widely used and have become predictive tools. In addition, physical models are more expensive than a computational equivalent. Examples of computa tional model studies dam-break flows can be found in Soulis (1992) and Glaster (1993) who compared these

with recent experimental data for dam-break flows. On the other hand, a range of novel experimental methods based on signal and image analysis system have been developed for measuring flow velocities which are particularly useful in unsteady flows such as dambreak flow. Such data can be used for the validation of numerical calculations. Traditional velocity measurement methods are laser Doppler anemometry (LDA) and hot-wire anemomerty (HWA) provide single-point measurements (Buchhave, 1989). These methods have high accuracy. Alternative methods are whole field measurement techniques, which should be viewed as complementary measuring tools. In these methods, the flow field is illuminated with a thin light sheet from a powerful source and might be filmed photographically or digitally. Once several particles appear in the illuminated area, then the velocity vectors can be obtained for this area using tracking algorithm techniques based on auto-correlation, cross-correlation or Young's fringe method see Cenedese & Paglialunga (1990), Adrian (1989) and Buchhave (1992). In this paper, the main objective is to investigate the instantaneous whole-field velocity of the dam-break flows by tracking particles seeded in the flow, after the bore has become established. Previous work concentrated on the initial stages of dam-break flow, theoretically, numerically and experimentally see Stansby, Chegini & Barnes (1998). A measuring system enables individual particles in the flow to be tracked directly. Particle tracking velocimetry (PTV)

and particle streak velocimetry (PSV) methods were

applied for a digital system. These methods do not

need photographic development and processing time,

although spatial resolution can be a problem using

standard SVHS video equipment. In this study, PSV

was used, measuring streaks to obtain maximum aver

age of the particle movements for all the downstream

dry and wet bed cases. The automated PTV method

was suited to subcritical flows which was assessed

by comparing with PSV measurements. Finally, the

experimental velocity measurements were compared

with computational calculation.

2 EXPERIMENTAL METHOD

The experimental rig was an open channel flume with a horizontal bed. The test facility consisted of a 15.24 m length of 0.4 m by 0.4 m rectangular cross section flume. Part of the upstream and downstream walls of the dam site were made with clear Perspex to view the flow. The upstream end of the flume was closed but the downstream end was open for the dry case and had different level weirs for the downstream wet bed conditions. These weirs were utilised to form the downstream wet-bed initial conditions. The dam site was set up at 9.76 m from the upstream end. A thin movable metal plate (3 mm thick) was used to simulate the instantaneous dam-break. This slid in small plastic channels mounted at a section around the flume bed and sides. A rope was attached to the top of the dam plate and loops through a pulley to a 7 kg weight which was released from about 0.8 m above the laboratory floor. The experiments were made with an upstream depth (H) of 0.1 m and downstream depths of dry, 0.1 H, 0.3 H, 0.45 H and 0.55 H. More details of the test facility used to generate the dam-break flows can be found in Chegini (1997).

In this study, an instantaneous whole flow field

plane visualisation and velocity measurements of the area of interest were investigated using PTV and PSV techniques. These methods are based on tracer parti cles which are added to the flow and then illuminated with a powerful light source. The particles were spher ical, 80 micron in diameter, solid polystyrene seeding powder with a relative density of 1.0 ± 0.2, which made the particles neutrally buoyant in water and able to follow the flow. The particles were mixed in the flow rig before running each test. The light source for illumination in the field of view was a 4 watt Argon ion laser. The laser beam was transmitted from the laser light source to the light sheet generator by using a 20 m long optical fibre link. The light sheet gen erator produced a vertical plane light sheet with the width of 1–3 mm along the flume. A JVC TK-1085E colour CCD camera was used to record a 8.4 cm by 6.9 cm picture field. The camera operates with PAL standard for video scanning of 25 images/second. The camera was connected to a VCR, PC and TV screen, allowing instant monitoring of the field of vision and enabling the motion of flow to be recorded for further processing. The schematic arrangement of the laboratory set-up is shown in figure 1. In order to analyse an analogue camera output or a standard video signal, this has to be converted to an array of digital information known as a digital image. A device known as a ‘Frame Grabber’is used to convert the original analogue signal. This device can be fitted internally into one expansion slot of the standard personal computer or can be externally connected to it. All frame grabbers freeze the analogue signal and discretely sample it to provide an image which is a series of discrete

digital values that are then stored in a two dimensional array of numbers. This array of individual element numbers (pixels) with an integer color (grey level) is represented as the digital image. Frame grabber boards are equipped with a minimum of two buffers per image but can have many more, each buffer image having 512× 512 pixels with 256 (8 bit) grey levels. The digital image can be processed on the board memory or the host computer from the buffer. Each digital data element (pixel) is denoted by a number, which represents the amount of light intensity of a small area of the visual image. The sampled number of each pixel conventionally gives the level of darkness or brightness of the small area. Zero represents black, the maximum value, 256, denotes white and intermediate values designate various shades of grey. This software was written in parallel C for a 3L compiler to control image capture and processing. 3 IMAGE ANALYSIS SYSTEM The captured images were cleaned-up by filtering and then thresholding.Therefore, the background becomes black (grey level 0) and the foreground particle images become white (grey level 256). At this stage, all seeding particles appear in the frame image sequence as white colour. The images are now suitable for further processing. The technique of applying image analysis to obtain quantitative velocity flow field information from particle movement encompasses a number of different methods. They are differentiated by the form of the captured image and the analysis technique employed. The displacement of individual particles within a field of view over the known short time period yields information about the velocity vector field simultaneously over the whole plane for which the particle image data was gathered. The following section describes two techniques PTV and PSV and concludes with a description of their application to a dam-break flow system. Dam-site 9.6m 5.5m

3.1 Particle tracking velocimetry

This method requires individual particles to be located

in an image and successive images to be recorded on

successive frames. The system analyses pairs of single exposed digital images to produce whole field maps of velocity vectors. Particle images at different times exist on the separate frames. There is no directional ambiguity in the calculated vectors and the direction of particle motion is easily found. There is also no lower limitation on particle motion between frames. The particle tracking technique is used to accurately determine the position of a particle in an image frame and compare it with its location at a known short time interval later (in a successive frame).The distance trav eled by an individual particle is then calculated and the velocity found knowing the time interval between images. This process is repeated for all of the particles appearing in the frame sequence. In this study, the automated particle tracking system was used for subcritical flows. The digitised images were improved by using image processing techniques, and the particles are tracked by means of a localised correlation function. This technique is based on the comparison of a small window around a particle image in one frame with a series of windows around many particles in a later frame. A match is required between the spatial pattern of neighboring particles around each window with a corresponding window in another frame. The window which gives the best correlation can be used to locate each particle pair. Various correlation algorithms have been developed to allow the tracking of particles from frame to frame. Examples

Figure 2. Typical time series of the raw digitised images at downstream of the dam site with initial water depth condition.

of these are Dalziel (1992), Brucker & Althaus (1992), Hassan et al. (1992). A number of complex flow sit uations has been analysed successfully by using PTV.

For example, see Nishio et al. (1992), Uemura et al. (1989).

3.2 Particle streak velocimetry

Seeding particles in the fluid medium may be recorded on a single frame of photographic or video film by using a relatively long exposure time. The application of particle streak in fluid mechanics has been used for qualitative flow visualisation as illustrated in Van Dyke (1982). Particle streak images can be digitised for development into the quantitative measuring technique known as particle streak velocimetry (PSV). This method is usually used when the fluid has a seeding particle concentration less than that for PTV. This method does not require individual streak images to be overlapped and distinguished from each other. PSV enables accurate individual streak lengths to be determined and then analysed. As the exposure time is known, it becomes possible to obtain the velocity associated with a particle streak. The processing of the streak images includes filtering the images to eliminate noise and thresholding to separate the streak from the background. The white streaks corresponding to the particles can then be located and measured, see Kobayashi & Saya (1988). The image analysis for locating streak images and measuring their lengths

with known exposure time to obtain the velocity field has been demonstrated in a wide variety of flow situations, see Utami & Ueno (1987), Green & Gerrard (1993).

The problem with streak image measurements is that in a real flow situation the particles may enter or leave the plane of interest (i.e. the light sheet) during the exposure time. This means that the actually recorded streak length of the particles will be less than the actual distance moved by the particle. Therefore, this will lead to an incorrect estimate of velocity, which is reported by researchers such as Khalighi & Lee (1989) and Adamczyk & Rimai (1988). According to the sensitivity of the recording medium particle streaks may not be recorded at all if they travel too fast. Some attempts have been made to resolve such problems with a degree of success, see Marko & Rimai (1985).

In this present study, particle images were digitised using equipment that has already been described. A manual method of streak line measurement is used whereby a cursor is carefully moved around the screen to measure the length of streak images. Tests were performed at a variety of initial conditions with different exposure times. These will be described including

some results in the following section. 4 RESULTS The most interesting of the experimental results will be shown here. More details regarding the experimental data can be found in Chegini (1997). In this paper, visualisation and measured velocity fields are presented by analysing images using PTV and PSV methods. The free surface profiles in the initial stages of the dambreak flow from the digitised images have already been published see Stansby et al. (1998). Visualisation and velocity field measurement of dam-break flows over obstacle have also been produced by image analysis methods, Chegini (1997). Surface elevations at various longitudinal positions were also measured using resistance probes and essentially confirmed the results from the digitised images. Details of the surface profile plot with the identified area (8.4× 6.9 cm) of the recording digitised images at centred 85 cm downstream of the dam-site for the downstream dry-bed and wet-bed initial flow conditions can be found in Chegini (1997). Figure 2 shows typical time series of the raw digitised images at location x = 85 cm downstream of the dam-site for different initial flow depth ratios. These raw digitised images of the flow are processed to obtain the time series of the whole flow field. Note that x = 0 corresponds to the dam-site. To aid illumination, seeding powder is dropped on the water around the area of interest. The powder is neutrally buoyant in water. The velocity fields are here defined by the tracking of the particle streaks. The raw digitised flow field images used to obtain the velocity field for the fixed camera position at 85 cm downstream of the dam-site. Some images suggest these regions are in fact a mixture of spray and particles. The results show white long straight and mixed lines with some brighter areas. These are due to high speed and turbulent flow with entrained air. Given the above problems and the fact that the time interval between image is too long the Particle Tracking Velocimetry (PTV) technique cannot match between the two sequence frames. Since the video images were not clear enough as explained, the particle streak velocimetry (PSV) method was applied to obtain the maximum average of velocity. The streak images were measured at several frames on the video play back system whilst the digitising procedure took place. As the relationship between pixels and object distance and exposure time were known the velocity could be determined. Taking the reading of the length of the straight lines, the results can be plotted on a graph, as shown in figure 3, based on streak line measurement technique. This figure shows that the velocity increased quickly at the beginning and then decreased with some variation, to a more or less stable value. This figure

also emphasises the bore velocity wave in the front of the flow propagation in the downstream section. The results show that the initial slope of the velocity variation with 0 20 40 60 80 100 120 0 0.5 1 1.5 2 2.5 3 3.5 4 Time (s) V e l o c i t y (c m / s) (a) dry (b) 1 cm (c) 3 cm (d) 4.5 cm (e) 5.5 cm

Figure 3. Variation of the streamwise velocity against time obtained by PSV for different initial water depth flow conditions.

time decreases as the downstream initial water depth

increases.

Finally, some frames of the digitised flow field

images were analysed to obtain the velocity informa

tion by the particle tracking technique for a down

stream initial depth of 4.5 cm and 5.5 cm which

presents the subcritical flows. The typical results are

shown in figure 4 as frames progresses. Observation

of the results from the particle tracking technique

and digitised images emphasises the similarity as

expected. The digitised flow field images of the wave

propagation in the downstream initial conditions also

show clearly that the flow particles in the stationary

area had moved before the wave as confirmed by PTV

results. A general comparison between the maximum

average of the velocity obtained by PSV (Fig. 3) and

PTV (Fig. 4), shows reasonable agreement for the

cases with the depth ratios of 0.45 and 0.55.

5 COMPARISON OF ANALYTICAL AND EXPERIMENTAL RESULTS

An analytical solution of the homogenous, incom

pressible, unsteady, one-dimensional flow, considering flow friction forces but neglecting wind and coriolis force effects, was applied. A hydrostatic pressure distribution was assumed throughout the flow field. Readers can find the theory in Stoker (1957) and more details of calculation in Chegini (1997). Figure 5 shows the comparisons between analytical solutions and experimental measurements for the test flume under dry-bed and wet-bed flow conditions. For all depth ratios, the velocity fields eventually became quite stable after the bore develops downstream. The experimental velocity fields show the upper limit of the flow including the air/water mixture as compared with analytical results. In general, these comparisons are considered to be satisfactory for the downstream supercritical and subcritical flow region. 6 CONCLUSIONS An image analysis system has been applied to the dambreak flow for investigation of the instantaneous whole flow field visualisation and measurement of the velocities. The whole flow field velocity data may be used to assess the ability of a computer model to simulate

1D model of surface waves generated by a reservoir's bank landslide:

a case study

P. García-Navarro, G. Pérez & P. Brufau

Fluid Mechanics, CPS, University of Zaragoza, Spain

M.E. Vázquez-Cendón

Applied Mathematics, University of Santiago de Compostela, Spain

ABSTRACT: The work presented is a contribution to the predictive numerical modelling of surface waves

generated by bank slides. The study is based on a one dimensional approach assuming that the flow generated

is governed by the St, Venant equations. The mechanism triggering the solid slide is out of the scope of the

work, therefore the slide properties are set as external parameters. The flow equations are solved with an upwind

scheme specially adapted to wetting/drying boundaries.

1 INTRODUCTION

The study of the sliding movement of land volumes

is of great complexity. Generally speaking, it can be

classified according to several factors such as the time

scale associated (from very slow like in glaciers to

very fast like in mud or debris flows), the content of

water, the slope of the terrain or the characteristics of

the involved materials. On the other hand, it can be

triggered by another diversity of factors. There is a

particular aspect, matter of this study, concerned with the impact of important volumes of sliding materials falling into water volumes, either in movement (rivers) or at rest (lakes, reservoirs). In such events the risk is not precisely associated to the sliding mass but in first instance to the waves generated by the energy transferred to water by collision. A second risk is the possibility of heavy deposition of material in the river bed forming an artificial dam able to accumulate an important volume of water but not for a long time, giving rise to further catastrophic dam failure.

In this work, a one-dimensional mathematical model for water flow and sliding mass movement is presented. The resulting equations are essentially the shallow water equations with time dependent bed level and/or time dependent channel width supplied with an external rule for the time dependencies and a modified friction term. They are solved by means of an upwind scheme based on Roe's method with special care put on the wet/dry or dry/wet interfaces.

The model is applied to the simulation of a real case. The Santa Liestra reservoir is a project on Esera River by Santa Liestra village in the Spanish Pyrenees. The project is intended to regulate 81.9 Hm 3 at the upper part of the river. There is controversy due to the risk associated to potential land slides in the nearby mountains forming the banks of the future reservoir. With the proposed model, the objective was to simulate the

consequences of the described potential slides in their interaction with the reservoir. The starting point for this study were previous geological studies of the area and a former study developed by CEDEX (Centro de Estudios y Experimentación de Obras Públicas). One of the risk areas identified by geologists is placed on the left bank of the river near a narrow section. It involves more than 50 Hm 3 of meteorized and fractured materials. One of the theories describing a possible risk scenario states that the lower part of this solid volume could become saturated when filling the reservoir, leading to instability. The topology of the area is markedly onedimensional with the hypothetic falling mass representing a transversal sliding. We have made the hypothesis of rigid sliding, that is, movement of the volume in a block with a falling celerity of 10 m/s, according to previous studies. The sliding volume was characterized by means of six geological cross sections every 250 m, estimating the average thickness and volume for each of them. The river channel was modeled by means of trapezoidal cross sections of variable bottom width and side slope. The simulation was performed using 1000 grid nodes along the river and a time step subject to CFL= 0.7 for the transient calculation. The initial

water depth in the reservoir was the less favorable

corresponding to full reservoir, that is, water surface

level h in = 642 m and water at rest (initial conditions).

The friction coefficient for the Manning law used was

n Manning = 0.04. The slide modeling was based on the

geometric description of the sliding volume and a

special mathematical treatment of transversal sliding

described in the main text.

2 GOVERNING EQUATIONS

2.1 Flow equations

Flow movement in the longitudinal reservoir consid

ered is assumed to be well described by the 1D shallow

water equations. The shallow water equations are an

approximation to the three-dimensional reality. The water velocity in a river, for instance, varies from bank to bank and in the vertical direction. However, for many practical applications, these variations may be ignored and the problem be approximated as variable only in the spatial direction along the main flow. In case of continuous solutions the differential form is deduced. In terms of the wetted cross section A(x, t) and the discharge Q(x, t)

where S 0 and S f are bed and energy slope terms and I 1 and I 2 are pressure terms, all of them well described elsewhere (). Equations (1), (2) can also be written in compact differential form

called the conservative form where

A different, non-conservative form can be derived

where J is the Jacobian matrix with eigenvalues and with eigenvectors u is the fluid velocity and c is the small water surface waves celerity Being a hyperbolic system, it admits characteristic formulation and the eigenvalues are equal to the slopes of the characteristic curves in (x, t). This is the property in which Roe's scheme is based. 2.2 Slide modeling The slide movement will be considered solid and compact, formed of the same material as the flow bed or walls, neglecting deformation and infiltration of water into the solid matrix. The sliding is modeled in the frame of a onedimensional approach by assuming the sudden motion of either the channel bed or the channel side wall, both conforming the solid–liquid boundary. This involves the assumption of a time and space variable channel geometry. From the mathematical point of view, these effects modify the dynamic equation as time variable source terms inducing transient flow (waves) in the mass of water. When the slide direction is the same as the channel main direction, the model is based on a channel bed movement (longitudinal slide). The channel bed level (z) depends on both position

x and time t. The slide size (volume or thickness) and velocity into the fluid are modeled by means of variations in the function z (x, t). Sliding along a direction normal to the channel main direction is referred to as transverse sliding and the modeling is based on channel breadth variations along distance x and time t, σ f (x, t). As in the case of bed variation, the adequate definition of the function σ f (x, t), characterizes the physical parameters of the sliding mass. This procedure is useful to model sliding shapes entering the channel as a pulse, parabola, triangle, etc, which can be completely submerged or emerge from the water. The movement followed by the shape function is that of the assumed sliding mass. In the longitudinal sliding, the bed movement induces a pressure excess that pushes also in the longitudinal direction.

Therefore, a wave traveling in the direction of the

perturbation is generated.

However, in the case of a transverse sliding, water

is pushed by one of the side walls against the oppo

site side and forced to climb up. The result is that the

initial surface level is raised and two front waves trav

eling both upstream and downstream are generated.

All movements follow a unique direction in the lon

gitudinal sliding case, being adequately modelled by

a one-dimensional approach. This is not the case for

a transverse sliding, since the transmitted waves are

normal to the perturbation direction. The water sur

face level pattern is complex and the fluid behaviour

depends on many factors. The actual phenomenon is

locally tridimensional. However, we model it with a

one-dimensional approach so that it can be plugged

into a 1D river or channel model. The main difficulty

associated with naively modelling transverse sliding in 1D is that, at a given cross section, the predicted centroid of the fluid cross section is at a different position than that of the real fluid, hence leading to different waves due to the potential energy accumu lated. Channel breadth variation is not enough and should be complemented with channel bed variation.

A way to introduce this kind of information into the one-dimensional model is required. The strategy used in this work is described in ().

It is customary in shallow water models to use a parametric formulation the energy slope, both in steady and unsteady turbulent cases, either in terms of the Chezy coefficient C chezy or the Manning roughness factor n (ref).

where D h represents the hydraulic diameter. This is the accepted friction model for fixed bed problems.

When the bed is moving at a celerity v d (x, t), that is, in the zone where a sliding is taking place, the relative velocity between flow and solid bed u − v d is the key variable in order to introduce a term containing the shear interaction between the solid mass inmovement and the longitudinal flow. Furthermore, and in order to model the presence of new materials in the channel bed, a friction coefficient different from the channel

bed roughness (n ∗) value must be introduced. In these

cases, the following is applied [40] [39] for S f : 3 NUMERICAL METHOD The numerical method used in this work is an upwind finite volume method based on Roe's approximate Riemann solver. This technique has proved efficient for unsteady shallow water problems over fixed bed [21]. The computational domain will be divided into a finite number of uniform cells (∆x= cte) for the numerical resolution of the equations. The time stepping procedure will be based on a variable time step ∆t, always determined by the numerical stability requirements. The criterion used is the CourantFriedrich-Lewy (CFL), which states that the maximum allowable time step, compatible with stability, in this case is given by therefore requiring that the dimensionless CFL number is always less that unity for stability CFL≤ 1. The numerical method has been implemented as described in () and () and will not be repeated here. When modelling landslides and their interaction with water volumes, it is possible and frequent to encounter at the same time wet (h> 0) and dry nodes (h= 0) in the domain, as pointed before. The limit between a wet node and a dry node will be called a wetting/drying interface and poses a special difficulty from the numerical point of view in the two following situations in which a dry cell is placed next to a wet-dry and has a higher bed level: h i+1 = 0 and z i + h i < z i+1 (Fig. 1) We need to redefine ∆z as ∆z= h i instead of ∆z= z i+1 − z i in order to ensure mass conservation at least in steady state [6]. i i+1 z i +1 h i +1 =0 z i h i Figure 1. Wet-dry interface (case A). i i+1 z i +1 h i +1 z i

h i = 0

Figure 2. wet-dry interface (case B)

h i = 0 and z i+1 + h i+1 < z i (Fig. 2)

We need to redefine ∆z as ∆z=-h i+1 instead of

z= z i+1 − z i for the same reason.

4 APPLICATION TO A REAL CASE

After the validation of the model against experimental

data for a longitudinal sliding and the calibration of

the solutions by means of academic test cases (), the

numerical method will be applied to a case of prac

tical interest characterized by irregular cross sections and realistic dimensions. The problem consists of the evaluation of the consequences of the potential catas trophic falling of an important volume of solid material into a reservoir. It is the projected Santa Liestra reser voir, on the Esera river near Santa Liestra village, at the Spanish Pirynees. The construction of a reservoir at that location is intended to regulate 81.9 Hm 3 , at the upper part of the river. There is an open contro versy linked to the dam building due to the potential landslide risk described by a sector of the scientific community. The starting point for the study has been based on a previous report made by the CEDEX (Cen tro de Estudios y Experimentación de Obras Públicas), and some useful geological data. The more relevant properties will be next outlined; for more geological Figure 3 shows a sketch of the topographic situation of the reservoir indicating the maximum envisaged water level of 642 m and the location of the poten tial sliding area at the left bank of the Esera river. The problem in this area is markedly one-dimensional and the sliding can be modelled by means of a transverse sliding model, as the figure suggests.

The volume of the involved materials is bigger than 50 Hm 3 according to the geological prospections.

Besides, the kind of materials and their fractured and

meteorized state, and the fact that the low parts would

become saturated when filling the reservoir contribute

to the possibility of a sudden and catastrophic failure.

This work, however, does not focus on the conditions SECTION A SECTION B SECTION C SECTION D SECTION E SECTION F 250m 200m0 Figure 4. Sliding volume defined by the two bounding surfaces. Table 1. Sliding volume geometric data. Location Thickness Area Celerity Section x (m) z 0 (m) A d (m 2) v d (m/s) A 750 5 1000 10 B 500 25 15000 10 C 250 70 50000 10 D 0 80 56000 10 E 50 30000 10 F 50 24000 10 under which the sliding could be triggered. Our study starts from the hypothesis that the sliding takes place and is motivated by the study of the consequences of the impact over the stored water. Figure 4 shows a detail of the potential sliding volume, with the red lines representing level isolines at the surface in contact with the air and blue lines level isolines at the discontinuity surface. For simplicity, the sliding was assumed rigid, that is, falling in a single block, and with a celerity of 10 m/s.This is a maximum risk scenario but follows the hypothesis made in previous studies. Six geological sections as shown on Fig. 4 were used to study the geometry of the sliding volume each of them associated to an average thickness z 0 (x) and a surface A d (x). These values are gathered in Table 1. Any other intermediate value is calculated by interpolation from them. As the table indicates, the simulation model locates the origin of the x axis at section D. The reason for this was the realization after several simulations that, due to the morphological properties, section D was a split

point where the induced water discharge divided into

two opposite directions, one heading towards Morillo

de Liena and the other to the opposite direction with

no interaction between them. Therefore, as we were

interested in the modeling of the North heading waves,

the South part was neglected.

The river geometry in the domain under study was

based on river cross sectional data approximated to

trapezoidal shapes. Table 2 shows their location along

the river axis as well as other variables of interest.

Figure 5 represents the longitudinal variation of

the top water width at initial conditions, that is, with the

reservoir at maximum water level (642 m), from the

3500 m considered in the simulation. The reach was

extended near the tail of the reservoir to include the

villages of Morillo de Liena and Navarri into the study

in order to evaluate their risk of flooding.

The simulation was performed using 1000 space

intervals and a fixed bed roughness n Manning = 0.04.

mass movement is assumed constant considering a balance between resistance forces and inertia forces over the sliding volume. The sliding motion at a computational node is finished when all the volume assigned to that point has fallen into the water. Every node has a solid slice of material assigned and the algorithm evaluates the size of transverse sliding at every time step. The numerical results are sumarized and plotted in Figs. 6 to 9. From the results shown in Figs. 6 to 9 it can be signaled that in the first seconds after the sliding motion starts, very high discharges are produced since water is displaced at a great velocity by the solid materials fallen into the reservoir. The surface wave generated advances towards Morillo against an adverse slope, hence losing energy and celerity. At about t= 60 s, the sliding area remains dry, acting as a solid obstacle and with all the volume of water moving towards the tail of the reservoir. On the other hand, it can be estimated from the numerical results that the wave celerity, when the wave front is nearly 10 m deep, is as high as 14 m/s. The wave is rapidly damped at the end of the reach due mainly to the wide section at that location. When the wave reaches Morillo it is still 3 m deep and advances at a velocity around 6 m/s. 5 CONCLUSIONS A one-dimensional numerical model has been presented as a tool to simulate landslide movements and their interaction with water volumes. Having been previously proved as adequate for wave propagation problems on rigid bed channels and validated with experimental data, it can also be adapted to situations

Figure 6. Shock wave propagation towards Morillo de Liena (read arrow at x= 3000). Blue line is bottom level at t= 0.

of channel bed variations in time, allowing for accurate

results. The simulation tool developed enables conser

vative, fast and dynamic calculations of a wide variety

of cases including irregular cross sections in presence of different sorts of sliding motions that are charac terized depending on their geometry and kinematic properties. From the numerical point of view, it can be concluded that the scheme used, based on the first order explicit Roe's method, is a suitable for this kind of problems.

Longitudinal slides generate both a shock wave traveling in the same sense as the moving solid and a depression wave travelling in the opposite sense. Both the thickness and celerity of the sliding volume are key factors at defining the momentum exchange and hence the wave generated. The particular shape of the solid moving front is less important. Transverse sliding modeling in a one-dimensional approach has to be carefully treated. An algorithm based on the movement of the center mass of the wetted section has been applied to simulate a real case of potential lateral sliding. The results show the characteristics of the wave generated, magnitude and celerity and the potential risk for the river bank population. This results can be considered the consequence of a preliminary study. It is

Figure 11. Detail of the discharges near Morillo de Liena.

doubtless necessary to perform more exhaustive and detailed studies of the sliding dynamics, and the river bed geometry since these are the most determinant factors for the wave advance.

Numerical simulation for destruction process of rubble stones dam

E. Harada & T. Hosoda

Dept. of Urban Management, Kyoto Univ., Yoshida Honmachi, Sakyo-ku, Kyoto, Japan

H. Gotoh

Dept. of Urban and Environmental Engrg., Kyoto Univ., Yoshida Hnomachi, Sakyo-ku, Kyoto, Japan

ABSTRACT: A rubble stones dam is sometimes destroyed at the time of the big flood. It is important for

the effective design of the rubble stones dam to understand the destruction mechanism due to the big flood.

Interaction between rubble stones is dominant in the destruction process, so key to the detailed understanding

of the destruction mechanism is how to evaluate the each rubble stones motion. And also the evaluation of the

interaction between solid phase and liquid phase is key too. In this paper, the solid phase is modeled by using

the Distinct Element Method, and the numerical simulation based on the solid-liquid two phase flow modeled

by Euler-Lagrange coupling is performed to investigate the detailed mechanism for the destruction process of

the rubble stones dam.

1 INTRODUCTION

Porous dam is made of rubble stones in considera

tion of harmony with the nature. By the way, disasters

of the destruction of the rubble stones dam due to a

big flood have been reported. Hence, to understand

the mechanism of the destruction process of the rub

ble stones dam is important for the effective design of

the rubble stones dam. The destruction process of the rubble stones dam is composed of collision between rubble stones, or solid-solid phase, and interaction between rubble stones and fluid, or solid-liquid phase, these processes are very complex, so it is difficult for the detailed investigation of the destruction pro cess of the rubbles stones dam by the measurement of experiments. And also, needless to say, development of the numerical simulation code, which can express these processes, is an effective tool for detailed anal ysis of the destruction process of the rubble stones dam. Therefore, the purpose of this paper is inves tigation of these processes of the rubble stones dam numerically by development of the solid-liquid two phase flow numerical simulation code by the two way method, especially solid phase is modeled by using the Movable Bed Simulator, or MBS, proposed by Gotoh, H. & Sakai, T. (1997), which is based on the Distinct Element Method, or DEM, propsed by Cundall, P.A. & Strack, O.D.L. (1979) which can evaluate the solid-solid interaction. The destruction mechanism of the rubble stones dam is investigated numerically from the driving force acting on the rubble stones. Furthermore, the comparison numerical simulation with experiments is discussed. 2 OUTLINE OF THE SIMULATION MODEL 2.1 Model of solid phase The distinct feature of the destruction process of the rubble stones dam is that the rubble stones shows the transition process from static

condition of rubble stones to movement process such as collision and repulsion by the driving force of water flow. So, to evaluate the each rubble stone motion with collision an repulsion, solid phase is calculated by the MBS, or Movable Bed Simulator, proposed by Gotoh, H. & Sakai, T. (1997), which is based on the DEM, or Distinct Element Method proposed by Cundall, P.A. & Strack, O.D.L. (1979). Each particle (= each rubble stone) motion is defined by the following translation and rotational equations:

where ρ= density of fluid (ρ water = 1.0 and ρ air =

0.001); σ= density of particle (σ= 2.65); C M =

added-mass coefficient(C M = 0.5); A 2 , A 3 = twoand

three-dimensional geometrical coefficients of parti

cle (A 2 =π/4 and A 3 =π/6); d = diameter of parti

cle (d = 0.005 m); V p = velocity vector of particle;

t= time; P= pressure of water; f gr = body force

vector; f p int = particle/particle interacting force vec

tor; f D = drag force vector; ω p = angular velocity of

particle; T= torque acting on particle; g= gravity

force vector; C D = drag coefficient(C D∞ = 0.4); and

ν= kinematic viscosity. The contacting condition of

each particle is looked for at every renewal of the

calculation time step (Δt). The acting force between

contacting particles is evaluated by spring and dash

pot system shown in Figure 1, which is introduced

in both of the normal and tangential direction. And

also, in this simulation, particles are non-cohesive,

hence the joint, which has no resistance to the ten

sile force, is assumed in the normal direction. While,

in the tangential direction, the friction force(friction coefficient μ= 0.577) works. To describe this charac teristics, the joint, which slips at the time limit of the shear stress, is assumed in the tangential direction.The detailed model of interaction between particles is men tioned in the paper (Gotoh, H. & Sakai, T. (1997)).

The tuning parameters (spring constants in normal and tangential directions (k_n , k_s) and damping con stants in normal and tangential directions (η_n , η_s)) are determined with following the optimization procedure given by Gotoh et al. (2001). The tuning parameter are as follows: $k_{n\,air}$ = 707.52 N/s; $k_{s\,air}$ = 272.12 N/s; $\eta_{n\,air}$ = 0.70 Ns/m; $\eta_{s\,air}$ = 0.43 Ns/m in the air, $k_{n\,water}$ = 840.82 N/s; $k_{s\,water}$ = 323.39 N/s; $\eta_{n\,water}$ = 0.83 Ns/m; $\eta_{s\,water}$ = 0.52 Ns/m in the water. These parameters are determined to show the good agree ment with experiment result. The share of particle concentration (c) and the component of drag force (f_{Di}) in each calculation domain cell are evaluated from the position of all particles calculated by the governing equations (1) and (2). And then these values are used in the solid-liquid coupling.

2.2 Model of liquid phase

Continuity and momentum equations to the local aver aged flow of incompressible fluid are described as

follows: particle i particle j i j η n η s [e n < 0] off [e s μe n] k n k s spring & dashpot system contact point Figure 1. Spring and dashpot system between contacting particles. c i,j P i,j v i,j v i,j+1 u i,j u i,j+1 Δx Δy Δx=0.01m Δy=0.01m S 1 V S 3 S 2 Δx Δy (b)(a) Figure 2. (a) share of the particles in the cell; (b) fluid-variable layout. where β= correction factor for three-dimensional effect (β= 0.67); x i =Cartesian components x, y; u i ; averaged fluid velocity in Cartesian components u, v; f Di = component of drag force of each particle;V= the cell area; S k = share of k-th particle in the cell (shown in Figure 2); τ ij = component of stress tensor; and ν t = kinematic eddy viscosity. And also, interaction force at interface between solid phase and liquid phase is evaluated by drag force.

2.3 Model of turbulent flow

In this paper, turbulent flow is modeled by standard k-ε

turbulent model of second closure model based on the

isotropic eddy viscosity. k and ε equations including

the existence of particles can be written as follows:

where k = turbulent energy; ε= energy dissipation;

Pr= production of turbulent energy due to shear

stress; and G k , G ε = term in consideration of com

ponents the turbulent fluctuating caused by the exis

tence of sand particle. The recommend values by

Launder, B.E. & Spalding, D.B.(1974) for the con

stants in the k-ε turbulent model are as follows:

C μ = 0.09;σ k = 1.0;σ ε = 1.3; C ε1 = 1.44; C ε2 = 1.92.

The evaluation of the G k and G ε are neglected for the

simplification.

2.4 Outline of computing method

The coupling between solid phase and liquid phase

is calculated by repeating calculation of liquid phase

and solid phase alternately.The marching procedure of

calculation from the time n∆t f to the time (n+ 1)∆t f

is as follows. For the first step, the prediction value of

velocity (u∗) 4.0 3.0 2.0 1.0 3.02.01.00.0 : exp.
(Koshizuka et al.) : sim. Z/L t 2g/L L Z water mass 2L
Figure 3. Motion of tip of the broken water. which is
obtained by discretization of equation (7) transformed into
the conservative form, is given by using the velocity(u n)
and the pressure(P n) at the time n∆t f where ∆t f = time
step of the liquid phase (∆t f = 0.00025 s); n=marching
time step; and τ= stress tensor. The second step, the
iterative calculation, which corrects the velocity and the
pressure, is performed by the Highly Simplified Marker and
Cell method, or HSMAC, proposed by Hirt, C.W. & Cook, J.L.
(1972) until the prediction value of velocity (u *)
satisfies the continuity equation for the multi phase flow,
which is derived from sum of each continuity equation of
the liquid phase and solid phase, and then the velocity (u
n+1) and the pressure (P n+1) at the time (n+ 1) ∆t f is
computed. Next, the particle positions are evaluated from
the MBS with using that renewed flow field (u n+1 , P n+1
). And the drag force and the share of solid phase in each
cell of the flow field are computed, and these are used to
the next time step of the liquid phase. This series of
processes are iterated till the designated calculation
time.And also, the governing equations are discretized by
the finite volume method, or FVM, on the staggered grid,
and also upwind difference scheme is used in the advection
term. 2.5 Boundary conditions and initial conditions The
upper side of Figure 4 shows the calculated domain.The
destruction and the flowing process of the mound (rubble
stones dam) is simulated. The mound is formed by arranging
the uniform diameter particles in the plover-shaped. To
visualize the fluid motion, the Lagrangian massless marker
particles are arranged in the fluid mass.The wall boundary
conditions of k and ε are given by the wall function, and
the velocity profile in the log-law region is given by
presuming turbulent flow on the smooth bed.

Figure 4. Snapshots of destruction process of the rubble

stones dam.

3 SIMULATION

3.1 Destruction process of rubble stones dam

The motion of the tip of the water mass running on

the bottom wall is shown in Figure 3 to verify the

liquid phase of present simulation code. Simulation result shows the good agreement compared with the experiment by Koshizuka et al. 1995. Figure 4 shows the snapshots of the destruction process of the rubble stones dam. The tip of the water mass reaches the toe of the mound (left side of the mound) around the time t= 0.1 s, and then infiltration of water to the pore of the mound occurs. Increase of the water surface level due to the resistance of the mound is shown around the mound at the time t= 0.15 s. And also, the mound slides with deflection at its center part by the drag force acting on the mound due to the relative velocity between mound and water mass at the time t= 0.20- 0.25 s. Furthermore, zooming in the deformation of the mound at this stage in detail, two tensile deformation lines occurs inside the mound and separation to three clusters are confirmed. After the time t= 0.30 s, flow mode of the mound particles are classified by cluster-A, cluster-B and cluster-C. The particles of cluster-B are transported with pushing out into the air, and most of the particles of cluster-C are transported with swelling in the water. While, the particles of cluster-A are transported with slight deformation in comparison with other clusters. 3.2 Mechanism of destruction The driving force concerned in the present simulation code consists of pressure gradient force, inter-particle force and drag force. Under these driving forces, the velocity vector of particles in the early destruction process of the rubble stones dam is shown in Figure 5. The accelerating process of the particles is shown clearly from the velocity vector of particles. The acceleration rate of the cluster-A is smaller than that of the cluster-C, the tendency to the dispersion of the particles between the cluster-A and the cluster-C shown in Figure 4 is reconfirmed. Next, the transport process of the particles due to the pressure gradient force is examined.

Figure 6 shows the time series of the pressure distribution, and also, gauge pressure is used in pressure indication. A high pressure part around the toe of the mound due to the collision with broken water mass at the time t= 0.15 s gradually permeates inside the mound, and influences the transformation of the mound. Furthermore, a high pressure part from center to back inside the mound is found at the time t= 0.20- 0.28 s, which might be a helpful to generate the cluster of mound. And also, this high pressure part inside the mound might push the particles of the cluster B out of the air. The transport of the particles due to the drag force acting on the particles and the inter-particle force at the mound is discussed. Figure 7 shows the time series of mean inter-particle force, mean drag force and the total number of the contact points between particles. The mean inter-particle force classified in two

blocks of increase section (block-1) and occasional occurrence section (block-2). The abrupt increase of interaction force between particles due to the colli sion with the collapsing water in the block-1 lead to the destruction of the mound inner structure, and also the energy, which make the mound disperse, would be concentrated. While, in the block-2, the dispersed par ticles mix with the broken water and transport under the solid-liquid two phase flow. And also, the inter particle force in this block-2 only occurs occasionally, hence the drag force and pressure gradient force dom inates to the destruction of the mound. The abrupt increase number of contact points between particles are also shown from the time series of the total num ber of the contact points between particles, and it is confirmed that the dominant force to the dispersion of the mound particles is the inter-particle force. In the transport process of the block-2, the slight change of the contact points between particles is found, there fore, the driving force by the inter-particle force is comparatively smaller than other factors of driving

force. And also, although the number of the contact

points between particles show the slight fluctuation,

the inter-particle force and the drag force are not shown

port process of the dispersed particles, in which the

relative velocity between particles and fluid are small,

would be shown.

4 EXPERIMENT

4.1 Outline of experiment

A destruction of rubble stones dam is reproduced by

acrylic open channel, which is 3.0 m long, with a slit

at 0.5 m shown in Figure 8. The cross section of the

acrylic open channel is 0.1 m width. The driving force

of the destruction of rubble stones dam is broken water

power, which is reserved in the left side of the slit, due

to pulling up the slit. Motion of the mound particles

are recorded by the digital video camera, shatter speed

of which is 1/4000 s, from the side of acrylic-resin

wall. The test mound particle is the glass beads, 2.5

in specific density and 0.005 m in diameter. After the (b)

stones dam in simulation. the glass beads in the left side
of the mound, and the glass beads are transported with
mixing with the broken water, are observed clearly. Figure
11 shows the destruction process of the rubble stones dam
under the same experimental condition. Although the water
surface level is different from experiment shown in Figure
10, the eroding process around the left side of the mound
due to the force of the broken water is simulated, the same
destruction tendency shown in the experiment can be
confirmed from the simulation result as well. 5 CONCLUSIONS
The destruction process and mechanism of the rubble stones
dam are discussed numerically by using the solid-liquid two
phase flow model based on the EulerLagrange coupling. The
present simulation shows that the static mound particles
disperses by the pressure gradient force and inter-particle
force in the early stage, and then the equilibrium state is
confirmed that the dispersed particles are mainly
transported by the drag force. Although the interface
between solid and liquid is expressed simply by the only
drag force in this paper, the simulation result about the
destruction process of the mound shows good agreement with

experiment. So, the validity of the evaluation to the

motion of the rubble stones is shown. However, the

repeatability of water dynamics are in poor agreement

with the experimental data. This might be a reason

that the evaluation of the interaction between fluid

phase and solid phase is insufficient. In the near fea

ture, unsteady process of the destruction of the rubble

stones dam have to be discussed in detail in consider

ation of the additional force due to the unsteady flow

and the modeling of turbulent fluctuation due to the

particles laden flow. And also, high accurate numer

ical simulation about the solid-liquid two phase flow

should be developed by comparison with experiments.

Effects of gradient pressure on resistance law in roll waves and

effects of tension surface

S. Longo

Department of Civil Engineering, University of Parma, Parma, Italy

ABSTRACT: Free surface flow in sufficiently steep channels is unstable and progressive waves develop as

periodic distribution of bores connected by smooth profiles. The amplitude of the breakers is higher than the

normal water depth. Roll waves in the initial phase development (before overtaking) develop, dissipating for

friction less energy than the equivalent uniform stream. Including the gradient pressure effects, an extra saving

of energy is computed, which can partially balance the dissipation in the breaker. Assuming different values of

the momentum and energy coefficients on the two sides of the breaker, physically acceptable value of the water

stream depths are obtained with a limited dissipation rate in the jump. Including the tension surface effects, a

new family of roll waves is depicted.

1 INTRODUCTION

Free surface instabilities of flows down inclined chan
nels have been widely observed in Newtonian and
non-Newtonian fluids. If there is enough space for the
instabilities to grow, in some condition roll waves
develop, with several bores having height, period,
length and celerity increasing downstream.

The observations of roll waves in a torrent by Maw
in the late 19th century were followed by the first
description due to Forchheimer (1903) and to Cornish
(1934). Observations of roll waves in mud flows are
reported by several Authors in many areas. The first
study of the phenomenon was based on linear stability
analysis of the basic equations written in the long wave
approximation. The development of a finite amplitude
wave theory is due to Dressler (1949). Dressler's the
ory, originally developed for fully turbulent flows, was
extended to laminar flows for Newtonian fluids by
Ishihara et al. (1954) and to power-law fluids by Ng &
Mei (1994), who essentially focussed on pseudoplas
tic fluids (mud). Recently Prasad et al. (2000) applied
Dressler's theory to flowing grains, and Longo (2003)
applied Dressler's theory to dilatant fluid.

Roll waves are essentially controlled by Froude

number, and can develop in laminar and in turbulent

streams. The usual approach is linear stability analy

sis: the basic flow field (the uniform flow), is perturbed

assuming small variations in the water depth and mean

velocity. The set of equations in perturbed variables is

linearised and solved. If perturbations grow, the basic

motion is linear asymptotic unstable, otherwise it is stable. Froude number correspondent to marginal stability (perturbation do not grow nor decay) depends on velocity profile and resistance law. In laminar flow, Yih (1954, 1963) and Benjamin (1957a,b), perturbed Navier-Stokes equations assuming free surface perturbation of sinus shape and recovered Orr-Sommerfeld equation finding a critical Froude number equal to 0.527. Similar result was obtained by Chen (1992), perturbing the shallow water 1-D equation including derivative of Boussinesq coefficient of momentum along the stream motion. Vedernikov (1945) introduced the so called Vedernikov number to state the necessary condition for roll waves formation. Montuori (1961) state the sufficient condition for roll wave formation. In turbulent flow in rectangular channels, assuming a Chézy resistance law with a constant coefficient, Jeffreys (1925), Stoker (1957), Liggett (1975) found a critical Froude number equal to 2. Several Researchers as Iwasa (1954); Koloseus & Davidian, (1966); Berlamont &Vanderstappen (1981) put in evidence the strong sensitivity of critical Froude number on velocity profile, Reynolds number, friction law. In particular according to Rouse (1963); Rosso et al. (1990), the Darcy-Weisbach friction factor increases for increasing Froude number in supercritical streams.According to Brock (1966, 1967), no firm conclusion on such a dependence could be drawn because experimental data were not enough accurate, especially the water depth measurements. Moreover an apparent increment of friction factor could better be explained as energy transfer from mean flow to waves.

In addition several laboratory experiments with

water streams were conducted by Ishihara et al. (1954),

Brock (1967), Julien & Hartley (1985, 1986). Brock

(1967, 1969) carried out experiments in a rectangu
lar small channel 40 m long and ~12 cm wide, and
essentially classified two families of roll waves.A first
family included natural roll waves, generally non peri
odic; a second family included artificial periodic roll
waves, obtained imposing a controlled disturb at the
inlet and characterised by a strong regularity. In both
cases there is an initial stage with waves of constant
period, and a second stage of growing and with a wave
period and length increment. The growth of natural
roll waves also happens as coalescence of two or more
waves. In the second stage the significant wave charac
teristics (wave height, celerity and mean wave length)
coincide in both natural and artificial roll waves with
similar Froude number and channel bottom slope.
Roll waves analysis is a challenging topic from a
mathematical point of view and roll waves knowl
edge has also a practical application. In fact roll waves
strongly enhance the maximum water depth (up to 3
times the normal depth) and the maximum fluid veloc
ity, increasing its threatening. Most of the available
results refer to the limit condition for roll waves exis
tence, but no one can infer the determination of roll
wave parameters (wave length, wave height, celerity)
for a given system. There are some experimental indi

cations due to Ponce & Maisner (1993), who using Brock's data (1967) found that the observed periodic roll waves are those corresponding to the maximum growth rate (in linear stability analysis). Ng & Mei (1994) infer that the observed roll wave has the lowest amplitude corresponding to no energy loss across the shock.

In the present study we analyse the energy balance in permanent periodic roll waves. Dissipation in a free surface flow is generally controlled by wall stress and depends on Reynolds and Froude numbers, wall rough ness, shape of the transversal section, channel profile, channel plan and non stationarity parameter. Uniform flow in a channel dissipates energy per unit weight and unit length equal to bottom slope. If bores or jumps are present, part of the energy is dissipated in the shock area with a dissipation depending on the conjugate water depth. Lamberti & Longo (2000) demonstrated that assuming a reliable wave form and resistance law for a free surface flow, in some condition the stream dissipates per unit wave length less energy respect to the uniform stream; the energy excess is then dissi pated in the shock. In such a situation the conjugate water depths are obtained imposing the energy bal ance over a single wave length.They also demonstrated

that using the same energy balance criterion and inte

grating the water depth in a moving reference solidal

with the wave form (Thomas, 1939; Dressler, 1949;

Brock, 1967), it is possible to evaluate all the waves characteristics for a given water discharge and bottom slope and wall roughness. In the present manuscript the first part of the analysis is devoted to the boundary layer effects on roll waves. Friction is usually evaluated assuming a quasisteady motion, neglecting the pressure gradient. If the boundary layer has an adverse gradient pressure, friction is reduced and also dissipation in the stream is reduced. The second part of the analysis is devoted to tension surface effects. In principle, tension surface can lead to a new family of solution obtained using Dressler's approach. These solution can have practical interest in fluid with a strong tension surface. The next Section is devoted to deriving the basic equations applying Karman's momentum integral method. In Section 3 we describe the structure of the boundary layer in a roll wave and its effects on resistance law. In Section 4 we describe the 'special solution'with a modified resistance law and in Section 5 we obtain the admissibility conditions for roll waves. In Section 6 the effects of tension surface on admissibility criteria for finite amplitude waves is studied. Sections 7, 8 and 9 are devoted to shock conditions and to energy balance in the discontinuity and in the unstable stream. 2 BALANCE EQUATIONS Let us consider a 2-D laminar flow of a fluid down a plane of inclination θ. The coordinate system has the x-axis along the bed and the y-axis normal to it (Fig. 1). For long waves, applying Karman's momentum integral method to mass balance and linear momentum balance, we obtain the following set of equations: Figure 1. Schematic of periodic waves with sharp front in shallow fluid flows.

where u is the depth average velocity of flow func

tion of the longitudinal coordinate x and time t, A is

the cross sectional area of flow, y is the depth of the

flow, β is the momentum flux factor, τ b is the average

boundary shear stress and R is the hydraulic radius

of the flow, ρ is the mass density of the fluid, g is

acceleration of gravity and σ is the surface tension.

Introducing a moving reference having celerity c

and assuming that in the moving reference the chosen

state variables U and Y are function of ξ= x- ct only

(Fig. 2):

The two equations (1, 2) for a wide channel (R≈Y)

become:

where the spatial variation of the momentum flux

correction term is neglected.

Eqs (4-5) can be rearranged as:

with $\gamma = \rho g$ the specific weight of the fluid. Dividing

these two equations and integrating results:

Figure 2. Definition sketch of a roll wave profile in the

moving frame. K is the constant discharge per unit width in the moving frame. It was defined as ‘overrun’ by Chow (1959) and ‘progressive discharge’ by Dressler (1949). The discharge in the fixed frame varies with space and time. 3 RESISTANCE AND BOUNDARY LAYER STRUCTURE Resistance to flow in open channels is function of several independent variables. For a rectangular straight channel of uniform inclination, the force per unit length, intended as that which, when multiplied by the mean velocity of flow yields the rate of energy dissipation, can be expressed as (Rouse, 1965): where y is the mean depth, U is the mean velocity, k is a length describing the surface roughness, ζ is a parameter describing the shape of the cross section, ρ is the fluid density, g is the gravity acceleration, μ is fluid viscosity and $\partial y/\partial t$ is the rate of change of depth with time. Using Buckingham’s theorem results in a relation among non dimensional group as: The term on the left hand is essentially a friction factor, the terms on the right hand are Reynolds’ number, non dimensional roughness, the cross section shape factor, the Froude number and the degree of unsteadiness. The effects of the Froude number have been widely discussed. According to Rouse (1965) there is an apparent increase in channel resistance as the Froude number exceeds the stability limit, with waves formation.

The increase in channel resistance can be intended as a transformation from mean-flow energy to wave energy instead of pure dissipation. Beyond the stability limit roll waves develop and the flow cannot be treated as uniform and steady. In a discussion to Rouse's paper by Brock (1966) the concept of apparent increase in channel resistance is better focused, highlighting that if part of energy gained by gravity is transferred to waves and then dissipated by waves, the apparent dissipation due to boundary friction is higher whenever waves effects are not taken into account in the energy balance.This hypothesis has been supported by detailed measurements (e.g. Rosso et al., 1990). The dependence of friction factor on the degree of unsteadiness is more complicated. Unsteadiness is usually connected with gradient pressure and it can

be verified that self preserving solutions in bound

ary layers (i.e. solutions invariant respect to horizontal

coordinate and function of non-dimensional verti

cal coordinate and non dimensional velocity) can be

obtained only with a careful adjustment of the pressure

(Clauser, 1956). As a consequence the dependence of

friction factor on unsteadiness parameter is not theo

retically available except for specific controlled flow

fields. Nevertheless it is interesting to study the effects

of the unsteadiness parameter on energy dissipation.

Assuming the wave profile obtained by Dressler as

a first approximation, we can demonstrate that the bot

tom boundary layer has an adverse pressure gradient.

Neglecting gravity effects and viscous forces in the

outer region, the pressure gradient is simply related to

fluid acceleration:

On using eq.(3) and eq.(8) the pressure gradient in the

external flow is expressed as:

The right hand term in eq.(12) is always positive

because fluid velocity increases from the back to the

front of the wave and water depth is always positive.

The qualitative plot of the external pressure gradient

is shown in Figure 3.

The structure of the boundary layer is clearly quite

complicate. In the laboratory reference the wall bound

ary layer has a periodic structure with wave length

equal to the length of the roll waves. The adverse gra

dient pressure tends to grow up the boundary layer

thickness behind the moving roller, with increasing

efficiency from the front to the back. We can infer that

for periodic roll waves the boundary layer attains also

Figure 3. Qualitative plot of the pressure gradient. a time periodic structure with possible similar solutions. In fact neglecting the time dependent term, the boundary layer can be treated as a stationary boundary layer in adverse pressure gradient subject to growing thickness and growing bottom tangential stress and decreasing pressure gradient. The Rotta-Clauser parameter: where δ 1 is the displacement thickness, can be constant or nearly constant. More experimental activity is necessary in order to assess a friction factor formula depending on unsteadiness parameter but it is plausible that friction factor decreases from the back to the front of the roll waves. However in eq.(10) the non-dimensional group (∂y/∂t)/U can be written as: and to investigate the structure of roll waves in presence of a decreasing friction factor, we assume a resistance law as: with a modified friction factor: where a is a non dimensional parameter. The modified friction factor collapses to the standard friction factor in uniform flow (∂Y /∂ξ= 0). In presence of roll waves it decreases from the back to the front because ∂Y /∂ξ is positive and growing. For the sake of simplicity, also considering that this model is not experimentally verified, we assume a

constant value for a. 4 THE DISCONTINUOUS SOLUTION WITH THE MODIFIED FRICTION FACTOR AND NEGLECTING THE SURFACE TENSION On using the modified friction factor in eq.(16), eq.(7) becomes: where the surface tension term has been dropped. The denominator of eq.(17) admits always at least a real

zero named Y c , which is positive if a> 0. The profile

would have to be vertical in the neighbour of Y c if

d 2 §/dY 2 ≠ 0 in Y c , otherwise for d 2 §/dY 2 ≠ 0 in Y c a

maximum or a minimum is expected. If a= 0 Dressler

(1949) demonstrated that the function d 2 §/dY 2 cannot

be zero in the critical point. It can be demonstrated that:

In the limit of the present analysis, this profile must be

disregarded because the basic equations were derived

in the hypothesis of small stream curvature, which

is not this case. Hence an acceptable profile can be

obtained using eq.(17) eliminating the zero of the

denominator, imposing that it is also a zero of the

numerator. If Y c is a zero of the denominator, using

eq.(8) results:

that can be reduced to:

The system admits the two couples of solutions, but

only the couple:

satisfies the condition of roll waves existence c>U c

(Whitham, 1973). The solution is real only if

a< 1/sin θ.

Using these quantities, the progressive discharge

rate necessary for this special case is: and the following

relation holds: Introducing the variable z=Y /Y c and eliminating the pole z= 1, eq.(17) can be written as: 5 LIMITING CONDITION FOR A POSITIVE STEEPNESS OF THE PROFILE In order to construct roll waves from the previous profile, it is necessary that: It can be verified that the numerator in eq.(26) is positive in z= 1 if: and the numerator is positive in z= 1 if: Also results: As a consequence results:

However only the first inequality in eq.(31) is accept

able, because the second inequality results in an

unphysical wave profile.The denominator in eq.(26) is

always positive for physically acceptable values of the

parameters, the numerator has two real roots named

Y 1 and Y 2 :

It can be verified that 0<Y 1 <Y 2 <Y c if the first

inequality (31) is satisfied. The eq.(26) can be inte

grated in analytical form as §= f (Y).

6 THE CRITICAL POINT INCLUDING

THE SURFACE TENSION

Including the surface tension term, eq.(17) becomes:

or

It is a non linear third order equation which can be

expressed as a third order non linear autonomous

system:

The system has a singular point at (Y s , 0, 0), where Y s

is the solution of the equation: It can be demonstrated that this equation has three real solutions if and a single real solution if In both cases there is always a real positive solution. Near the critical point we let (Y , Y 1 , Y 2)= (Y s + ε, ε 1 , ε 2) and we approximate the system of equation as: It is a linear autonomous system of equations in the perturbations of the singular point. In

compact form it can be expressed as and the eigenvalues are the solutions of the characteristic equation: The classification of the singular point is based on the eigenvalues. The eigenvalues are all real if

In the present analysis this condition is satisfied for

reasonable values of the parameters involved. The sin

gular point is classified as hyperbolic fixed point. A

zero eigenvalue is obtained if d = 0 or

and the singular point becomes nonhyperbolic. The

analysis on the singular point is in progress but the

great variety of singularity suggest different families

of solutions if tension surface is non negligible.

7 SHOCK CONDITIONS

The shock condition is obtained from the mass and

momentum balance equations for a control volume

across the shock:

where the square brackets are the operator [<.>] b a =

<.>| b −<.>| a and b and f stand for the back and front

sections of the shock. The mass balance equation (8)

in extended form is:

with K the apparent discharge in the moving frame.

The linear momentum balance equation (6) can be

written as:

where eq.(46) has already been used. The usual trivial

solution Y f =Y b (no shock) holds if in additionβ f =β b

is assumed. Equation (47) can be solved obtaining

Y b = f (Y s) and choosing the solution Y b >Y f > 0. Note

that in general the momentum correction coefficients

should depend on the ‘age’ of the boundary layer and

on the jump height Y b −Y f . 8 ENERGY DISSIPATION IN THE SHOCK The rate of change of mechanical energy across the jump is equal to: where α b and α f are the energy flux correction factors. Assuming Y ∗ <.> =Y <.> g/c 2 , eq.(48) reads: Substituting the expression for discharge in the moving reference and dividing by the discharge per unit width in the moving reference, it is possible to obtain the energy drop across the jump. The expression is cumbersome and is not reported. For α f = β f =α b =β b = 1 the energy drop has the classical expression: The assumption of a boundary layer with a gradient pressure is not consistent with the common assumption of constant momentum and energy coefficients. Instead, if we assume β b >β f > 1 and α b >α f > 1 a domain of acceptable conditions (Y ∗ b >Y ∗ f) and limited dissipation rate (∆E ∗ j → 0) is possible (see Fig. 4). 9 DISCUSSION ON ENERGY DISSIPATION IN THE UNSTABLE STREAM The mean energy dissipated for friction in a wave length is computed as:

Figure 4. Energy balance in the jump. The hatched area

is unacceptable because Y ∗ f >Y ∗ b . The closed hatched area

corresponds to energy production in the jump, physically

unacceptable. β b = 1.03, β f = 1.02, α b = 1.06, α b = 1.03,

θ= 10 ∘ .

A stream in steady uniform motion obviously results

in ∆E f + λ sin θ= 0 for any value of the wave length

λ. In the presence of roll waves, including the energy

dissipated in the jump, the energy balance over a wave

length results in:

Assuming the modified resistance, which includes

the gradient pressure effects, an energy saving term

appears (the last term on the right hand of eq.50), although, on the basis of some numerical experiments, it is still not enough to close the energy budget, i.e. the system dissipates more energy than the energy gained from gravity. The jump enhances dissipation and the stream in unstable motion dissipates more than the equivalent stream in stable steady uniform motion (equivalent means having the same average discharge with identical channel characteristics). All the com putations have neglected the finite size of the moving shock, the contribution of the weight of the fluid in the shock, surface tension effects and the trajectories cur vature. It has been demonstrated that inclusion of the weight of the fluid in the jump in linear momentum bal ance across the shock, tends to reduce the ratio Y * b /Y * f (Brock 1967) and favors smaller wave lengths. Surface tension contrasts instabilities growth and rounds the wave crest (Hwang et al. 1994). In addition, neglect ing dissipation due to friction in the shock (assumed of finite length) it is possible to find a zero energy budget (eq.52) corresponding to a situation where the dissi

Mathematical simulation of the effects of bridges and structures

on flood waves propagation

L. Natale & G. Petaccia

Department of Environmental and Hydraulic Engineering, University of Pavia, Pavia, Italy

F. Savi

University of Roma “La Sapienza”, Roma, Italy

ABSTRACT: The movement of flood wave in rivers is greatly influenced by channel transitions and controls

such as bridges, sills, weirs, sluices or other types of hydraulic structures. The mathematical simulation of

the flow conditions through these obstructions often asks for the reproduction of changes from subcritical

to supercritical flow and vice versa. This paper presents a suitable technique for simulation of flow through

channel controls that uses internal boundary conditions of 1D shallow water mathematical model. The numerical

solver is first order finite volume, and is able to reproduce changes of the flow regime through the hydraulic

structure and tailwater control. The model was verified simulating experiments on flume reported in literature.

Moreover several experiments were performed in the Hydraulic Laboratory of the Department of Hydraulic and

Environmental Engineering of the University of Pavia: calculated water profiles fit acceptably observed ones.

The 1D mathematical model can not simulate the weir-nappe profiles immediately downstream the structures

which are curvilinear and three-dimensional, but it is a practical tool that usefully reproduces the increasing of

the water stages and the slowing down of the wave movement caused by structures.

1 INTRODUCTION

The mathematical simulation of flood routing in rivers has been increasingly studied in the last decades.When a flood wave moves along mountain reaches the flow regime varies from subcritical to supercritical and vice versa in space and time due to the formation of hydraulic surges and control sections.These variations of flow regime are mainly due to abrupt changes in channel geometry and can be simulated only by numer ical solvers able to reproduce discontinuities (shocks) of the free surface.

Many numerical solvers have been proposed to integrate the shallow water equations and to schema tize the effects of source terms for transcritical flow (Toro, 1997; Hirsch, 1990): their accuracy was veri fied by simulating experiments on flumes in a wide range of abrupt channel transitions (Morris, 2000; Morris and Galland, 2000; Petaccia and Savi, 2002).

Even in natural watercourses, flow regime can be con trolled by hydraulic structures such as bridges, weirs or sluice-gates, causing subcritical flow upstream and supercritical flow downstream. The tailwater effects due to these structures must be carefully simulated in order to recognise where levees might be overtopped. Goutal and Maurel (2002), Rissoan et al. (2002) simulated simple obstacles, such as weirs or constrictions, modifying locally the river geometry (bottom elevation or channel

width). Soares Frazao and Zech (2000) simulated flow through bridge with a local constriction of the cross section. This schematization is not suitable when different hydraulic flow conditions through bridges can occur: free surface flow, pressure flow, pressure and overtopping flow. Moreover minor losses cannot be directly taken into account by shallow water equations. Therefore, as a common practice, internal boundary conditions (rating curves) are adopted. An internal boundary condition relates the flow conditions in the two river reaches, upstream and downstream the structure, where shallow water equations are valid. Usually these rating curves are computed in steady flow conditions taking into account minor losses. This approach is widely used by models that deal with a single flow regime (subcritical or supercritical): for instance ISIS (Rosu and Ahmed, 1999), NWS FLDWAV (Jin and Fread, 1997; Fread and Lewis, 1998) computer codes. TEVERE (Natale et al., 1999) model, based on Preissmann scheme, simulates in this way flow through a wide range of hydraulic structures.

Some of these models, such as MIKE11 (DHI,

2000), NWS FLDWAV (Fread and Lewis, 1998),

RUBAR 3 (Paquier, 1998) simulate flow through

structures using numerical solvers able to reproduce

subcritical and supercritical flow regimes. However

some of these codes simulate in simplified way trans

critical flow: for instance in NSW FLDWAV and

MIKE11 codes, the convective inertial terms are pro

gressively reduced as Froude number increases, up to

neglect them when its value approaches unity. Such

models simulate the tailwater effects approximately

and do not reproduce changes in time of flow regime,

upstream and/or downstream the structure.

Garcia Navarro and Alcrudo (1992) simulated a

series of weirs using internal boundary conditions; in

their application the flow regime did not change and supercritical flow occurred downstream any weir.

In the following is presented the simulation of the flow across structures taking into account transcritical flow conditions, adopting 1D shallow water equations written in complete form and solved by means of an upwind finite volume scheme. The numerical results are verified on the basis of laboratory tests reported in literature or expressly carried out in the Laboratory of Hydraulic and Environmental Engineering of the University of Pavia.

2 MATHEMATICAL MODEL

Propagation of a dam-break wave can be described by the shallow water equations coming from the mass and momentum balance equations (Cunge et al., 1980):

where x is the spatial co-ordinate measured along the channel, t the time, Q the discharge, A the wetted area, g the gravitational acceleration, S 0 the bottom slope, S f the friction slope. The terms I 1 and I 2 are related to the hydrostatic pressure force:

h is the water depth and b(x, η) the width of the cross section at the distance x and height η, above the channel bed. 3 NUMERICAL SOLVERS System (1) is solved by means of a first order finite volume numerical solver based on Roe’s approximated Jacobian of the flux schematization (Roe, 1981): The numerical fluxes F are computed as with and The eigenvalues a and the eigenvectors e of the

Jacobian matrix depend on the flow velocity u and celerity c: In order to avoid non-physical discontinuities (zero eigenvalues), that are incompatible with the entropy principle, the absolute value of the eigenvalues of J is modified by defining the quantity: The new absolute value of each eigenvalue in equation (5) is defined as:

4 SOURCE TERMS

The source terms (2b) are schematized in two different

ways:

4.1 Pointwise (Brufau et al., 2002)

where n is the Manning roughness coefficient.

The I 2 term is schematized as

where b is the flume width.

4.2 Upwind (Garcia Navarro and Vasquez-Cendon, 2000)

According to equation (1), the decomposition of the

source terms can be expressed as

where the values of β coefficients are chosen in order

to produce the balance the momentum equation for

rectangular cross sections.

5 INTERNAL BOUNDARY CONDITIONS

Internal boundary conditions were introduced in the

unsteady flow simulation in order to reproduce minor

losses through structures. Let’s focus on the generic

structure (i.e. sluice-gate, sharp channel contraction)

located at the cross section (i) in Fig. 1. Upstream

(i- 1) and downstream (i+ 1) channel cross sections

have the same shape of the intermediate section (i).

The computational domain is then disconnected in two

reaches upstream (from section 1 to i- 2) and down

stream (from section i+ 2 to section N) the structure,

where equations (4) are applied and the values of A n+1 i

and Q n+1 i are computed.

Considering that no water is stored in the short

stretch from (i- 1) and (i+ 1) since the two sections

are very close, the mass balance equation across the

structure is considered:

Further relationships that depend on the flow regime

are needed to estimate the three unknowns A n+1 i-1 , A n+1 i+1 i i+1 i+2i-1i-2 Figure 1. Schematization of an internal boundary condition. and Q n+1 i-1 . The model computes both subcritical and supercritical flow solutions and compares the total momentum fluxes plus the total hydrostatic pressures to assess which solution is correct. In the following this procedure will be explained in details. Supercritical flow through the structure may occur if in section i- 2 the flow is supercritical. In this case the values of Aˆ n+1 i+1 and Qˆ n+1 i+1 (the symbol ∧ means that this a possible supercritical solution) are estimated considering a backward schematization of the fluxes, i.e. The energy or the momentum equation in steady state condition is applied between section i- 1 and i+ 1 to simulate the contraction and the expansion of the supercritical flow through the structure. This equation relates Aˆ n+1 i+1 to the values of Aˆ n+1 i-1 and Qˆ n+1 i+1 only. If the flow in section i+ 2 is supercritical no backwater effects occur, then Otherwise, subcritical flow condition may exist. In this case the flow regime depends on the flow conditions both in sections i- 2 and i+ 2 simultaneously. The following system of 3 equations can be written: (a) continuity equation between sections i+ 1 and i+ 2, i.e. (b) rating curve in subcritical flow conditions between sections i+ 1 and i- 1, i.e.

(c) continuity equation between sections i-1 and

i-2, i.e.

The symbol ~ means that this a possible (subcritical)

solution and it can be computed by solving the above system of equations.

In many cases both subcritical and supercritical solutions do not exist. This means that section i controls the flow with subcritical flow upstream and supercritical flow downstream the structure. Continuity equations are applied to evaluate water depths in i- 1 and i+ 1 which depends on the rate of discharge only.

If more than one solution exists, i.e. both subcritical and supercritical solutions can be obtained, to check which solution is correct, the momentum functions are compared starting from section i+ 1 and moving upstream.

6 SURGE FORMATION

The equations described in section 2 do not represent properly the dynamics of the surge formation since the volume of water in the roll of the hydraulic jump is neglected.

In fact the model represents a shock discontinuity in the mathematical solution and the numerical solver locates the variations of the flow regimes in a few space intervals (x); all in all it does not consider the length of the hydraulic jump.

The backward movement of the surge was simu

lated as follows: when the supercritical flow impact against the gate the lower part of the current remains essentially undisturbed.Therefore in the model the dis charge through the gate is maintained constant in time. The difference between the discharge in the upstream section and the discharge through the gate is stored by the model until it becomes equal to the volume in the roll of the hydraulic jump (V j).

The upper part of the current impacts against the gate and accelerates vertically generating the roll of the hydraulic jump. The surge does not move until the volume of water in the roll, taking into account a con stant value of air concentration in water (C w = 0.3), corresponds to the hydraulic jump length evaluated by means of the Peterka formula (1958).

Up to this time the lower part of the current and the flow through the gate remains supercritical. The volume of water in the jump (V j), assuming a linear roll profile, is estimated.

When the hydraulic jump is formed at the upstream face of the gate (section i- 1 of Fig. 1) subcritical con ditions occur. The model simulates the switch between undisturbed current and under gate flow, described adopting the rating curve in Fig. 4. The surge keeps then to move backward. 7 EXPERIMENTAL VERIFICATIONS 7.1 WES test case The proposed approach was firstly tested comparing the results of the model with the observations of a flume

experiment (5.1 test case) carried out at the USACE Waterways Experiment Station (Chen, 1980). The experimental setup consists of a 122 m long, 1.22 m wide rectangular flume with a slope S 0 = 0.005. A removable dam, 0.305 m high, is located at the midpoint of the flume (x= 61 m). It involves a constricted breach width of 0.122 m, or 1/10 channel width. The Manning coefficient applied is 0.009 ms −1/3 . This experiment, which constitute a severe benchmark for numerical solver since is characterized by an abrupt variation of the channel width, was simulated by Sanders (2001), that used a II order scheme and more recently by Bradford and Sanders (2002), a 2D approach. First of all we simulated WES experiments integrating shallow water equations without imposing any internal boundary conditions. In Fig. 2 the observed water depths hydrographs are compared with those computed adopting both pointwise (continuous line) and upwind (dotted line) schematizations of the source terms. Pointwise schematization is unacceptable since overestimates the outflow so that in the simulation the reservoir empties much faster than real one and the computed wave front celerity is considerably higher than the experimental one. For this reason in Fig. 2 the pointwise simulation of the reservoir emptying is not shown. 1 2 3 4 5 Figure 2. Comparison between upwind and pointwise source term schematizations without internal boundary conditions: (1) at x= 30.5 m, (2) at x= 45.75, (3) at x= 68.6 m, (4) at x= 85.4, (5) at x= 106.75 m.

The upwind schematization is significantly more

accurate.

If internal boundary conditions are introduced, also

the pointwise schematization gives acceptable results:

the simulations obtained with internal boundary con

ditions applied to the pointwise treatment are shown

in Fig. 3. Similar results are obtained coupling the

upwind treatment and internal boundary conditions.

7.2 Pavia test cases

In order to investigate more extensively the importance

of internal boundary conditions, experimental tests

were carried out at Hydraulic Laboratory of the Uni
versity of Pavia. The flume was 9.30 m long, 0.48 m
wide, horizontal, with a bottom friction coefficient
of 0.12 ms −1/3 . The steep wave was generated by the
instantaneous opening of a hinged sluice gate placed
at x= 3.36 m. The still water stored upstream the gate
was 0.20 m deep.
The experiments considered a first sluice-gate, 4 cm
open, placed at x= 8.40 m and a second sluice-gate,
2 cm open, at the end of the flume (x= 9.3 m) to pro
duce evolving tailwater condition in the flume. To
estimate the rating curve through the first gate, prelim
inary experiments in steady state conditions were per
formed supplying constant discharge and measuring
water stages immediately upstream and downstream
the gate and fitting the experimental observations
using discharge coefficient reported by Ven Te Chow
(1959)(Fig. 4).
In the following pictures (5, 6, 7, 8, 9, 10 and 11),
the computed (grey and black line) and experimen
tal instantaneous surface profiles taken by a standard
video camera (25 frame per second) are compared at
various time steps. 1 2 3 4 5
Figure 3. Comparison between upwind and pointwise
source term schematizations with internal boundary condi

tions: (1) at x= 30.5 m, (2) at x= 45.75, (3) at x= 68.6 m,

(4) at x= 85.4, (5) at x= 106.75 m. The black line represents the simulation I obtained with the surge formation model explained in section 6. The grey line represents the simulation II obtained without the surge formation model. Both the mathematical models simulate supercritical flow (Fig. 5) when the flow depth is lower than the upstream gate opening. Figure 6 shows that only a part of the current supplies water to the roll of the hydraulic jump; the computed volume stored by the model at that time is represented by the thinner black line; until the water volume stored by the model I does not equal V j the model I does not simulate the formation of the surge. The model II (grey line) simulates erroneously the formation of the surge. The stored volume for the Figure 4. Rating curve for the gate. Figure 5. Measured and computed instantaneous profiles at t= 4 s. Figure 6. Measured and computed instantaneous profiles at t= 5 s.

second gate is not represented since is too far from

the experimental window.

Figure 7 depicts the instant where the flow regime

upstream of the gate changes from supercritical to

subcritical.

Figure 8 shows that the downstream surge reaches

and submerges the upstream gate.

In Fig. 9 computed and observed water depth after

7.7 s are compared. Upstream the gate water depth

increases immediately after submergence of the gate

becomes effective.

The comparison with the experimental images

shows that the model II fails in the simulations of

the first instants of the flow impact against the gate

(Fig. 6). The discrepancies between the results of the

simulation II and experiments mainly depend on the

simulation of the bore upstream the gate. It is con

firmed that the model does not reproduce correctly

Figure 7. Measured and computed instantaneous profiles

at t= 6.0 s.

Figure 8. Measured and computed instantaneous profiles

at t= 6.9 s.

Figure 9. Measured and computed instantaneous profiles

at t= 7.7 s. the changes of the flow regimes immediately after the impact against the gate (Fig. 6): in this short transient the model simulates subcritical flow although the experiments show that the flow is essentially supercritical. The results of the model II (grey line) underestimate the discharge through the gate and overestimate the celerity of surge moving from the upstream gate. As a consequence the celerity of the surge moving from the downstream gate is underestimated. As time goes on, the model II reproduces maximum water depths upstream the gate but overestimates the celerity of the surge moving upstream from the gate (Fig. 7). Consequently the model II simulates the submersion of the upstream gate with a short delay in comparison with the experiments (Fig. 8). Comparing the two simulations can be remarked that the celerity of the surge is not affected by the mechanics of the surge formation, since both the simulated celerities are greater than the observed one. On the basis of these results some more investigation are going to be performed in the Hydraulic Laboratory of the University of Pavia. The experimental setup includes a sharp contraction that reduces the cross section to one half of the original one and a bridge. As an example of preliminary results, the computed and observed water depths profiles for the constriction are compared in Figs. 10 and 11. Figures 10 and 11 show that the downstream water depths are underestimated due to aeration of the flow and strong surface turbulence induced by the falling Figure 10. Measured and calculated instantaneous profiles at t= 3.2 s Figure 11. Measured and calculated instantaneous profiles at t= 4.0 s.

nappe; instead water depths upstream the constriction

are described with sufficient detail.

The two dimensionality of the phenomenon will be studied and the limits of the one dimensional model will be analysed.

8 CONCLUSIONS

The flow conditions through hydraulic structures and channel transitions were investigated very extensively, at first working on the schematization of source terms, then inserting internal boundary conditions and mod ifying the mathematical model. A first order accurate finite volume numerical solver was used and the results obtained with the internal boundary conditions as well as modifying the mathematical model are compared with experimental investigations on laboratory flumes.

The mathematical model that takes into account the volume of the hydraulic jump reproduces satisfactorily the impact of the wave front against the obstacles when the flow is three dimensional and the shallow water model is inadequate. The model simulates satisfacto rily the water depth upstream the gate and the change of the flow regime through the obstacle from supercriti cal to subcritical due to tailwater. More specifically the position of the surge moving upstream and the conse quent submergence of the sluice-gate with the increase of the water stage immediately upstream the gate are

simulated correctly.

Soil/water interaction during the breaching process of

overtopped embankments

Pickert, G. & Jirka, G.H.

Institute for Hydromechanics, University of Karlsruhe,
Germany

Bieberstein, A. & Brauns, J.

Division of Embankment Dams and Landfill Technology,
Institute of Soil Mechanics and Rock Mechanics,

University of Karlsruhe, Germany

ABSTRACT: When a flood exceeds the design level of an embankment dam, the dam will be overtopped and

breaching can occur. Consequences are major flooding of the area beyond the dam, which can at least cause

high economical damage. Residents, local governmental administrations and environmental agencies are highly

interested in knowing the precise description of possible breach development and outflow hydrograph Q(t). Many

publications and models are available on this topic and model outputs can vary up to±50% from the original data.

This is due to a limited understanding of the processes involved in the breaching of embankments and the lack

of fundamental experimental data. The research presented in this paper has the following aims: First, to generate

a reliable data base by carrying out physical experiments (scaled 1:10) and measuring the outflow hydrograph

and the erosion of the embankment material per time (erosion curve). Second, to improve the knowledge of the

soil/water interactions in partly saturated soils, represented by the water tension in the breach slopes. And third,

to provide a 3D elevation picture of a breaching geometry in homogeneous embankments.

1 INTRODUCTION

When a flood exceeds the design level of an embank

ment dam, the dam will be overtopped and breaching

will occur. Consequences are major flooding of the area beyond the dam, which can at least cause high economical damage. Residents, local governmental administrations and environmental agencies are highly interested in knowing the precise description of the breach development and outflow hydrograph Q(t). Appropriate emergency plans and scenarios could be developed based on this information and the loss of life and/or properties could be minimized.

Existing models, for example the NWS-BREACH model developed by Fread (1991), describe over topping events by hydrodynamic equations, erosion equations and simple geotechnical considerations. These simplifications of the breaching process, and especially the processes for the breach widening, have negative influence on the modeling results. Breach widening strongly depends on the neglected soil/water interactions in the soil matrix. These interactions, for example the tension in partly saturated soils have a strong influence on the erodibility of the soil and on the stability of the breach slope. The present research is focusing an overtopped earthen embankment and has the following aims: First, to generate a reliable data base by carrying out physical experiments (scaled 1:10) and measure the outflow hydrograph and the erosion of the embankment material per time (erosion curve). Second, to improve the knowledge of the soil/water interactions in partly saturated soils, represented by the water tension on the breach slopes. And third, to provide a 3D elevation picture

of a breaching geometry in homogeneous embankments. 2 BACKGROUND 2.1 State of the art A comparison of different dam breach models by Morris (2000) done within the EU workshop of Concerned Action on Dambreak Modelling (CADAM) showed the wide variability of model results. Figure 1 shows the computed breach discharges over time (Q [l/s]) of six models. Apart from the results of the Broich2D model which was calibrated against their own measured data, the output variation is rather high.

Figure 1. Breach discharges of six models compared to

experimetal data (Morris, 2000).

Broich (1998) reports that the accuracy of predict

ing the peak discharge is perhaps ±50%, and consid

ered the accuracy in predicting the onset of breach

formation as even worse.

Morris (2000) published a list of existing dam

breach models specifying the implemented breach

morphology, flow equations, sediment transport equa

tion and the geomechanics of the breach-side slope.

Other summaries and analysis of dam breach mod

els were done by Wahl (1998), Broich (1998), Lecoint

(1998) and Mohamed et al. (2000).

During the CADAM workshop Graham (1998)

stated that the modeling of breach formation through

embankments is done by using process based models.

Most breach models are based on steady state sediment

equations related to homogeneous banks and adopted

breach growth mechanisms. The modelers must there

fore make a significant number of assumptions and

simplifications in order to model the breach, all of which can greatly affect the modeling results.

The breaching process is dominated by the interaction of these three processes:

- hydraulics of the flow over the embankment and through the breach
- erosion process
- soil properties and geotechnical considerations.

Simplification in one of these processes will certainly affect the overall modelling results. Especially the geotechnical simplification concerning the breach widening processes, affects the modelling results.

Breach widening depends mainly on two effects. First the erosion of embankment material due to the transport capacity of the breach flow, and second on the failure of the breach side slopes.

2.2 Erosion process

Mohamed et al. (2002) stated that the implemented sediment transport equations are derived for subcritical steady state flow conditions, for a specific type of sediment, and for a certain range of grains sizes. These conditions are likely to be violated during the breaching process since conditions change from subcritical flow to unsteady supercritical flow and back. Soil types do also vary widely in embankment construction. But in the absence of any other method to predict the sediment transport, a careful selection from the existing sediment transport formulas should be done, by considering their applicability to flow on steep slopes and for supercritical flow and additionally their derivation, based on dam breach experimental data. As stated above, the choice of a sediment transport equation requires professional judgment

and knowledge about the breaching mechanisms. In addition to the above stated considerations following verifications of the transport equation can be done: 1. Verify the developed model on very good documented historical dam failures, for example the Teton dam failure 1975 (USA), and compare the results with the actual breach width and depth. 2. Experimental data of the erosion curves for a falling water level in the reservoir. (Bechteler) 3. Explicit breach width and depth for different breaching times. (Coleman, 2000) 4. Carry out experimental models. 2.3 Key issues for research A more accurate failure analysis of the breach side slope, especially the soil/water interactions within the embankment material, would highly improve the understanding of the breaching process. Experimental data of erosion and transport of embankment material for calibrating numerical models would close the gap between model results and real breaching events. 3 BREACH SLOPE FAILURE Slope movements are classified in many ways in the geotechnical and geologic sciences, each having some usefulness in emphasizing features pertinent to recognition, avoidance, control, correction or other purpose for the classification. 3.1 Classification of slope failures Among the attributes that are used as criteria for identification and classification of failures, in respect to the subject of breach slope failures, are: - type of movement - kind of material - rate of movement - geometry of the area of failure.

In geotechnics the following failure characteriza

tion (type of movement) is done:

- falls

- topples

- slides

- lateral Spreads

- flows

- complex.

The breaching of an embankment is certainly a com

plex failure, which has to be simplified based on the

experimental research.

3.2 Causes of slope movements

The processes involved in slides, movements or fail
ures, comprise a continuous series of events from cause
to effect. All slides involve the failure of earth materi
als under shear stress. The initiation of the process can
therefore be reviewed according to (a) the factors that
contribute to increased shear stress and (b) the factors
that contribute to low or reduced shear strength.
Factors that contribute to increased shear stress can
also be classified in different categories:

- the removal of lateral support
- removal of underlying support
- lateral pressure
- surcharge (additional loads)
- transitory earth stresses (e.g. earthquakes)
- regional tilting.

The important factors concerning the breach slope
failure are the first and the second.
Factors that contribute to reduced shear strength
of rock or soil may be divided in two groups. The
first group includes factors based on the initial state
or inherent characteristics of the material, such as
composition, texture, structure and slope geometry.
Organic materials, clays, decomposed rock are inher
ently weak or become weak upon change in their water

content.Additionally, these materials may have a loose structure and/or texture.

The second group includes the variable factors that tend to lower the shear strength of the material. These factors (a) are changes due to weathering and other chemical reactions and (b) changes in inter-granular forces due to water content and pressure in pores and fractures: Water in soils causes an increase in weight of the mass, an increase in pore water pressure, and a decrease in apparent cohesion.

The second factor, changes in intergranular forces (b), has an important influence on the breaching pro cess.Thus, the presented investigations and the current experiments respectively are focused on it.

3.3 Soil water interactions

The analysis of the breaches in dams and embankments showed a wide variation of the breach slope, some are very steep others are flat (Bücker, 1998).This is mainly due to the dam material parameters and the effluent water volume. As stated before the water content of the soil has a great influence on the slope stability. First, as a destabilising factor if the water content is too high, and second, as a stabilising factor in unsaturated soils with a moisture content w< 1 [-].This stabilising force introduced on the soil matrix by the soil/water interactions is based on the soil-moisture tension. Soil-moisture tension can take values of a compressive stress (positive) or tensile strength (negative), depending on the water content of the soil matrix. The tensile strength also known as suction power, increases the effective stresses and so the apparent cohesion of the soil. All water movements in the soil depend directly on the soil-moisture tension, since water will tend to flow from areas of high potential to those with lower potential. The soil-moisture tension reflects

the sum of the water holding forces of the soil. With tensiometers, this force can be determined directly: where ψ=water tension [Nm]; m=mass [kg]; g= gravity [m/s 2]; and h= height [m] above level of saturation. Compared to all other measuring principles, the capillary binding of water to soil is measured with tensiometers directly. 4 EXPERIMENTAL SETUP AND PROCEDURE In the research laboratory of the Institute for Hydromechanics of the University of Karlsruhe a 1:10 scaled model of a homogeneous embankment has been realized in a flume of 15 m length, 1 m in width and 0.7 m in depth. The model has a height of 0.3 m, is 1.9 m long and is built over the whole flume width of 1 m (Figure 2). The homogeneous embankment model is built up with three sands on a fixed bed (see Table 1). With respect to a flood embankment the upstream as well as the downstream slope is 1:3, which ensures the geometrical similarity of the embankment model. In fact the slopes angles are smaller than the angle of friction of the used soil. Thus the slopes are stable. The embankment is constructed of several layers of sand. In all experiments the mean moisture content of the embankment material is w= 0.05 [-] and the mean material compaction factor is D= 0.5 [-]. Within the embankment six tensiometer probes are installed during the construction. The tensiometer probes are located in different heights and in different distances from the breach.

Figure 2. Side view of the experimental setup. Table 1. Dam materials used in the experimental models. Label Type d 50 [mm] Sand 1 Coarse sand 2 Sand 2 Medium sand 0.22 Sand 3 Coarse silt 0.035

A drainage toe ensures that the embankment with

stands the hydraulic load and that seepage is dis

charged safely at the drainage toe. The reservoir level

will have no effect on the downstream slope.

Before filling the reservoir, the initial breach plug

is located on one of the side walls. This plug is a

wooden block with a length of 0.1 m (crest width),

width of 0.02 m. With this plug a rectangular initial

breach channel of 0.02 m width and 0.02 m depth over

the total width of the embankment crest of 0.1 m is ini
tiated. The plug is used for initialising the overtopping
at a defined location at the glass wall.
The reservoir is filled up slowly, so that a constant
seepage line will arise in the embankment. The exper
iment is started by withdrawing the plug, when the
reservoir is filled up to water level of 0.29 m (0.01 m
below the embankment crest) and a constant seepage
is reached.
During the breaching process the outflow hydro
graph, the erosion rate and the suction pressure are
measured. Furthermore, the breaching process is
recorded for a detailed analysis.

5 MEASUREMENT TECHNIQUE

5.1 Erosion and flow measurement

The experimental setup described in Chapter 4 and in
Figure 2 is designed in such a way that it is possi
ble to measure the erosion of the dam material with
constant water level in the reservoir and no backwater
influences on the breaching process.
Right behind the dam toe a sill leads to a channel
within the flume where the flow velocity is reduced
by three grids in such a way that the eroded dam
materials will deposit. This channel is bedded on weighing
sensors so that the instantaneous weight of the eroded
material and the outflow is measured as W total [kg]. The
outflow from the breach is measured at the end of this

channel by a measuring weir. The erosion curve is obtained by subtracting the weight of the water W wat [kg] from the total weight W total [kg] for each time step, see equation 2. During the calibration phase, a deposition rate of 95% of the eroded material was achieved as well as a measurement error of ±1% of the total weight. Water leveling probes measure the reservoir water level and the water level in the sedimentation channel. Additional to the reservoir level the inflow to the reservoir is measured with a inductive flow meter (IDM). 5.2 Fringe projection The breaching of an embankment is a highly transient process. Due to that, it is difficult to receive a profile of the breach itself. Coleman (2000) has achieved very good results by stopping the breaching process and mapping the dried breach at certain time steps. But to evaluate or even to model the different stages of collapse of the breach slopes another nonintrusive mapping technique has to be used for continuous measurements. A technique which is frequently employed in mechanical engineering and in medicine to measure surface distortions or curvations is the Moiré Projection, also named Fringe Projection. The simplest Fringe Projection for contouring an object is to project interference fringes or a grating onto an object and then view from another direction. Figure 3 shows a definition diagram for Fringe Projection and in Figure 4 the present experimental setup. From the triangle B-a-b in Figure 3, we find the out-of-plane displacement equation (3) at point B with: where W= displacement; N z = the fringe order at point B, g= grading pitch; and α= angle.

Figure 3. Optical setup for Fringe Projection (Post, 1994).

Figure 4. Fringe Projection setup (top view).

Figure 5. Fringe Projection and extracted fringes.

The easiest way to produce a stripe pattern on the

surface is the direct projection using a light source and

an alternating black/transparent stripe pattern image

and an optical system to project a sharp image of the

stripes onto the surface. Most convenient a slide pro

jector is used with a framed stripe image of black and

transparent stripes of a distinct stripe width. As these

stripes are projected, however, only nearly parallel light sheets are received, depending on the distance of the projector. The planes of equal light intensity or light phase are – more or less parallel to the axis of the light projector.

The camera must have a distinct angle relative to the projection axis. If the camera has the same axis like the projector and the surface is moved away from the projector, it will not be able to detect any change in the stripe pattern except for a slight change of stripe frequency induced by the not completely parallel light sheets. Figure 6. Principle setup of a micro tensiometer probe (UMS, 2003). As the stripe width is very large compared to the wave length of the light, even very rough surfaces can be inspected. This is the case in the conducted experiments, preliminary experiments showed that the breach slope is rough with overhang. The analysis system consists of a slide projector which produces the pattern of white and black stripes on the dam profile. The accuracy of all optical methods strongly depends on the knowledge of all geometrical information of the measuring setup. These are projector distance and angle, the optics of the projection system, camera distance and angle relative to the projector and the surface. If all this information is available, the reconstruction of the surface can be done very accurately. Subpixel algorithms, i.e. algorithms that take into account the gradient of gray level changes in the image, provide a much higher resolution than the size of a single pixel. Depending on the pattern and the algorithm used, a resolution of 1/10 of a pixel size can be achieved when looking for edges or the center of gravity of the area of objects. 5.3 Tensiometer probes Tensiometers are inexpensive moisture measurement tools. The accuracy of a well-maintained tensiometer is in the 90–95% range. They use a porous ceramic cup at the end of a long tube which is inserted in the soil, see Figure 6. The tensiometer is a point sensor because the ceramic cup at the tip of the tube is the contact point with the soil. The measurement is based on a soil tension effect that

occurs when the tube is partially filled with water and sealed at the top with a tension measurement device. As the soil drys it absorbs water

through the porous ceramic cup and creates a suction

(partial vacuum) inside the tube that is proportionate

to the change in soil water content.

As the soil water content increases, the ambient soil

water pressure increases and forces water back into the

ceramic cup, thereby reducing the suction or applying

a positive pressure to the sensor. Tensiometers are not

affected by salinity or other soil conductivity factors.

5.4 Data acquisition

For the data acquisition and experimental setup con

trol a DAQ-PCI-card is used. The 16 analogue input

channels are scanned with 100 Hz and saved directly to

the hard drive. Two digital outputs are used to control

the motor gate valve.

The National Instruments software Labview 6.0 is

used as control and acquisition software.

An IEEE 1394 CCD video camera with a resolu

tion of 1280*980 pixels records the breaching process

through the glass wall of the flume. This system has

the advantage that video films can be recorded directly

on hard disc up to the maximum hard drive space of

80 GBytes, which is very useful for cohesive materials

where the breaching process is very long.

6 EXPERIMENTAL RESULTS

The test embankment has a height of 0.3 m, a length of 1.9 m, a crest width of 0.1 m and a total width of 1 m. The embankment was built from medium sand with a compaction of D= 0.5 [-] and a moisture content of w= 0.15 [-], the total weight of the embankment was approximately 650 kg.

From removal of the initial breach plug to the end of measurements with an unaffected flow 110 sec elapsed. Figure 7 shows a time series of pictures from this test.

At t= 0 sec the embankment is intact, the reservoir is filled up to the crest and the initial breach plug is still in place. The second picture (t= 40 sec) shows the initial breach phase. This phase is dominated by set of vertical steps which are merging together. This type of erosion is introduced by Hanson (1997) as headcut ero sion in cohesive materials.The breaching phase begins in picture 3 (t= 65 sec). All steps are merged and an erosion channel parallel to the downstream embank ment slope is formed. The breach channel has been cut upstream, across the total width of the embankment crest.

At t= 80 sec breach crest is migrating upstream on the embankment slope, whereas the discharge funnel

migrates with the breach crest. The breach inclina

tion increases referred to the downstream embankment

slope. At t= 110 sec the breach crest migrates further

upstream and the inclination of the breach increases.

Figure 8 shows the breached embankment viewed

from upstream looking downstream after the depletion Figure 7. Breaching sequence. Figure 8. Breached test embankment (view from upstream). of the reservoir. The hourglass shape with the bottle neck at the embankment crest of the breach well defined by Coleman (2000) is recognisable. Additionally the streamlines of the breach flow are clearly visible in the embankment material. The geotechnical aspect of this research is also evident. Looking at the bottle neck the overhang of the breach slope is stable due to the negative soil-moisture tension. A dry medium sand (d 50 = 0.22 mm) is cohesionless and has an angle of friction of ϕ ≈ 30 ∘ with a standard slope stability, which would make an overhang impossible. But taking the negative soil-moisture tension into account the so-called capillary cohesion stabilizes this overhang. Thus soil mechanical and geotechnical considerations must be included in the understanding of breaching processes.

Figure 9. Measured erosion curve of breached

embankment.

Figure 9 shows the graph of the correspondent ero

sion curve. A quantitative comparison of the photo

graph and the erosion curve indicates that half of

the embankment was eroded. The mass of the eroded

material was measured in the sedimentation channel.

This graph (Figure 9) with the increasing mean sed

iment weight per time is in good accordance to the

video taped breaching process (Figure 8). The initial

breaching phase and the main breaching phase can be

identified. Additionally to this, major collapses of the breaching channel due to failure of the breach slope can be correlated in the graph and in the video.

7 CONCLUSION

This paper first results of ongoing work on the understanding of breach development and the aim of developing a fundamental data base for modelers.

The preliminary experimental results show good support for the concept of a breaching process occur ring in three phases:

- breach initiation
- breaching
- depletion of the reservoir.

But not only the breaching phases correlate with literature results (Coleman, 2000). The breach devel opment and the breach propagation also show good agreement with results of other experiments (Hanson, 1997; Coleman, 2000).

With respect to the erosion curve it can be stated that the breaching process is measured quite well, but further improvement on the analysis is necessary.

Based on this experiments, the failure mode of the breach side slope can be identified as a fall failure.

Experiments of dam-break flow in the presence of obstacles

S. Soares Frazão

Université catholique de Louvain, Belgium

B. Noël & Y. Zech

Department of Civil and Environmental Engineering, Université catholique de Louvain, Belgium

ABSTRACT: Dam-break flows are likely to occur in area that are not subject to more common floods. Also,

the importance of the wave might be such that the flow route is no more directed by the thalweg of the river. The

whole valley is involved, and the roads, bridges and urban buildings become obstacles to the flow. The purpose

of the paper is to study the influence of such an obstacle on a dam-break wave, the obstacle being an idealized

representation of a single building. The experimental set-up consists in a channel with a rectangular shaped

obstacle, representing a building, placed immediately downstream from the dam. The building is not centred in

the channel, and is not aligned with the flow direction. Flow observation shows that after the violent impact

of the wave on the building, the flow is forced to change its direction to pass the building. This implies the

formation of hydraulic jumps with the consequence that the water level is locally more important than without

building. Behind the building, a wake zone is observed. Then, further downstream, the flow slowly recovers

the structure it would have without the building. Several measurement devices were used to characterize the

flow. The water level evolution was measured at five different locations by means of water level gauges. At each

gauging point, the velocity was measured by means of acoustic Doppler velocimeter. Then, the surface velocity

field was obtained using digital imaging techniques. This study is part of the IMPACT European project which

aims at investigating extreme flood processes and uncertainty. The experimental data set presented here was

used in the IMPACT benchmarking programme, as a validation means for numerical models.

1 INTRODUCTION

Flows may be considerably affected by the presence

of natural or artificial obstacles. In the case of severe

floods, for example due to damor dike-break, the

influence of such obstacles is even amplified. Neglect

ing this influence in numerical simulations of such

flows could lead to heavy misinterpretation.

The presence of obstacles is common in river as well

in minor bed (bridge piers) as in floodplains (abut

ments, dikes, trees and vegetation, debris from former

floods, etc.). Moreover, if the river embankments are

overtopped or the flood dikes breached, flow will occur

in areas that are normally not subject to inundation, not

prepared to support such a hazard, and thus present

ing a series of obstacles (roads, railways, dwellings,

industrial and commercial structures, etc.).

In steady flows, two major effects of obstacles are

observed: an obstruction effect and a wave formation

due to nonlinear alignment of the obstacle.

The obstruction effect, even in straight reaches, is

best illustrated by the bridge-pier case (see for instance
Wake L 1 L 2 L 2 Figure 1. Schematization of bridge-pier constriction. Chow, 1959). The flow is schematized as represented in Figure 1, where an additional constriction appears due to the limitation in flow-filament curvature. In uniform-flow channel with mild slope, the flow is mainly subcritical. If the cross-section reduction is limited, the obstruction induces a backwater effect that may extend over a long distance upstream (Fig. 2a). However, if the relative obstruction is larger, it may happen that the specific-energy curve rises in such a way that its minimum C2, corresponding to the critical Standard section (a) Mild slope : (b) Mild slope : Constricted section

Figure 2. Water profiles along bridge piers in mild-slope

cases. Standard section Steep slope Steep slope Constricted section

Figure 3. Water profiles along bridge piers in steep-slope

cases.

stage, is higher that the uniform condition in the stan

dard section (Fig. 2b). This results in a control section

in the constricted section and in the development of

a supercritical water profile, which returns to normal

conditions through a hydraulic jump.

A similar behavior may be observed in steep-slope

conditions, where the flow is generally supercritical.

In these situations, the water profile presents the two

configurations of Figure 3.

If the constriction is limited, only the water surface

close to the constriction is disturbed and the effect
Positive wave front Negative wave front Figure 4. Cross
waves in nonlinear alignment (after Chow, 1959). will not
extend farther upstream. If the constriction becomes
significant, the minimum possible energy in the constricted
section becomes too high to be reached immediately. The
specific energy thus needs to increase in the upstream
reach, which is only possible in subcritical flow, thus
requiring the formation of a hydraulic jump. The resulting
upstream water profile extends only over a short distance.
The above description of the obstruction effect caused by
the presence of an obstacle is based on a one-dimensional
flow modeling. If the resulting constriction is important,
two-dimensional aspects may predominate and change
significantly the location and shape of discontinuities.
The second observed consequence of an obstacle concerns the
effect of nonlinear alignment, which may be rather complex.
In subcritical flows, a transverse superelevation may arise
near the outer bank (or along the obstacle). In
supercritical case, the outer wall, which turns inward to
the flow, will produce an oblique hydraulic jump and a
corresponding positive wave front, while the inner wall,
which turns away from the flow, will develop a negative
wave front, both forming cross waves (Fig. 4). When the
flow is unsteady, and above all in severe transient
situations (damor dike break for example), this already
complex behavior becomes even more complicated. The
obstacle now induces reflected waves that in turn may
reflect against the banks or other obstacles. Few
descriptions of such transient flow phenomena against

obstacles are available. However, they could be of great interest in the modeling of dam-break flow. Above all it is important to evaluate the extension in space and time of the influence of an obstacle to limit accurate and refined computations where they are really needed. At the large scale of a real flood event, it is not always possible to distinguish between the different features of the flow. Therefore, it was decided to design an idealized experiment that limits the parameters involved in the flow. A single obstacle representing a building is placed in a channel, immediately downstream from the dam. Through appropriate measurements of the flow, it is possible to identify its specific features.

The experiment presented in this paper was used in the benchmarking program of the IMPACT European project (Soares Frazão et al., 2003). This research project, which addresses the assessment and reduction of risks from extreme flooding caused by natural events or by the failure of dams and flood defense structures (Morris, 2002; Morris and Vask inn, 2002) has also a special focus on floods in urban areas and in the presence of obstacles.

2 EXPERIMENTAL SET-UP

The experiments were carried out in the laboratory of the Civil Engineering Department of the Université catholique de Louvain (UCL) in Belgium.The channel is sketched in Figures 5–7.

It has a total length of 35.80 m and is 3.60 m wide. The upstream reservoir is 6.90 m long. The cross sec tion is trapezoidal near the bed (Fig. 7a). The dam is

represented by a gate located between two solid blocks;

its cross-section is rectangular and it is 1.00 m wide

(Fig. 7b).To simulate a dam break, the gate is pulled up

rapidly.The building, located 3.40 m downstream from

the dam, consists in a rectangular block with dimen

sions 0.80 × 0.40 m. It makes an angle of 64 ∘ with

the channel axis (Fig. 6). After measurement in uni

form conditions, the Manning bed friction coefficient

is n = 0.01 s m −1/3 . 1.30

Figure 5. Experimental set-up (dimensions in meters). y x
Gate 1.75 3.40 64° 0 . 8 0 0 . 4 0

Figure 6. Location and dimensions of the building (in

meters). The channel is closed by a wall at the upstream end. The downstream boundary condition consists in a weir and a chute, but has no influence on the flow during the test duration, which is 30 s. The initial conditions consist in a water level of 0.40 m in the upstream reservoir and a thin layer of 0.01 m of water in the downstream part of the channel. 3 GENERAL FLOW DESCRIPTION After the rapid opening of the gate, the strong dambreak wave reflects against the building, almost submerging it, and the flow separates, forming a series of shock waves crossing each other. A wake zone can be identified just downstream from the building, surrounded by cross waves. The flow rapidly reaches an almost steady state with a decreasing discharge due to the emptying of the reservoir. Also, re-circulation zones can be identified between the building and the walls. This description of the flow is illustrated by means of figures obtained from computed results (Noël et al., 2003). Figure 8 shows the free-surface elevation at t= 1 s, with the two-dimensional spreading of the flood wave. At t= 3 s, the reflection of the wave against the building has occurred and results in the formation of 0.155 0.34 1.00 (a) (b) 3.60 Figure 7. an oblique hydraulic jump (Fig. 9). The circular front wave also reflects against the side walls of the chan nel and lateral jumps are formed. Figure 10 shows the flow after 10 s: the upstream reservoir empties and the hydraulic jump formed by the reflection against the building migrates in the upstream direction. The sep aration of the flow around the building and the wake zone can also be identified.

4 FLOW MEASUREMENT

4.1 Point measurements

The water level is measured by means of 6 water level gauges located in the channel as indicated on Figure 11: one gauge in the reservoir to monitor

its emptying and thus the inflow discharge, and the

others around the building. Their exact position is

summarized in Table 1.

The experiment was run several times and showed a

very good reproducibility. The velocity was also mea

sured at the same locations by means of an Acoustic

Doppler Velocimeter (ADV). However, no complete

vertical velocity profiles were measured. Only one

velocity data was measured at each gauging point, at

a height of 3.6 cm above the channel bed to ensure

that the transducers were submerged during the whole

experiment. As the flow is a rapid transient with G6 G2 G3 G4 G5 G1 Gate y x Figure 11. Sketch of the position of the gauging points where the water level and the velocity are measured. Table 1. Position of the gauges. Gauge x (m) y (m) G1 2.65 1.15 G2 2.65 −0.60 G3 4.00 1.15 G4 4.00 −0.80 G5 5.20 0.30 G6 −1.87 1.10 hydraulic jumps and re-circulation zones, it is not fully developed i.e. there is no logarithmic velocity profile. The velocity distribution is closer to a uniform distribution and this kind of “mid-depth” measurement yields good results. This will be detailed in a further section. 4.1.1 Field measurements A complete surface-velocity field was measured by a digital imaging technique yielding high-quality results. High-resolution CCD cameras were placed above the channel to film the flow seeded with tracers at a rate of 38 images per second. This results in a series of images where the white tracers can be clearly identified. Using the Voronoï technique (Capart et al., 2002, Spinewine et al., 2003) to reconstruct the trajectories of the tracers on the free surface, it is possible to measure the velocity field in the filmed zone. Thanks to the good reproducibility of the experiment, it was possible to run it several times and to combine the resulting images to cover a large area of the channel. Such a combination of filmed images is shown in Figure 12. The white tracers can be also be identified on the figure. 4.1.2 Validity of velocity measurements By means of the ADV probe, the velocities u and v in the x and y directions respectively

are obtained at a position 3.6 cm above the channel bed. The digital imaging technique provides the surface velocity. Both are different from the depth-averaged velocity in fully developed flows. However, in this rapidly varying

Figure 12. Combination of filmed images from five exper

iments to cover a whole field around the building (t = 1.2 s).

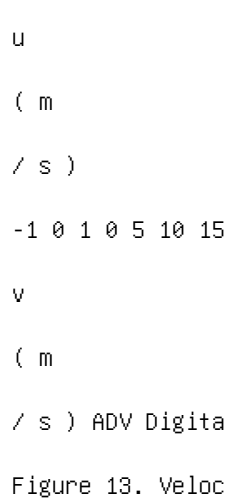

Figure 13. Velocity measurements at gauge G2, (a) uand

(b) v-component of the velocity.

flow, we can observe that both measurements are in a surprisingly good agreement. Figure 13 compares the ADV and digital imaging data at the location of gauge G2, while Figure 14 shows a similar comparison at gauge G4.

Gauge G2 measures the arrival of the reflected front around time t= 15 s. Before this time, the flow is supercritical and the u-component of the velocity is high. A difference is observed between ADV and dig ital imaging measurements, which indicates that the

u-velocity distribution is not completely uniform. For

the v-component, the correspondence is very good, as

well as for the measurements at gauge G4.

Velocity measurements at gauge G4, (a) uand (b) v-component of the velocity. Figure 15. Measured velocity field at t = 1 s. Capart et al. (2002) and Spinewine et al. (2003), surface-velocity fields are obtained as shown in the following figures. Figure 15 shows the flow at t= 1 s. The twodimensional spreading of the front wave is clearly visible. Then, at t= 2 s (Fig. 16), the front reaches the building and also the inclined side walls of the channel where a first reflection occurs. This reflection appears in the figure as a sudden change in direction and in amplitude of the velocity vectors. At time t= 5 s, the hydraulic jumps formed by the reflection of the front wave against the building can be identified in Figure 17 as the limit between high velocities upstream from the building and an area of water almost at rest.The lateral hydraulic jump are still present. The flow separates to pass around the building and a wake is formed behind this. Those latter features then remain and attenuate while the flow reaches an almost steady state as the reservoir empties. Figure 18 shows the velocity field after 10 s: the hydraulic jump has propagated slowly

Figure 16. Measured velocity field at t= 2 s.

Figure 17. Measured velocity field at t= 5 s.

Figure 18. Measured velocity field at t= 10 s.

in the upstream direction, the lateral jumps take also

more space in the flow, the wake zone is still present

but the velocities have a decreasing amplitude.

5.2 Water-level measurements

The points where the water level was measured are

indicated in Figure 11. Gauge G6, located in the

upstream reservoir, shows a steady decrease of the

water level as the reservoir empties (Fig. 19). Oscil

lations of the free surface in the reservoir occur as

the back wave reaches the borders of the reservoir at 0 0.1 0.2 0.3 0.4 0.5 0 5 10 15 20 25 30 t (s) z (m) Figure 19. Water level evolution at gauge G6. 0 0.05 0.1 0.15 0 5 10 15 20 25 30 t (s) z (m) Figure 20. Water level evolution at gauge G1. 0 0.05 0.1 0.15 0 5 10 15 20 25 30 t (s) z (m) Figure 21. Water level evolution at gauge G2. different times and reflect, resulting in a superposition of smooth waves. Gauge G1 (Fig. 20) is located upstream from the building and close to the left bank of the channel. The water level rapidly rises due to reflection of the front wave against the inclined banks of the channel, appearing as a “splash” in the gauge measurements. Then, around t= 8 s, the oblique hydraulic jump formed by the reflection against the banks reaches the gauge. The main hydraulic jump formed by the reflection of the wave against the building is well captured by gauge G2 (Fig. 21) around t= 15 s. Gauge G4 (Fig. 22), located on the right side of the building, records several reflections of the water. First, there is a kind of “splash” at t= 2.5 s due to the strong reflection of the water against the building. Then, the 0

0

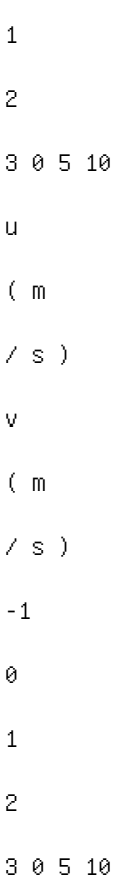

Figure 23. Velocity measurements at gauge G5.

arrival of the oblique hydraulic jump formed by the reflection of the front wave against the side walls of the channel (t= 5 s) can be observed. Finally a new rise of the water level is observed (around t= 15 s) when the oblique hydraulic jump and the main hydraulic jump come together and start moving in the upstream direction.

5.3 ADV-velocity measurements

The good agreement between both measurements techniques has already been outlined in a preceding

section.

Interesting results were also obtained at gauge G5,

located in the wake of the building. Figure 23 shows the

uand v-components of the velocity. The oscillations

clearly indicate the presence of wake eddies.

6 RESULTS INTERPRETATION

6.1 Zone of influence of the building

Dam-break modeling aims at reproducing the water

level and the velocity where water rise and/or forces
Figure 24. Difference of water depth (in meters) between results computed with and without obstacle.
induced by the current may endanger the population or the properties. The presence of an obstacle may considerably modify those figures and thus also the associated risks. It is thus beneficial to estimate the changes induced by the obstacle. Figure 24 shows such a result for times t = 5, 10 and 20 s, respectively. The upstream part of the flow, between the dam and the obstacle, is practically not influenced by this, which is not the case just in front of the building where significant increase of the water elevation occurs (0.14 m above the flow without obstacle, for a water depth of 0.40 m in the upstream reservoir). Also along the banks, above all the left bank, the influence of the obstacle is considerable. Behind the building, the influence is less noticeable. Only a relative depression appears in the wake zones, which is not unexpected. At t= 20 s, the influence downstream is very limited, in such a way that a modeling without obstacle would not affect too much the results in the far field. 6.2 Comparison with steady flow If we now compare the longitudinal water profile at a certain distance (0.75 m) of the canal axis, at a time (20 s) when the first transient effects vanish, it is remarkable to observe that the profile is very comparable to the steep-slope case of Figure 3b, although the flume bed is horizontal. But, in case of dam break, the flow is highly supercritical, which corresponds to the typical steep-slope behavior. For mild

Figure 25. Water profile at t= 20 s along the line

y= 0.75 m.

Figure 26. Supercritical (in dark gray) and subcritical-flow (in light gray) regions (t = 20 s).

or horizontal slopes the specific energy is decreasing along a supercritical water profile whereas this has to increase to reach the minimum energy required by the constriction. Only a passage to subcritical flow through a hydraulic jump may ensure this rise in energy. Obviously this region just in front of the building would be poorly modeled by a simplified representa tion without obstacle.

Figure 26 shows the regions where the flow is superor subcritical.The succession of regimes clearly appears: supercritical upstream, passing to subcritical flow through a hydraulic jump, then a control section near the constricted section and a second jump to return to normal regime.

7 CONCLUSION

The purpose of the paper was to study the influence of an obstacle on a dam-break wave, the obstacle being an idealized representation of a single building.

The measurement of water depths and velocity field were challenging, taking into account the lim ited thickness of water at many places and the large velocities in those regions. Digital imaging appeared as the best solution at least for surface velocity field.

The measurement confirmed that the flow pattern

Sph simulation of dam-break flow in shallow water approximation

M. Gallati & D. Sturla

Hydraulic and Environmental Engineering Dept, University of Pavia, Italy

ABSTRACT: This paper reports on the application of the Smoothed Particle Hydrodynamics technique to

model 1D and 2D dam-break flows under the shallow water approximation. Following an introduction of the

basic equations and a short description of the numerical technique, one dimensional simulations are presented

and compared to analytical solutions or to laboratory experiments taken from technical literature. Finally the

results of two dimensional dam-break flows are reported: several cases have been simulated comparing results

to the ones obtained by an eulerian code (PFP) and experimental evidence.

1 INTRODUCTION

Smoothed Particle Hydrodynamics (SPH) is a

meshless lagrangian method for modeling mass flow

that was introduced independently by Gingold &

Monaghan (1977) and Lucy (1977) in order to model

complicated phenomena in astrophysics. Since then

the method has been successfully applied to a vast

range of problems, including elastic-plastic flow, heat

transfer and incompressible flows, to name but a few.

At the Hydraulic and Environmental Engineering

Department of Pavia University in 2001 SPH began to

be applied to Hydraulics. Several studies and numeri
cal experiments have been performed (Gallati & Sturla
2000, 2001; Braschi & Gallati 2000, 2001, 2003),
showing the capability of the method to model rapidly
varied unsteady flows with free surfaces.
The aim of the present work is to report on the stud
ies and the experience gained regarding the application
of SPH to solve the shallow water approximation of
Navier-Stokes equations: the De Saint Venant equa
tions. SPH has already been applied to solve these
equations by Wang and Shen (1999) to simulate the
Stoker problem. Here more complex 1D and 2D cases
of dam-break simulation are reported.
Several adaptations have been introduced into the
original technique (developed to solve Euler equa
tions) in order to adapt SPH to the shallow water
context. Another computational skill deals with the
treatment of domain boundaries since the original
SPH was in an astrophysical context with unbounded
domains.
The main part of this paper is devoted to the descrip
tion of the code, named SW-SPH, developed by the
authors. Its performance is shown in 1D cases by comparison
to analytical solutions or to laboratory experiments taken
from technical literature. In the 2D dam-break simulations
results are compared to ones obtained by an eulerian code
or laboratory data expressly obtained for this purpose. 2

MATHEMATICAL MODEL The shallow water equations, also referred to as the De Saint Venant equations, describe two-dimensional unsteady, free-surface flows under the assumption of hydrostatic pressure distribution, small channel bottom slopes and uniform velocity distribution in the vertical direction. These assumptions are usually valid except when the water surface has sharp curvatures. In lagrangian form these equations are written as: where η=water depth; v= flow velocity vector; g= gravity acceleration; S 0 = channel bottom slope vector; S f = slope of energy grade line vector, computed using the steady state friction formula in which n=Manning's roughness coefficient. Equation (1) and (2) describe, respectively, the mass and momentum conservation principles. Once specified the boundary conditions their solution allows the

state variables η(r, t) and r(v, t) to be defined. It is well

known that such variables may be discontinuous along

moving boundaries (hydraulic jumps).

3 NUMERICAL MODEL

3.1 The basic idea of SPH

Standard finite element or finite difference techniques

in hydrodynamics follow an Eulerian approach: the

space is discretized with fixed grid of cells across

which the inflow and outflow together with the stored

mass are computed. A lagrangian approach, as SPH,

on the contrary, follows the evolution of selected fluid

elements over space and time. We describe in this sec

tion the fundamentals of this formalism as it provides

sound bases for the SW-SPH code.

The foundation of the SPH is an interpolation the

ory. The conservation laws of continuum fluid dynam

ics are transformed into integral equations through the use of an interpolating function that provides the “ker nel estimate” of the field variable at a point. The term “kernel” refers to a weighting function and defines how much surrounding field variable values contribute to the value of the field variable at the point r.

For a better understanding let’s start with the exact relation for any quantity (scalar or vector) A,

where is the space domain, δ is the delta Dirac function and dω is the space element.

If we replace δ-function by an interpolating ker nel W (r, h) we obtain an integral interpolation of the function A(r),

In (5) h is the so-called “smoothing length” that defines the width of the kernel.

The kernel, that mimics a δ-function, has the fol lowing two properties:

The integral interpolation A int can be thought as a smoothed version of the original function A. This is the origin of “Smoothed” in SPH.

If A(r ′) is known only at a discrete set of N points (particles) r 1 , r 2 ,…, r N , then we can approximate the

integral interpolant with a summation interpolant as, The final step is to express the differential space element dω as m j /ρ(r j) where m j is the mass associated with particle j and ρ(r j) is the density at point r j . The crucial point to note is that, if W is a differentiable function, we can calculate the derivatives of A by

differentiating (8). For example the gradient of the function A is, In SPH the continuum is discretized by particles each one has a defined mass and brings its information in terms of velocity, pressure, etc. distributed around the center according to the kernel function. These particles are free to move under their mutual interaction and the action of any external body forces. Then, since we have to follow these particles, we are interested in knowing the value of variable A at the particle position A i =A(r i). Eqs. (7) and (8) become: where Once the value at the particle position is computed, using (8) the properties of fluid can be found at any point of the domain. 3.2 The kernel function Theoretically, the choice of kernel is arbitrary, provided that it satisfies equations (6.1) and (6.2). In this paper the cubic spline (figure 1) has been employed, where s= r/h, ν is the number of dimensions and σ is the normalization constant with values 2/3,10/7π, or 1/π in one, two, or three dimensions respectively. The cubic spline kernel is adopted since it belongs to the family of compact support kernels: a potentially small number of neighboring particles are the only contributors in the sums over the particles (particles belonging to the circular region with radius 2h centered at the specific point, see figure 2). This is, of course, a great computational advantage. -1 1

-3 -2 -1 0 1 2 3 WW' x/h

Figure 1. Cubic spline (W) and its derivative (W ′) in 1D.
2h i

Figure 2. Particle i interacts with other particles only out to

a distance of 2h.

3.3 Smoothing length

The smoothing length represents the effective width of

the kernel, or the distance at which the particle in ques

tion interacts with other particles (figure 2). Changing

smoothing length in SPH corresponds to changing the

numerical resolution. If the fluid to be modeled does

not undergo substantial rarefaction (or compression)

constant h is sufficient. If particles become so distant, that they cease to interact (or so close, that a large number are within a smoothing length) h should be changed accordingly. The interpolation precision of SPH depends on having a sufficient number of par ticles within 2h and the speed of the computation depends on this number being relatively small. SPH works best when the number of neighbors is about 5 in one dimension and about 21 in two dimensions. These numbers all correspond to the number of neighbors on a cubic lattice with a smoothing length 1.2 times the particle spacing (using cubic spline).

There are many ways to dynamically change h so that the number of neighbors is kept approximately constant. In this study the simplest approach is used: each particle has its own smoothing length which varies in space and time according to particle density. Later, it will be shown that particle density is proportional to water depth, then the following expression is used to calculate smoothing length associated to particle i: where h 0 and η 0 are the reference (initial) smoothing length and the reference water depth respectively. Since each particle has its own smoothing length, each particle pair interaction, must have a smoothing length h ij associated with it. In order to conserve momentum exactly, symmetry of particle interaction is preserved defining: where 3.4 The SW-SPH model With the previous basic rules the shallow water equations in the lagrangian form are converted into equations for particles. The fluid is sampled by a set of particles. A particle i has a fixed volume V i (that correspond to the particle mass m i in the original SPH context), a position r i , a velocity v i and a water depth η i (that correspond to the densityp i in the original SPH context).The differential area element dω i is V i /η i . In the Lagrangian approach we move the particles with the velocity of the fluid, thus, where v i is updated using

(2). With (8.1) we can calculate the gradient of η and then we obtain the SPH approximation of the motion equation (2), in which ij is the so-called “artificial viscosity”. This term is introduced in the computation in order to avoid large unphysical oscillations (particle interpenetration) near to discontinuities (shocks). In this paper the standard artificial equation of Monaghan

and Gingold (1983) has been employed and adapted

to shallow water context.

where

and

Here c i denotes the shallow water wave speed

c i = (gη i) 0.5 ;α is an empirical constant commonly= 2,

ε= 0.01 is introduced to keep the viscosity bounded

for particles as they approach.

Finally, the SPH representation of the continuity

principle is obtained in integral form by means of (7.1)

applied to η:

Shallow water equations have been discretized in

space for each particle and for the time interval t

to get the flow characteristics (velocity, water depth,

etc. for each particle) at the advanced time step start

ing from an initial distribution. The time integration of

the SW-SPH equations is explicit thus the time step is

chosen to accommodate CFL condition which, keep

ing in mind that the natural SPH scale length is h, is:

The time integration strategy from time t N to time t N+1

is the following (excluding first time step):

- calculation of time step Δt N using h N i ,c N i ,v N i in (20);

- calculation of particles acceleration at time t N using

equation (15), separated in two parts: Boundary Domain field Image field V B,n V A,n V B,T V A,ta B A 2h 2h Figure 3. Image (B) of the particle A. Free slip condition: v B,n = - v A,n and v B,t = - v A,t . - velocity updating of each particle at time t N+1/2 in a semi-implicit way - position updating of each particle - water depth updating using (19) - smoothing length updating using new water depth in (11). In this paper only free slip boundary conditions are considered. They are assigned as follows: the field is extended out of its borders by adding a strip of thickness 2h where image particles. To each image particle the values of variables of the corresponding field particle are given except for the velocity component normal to the boundary, which is reversed in sign (figure 3). 4 DAM-BREAK SIMULATIONS In this paragraph the results of several test problems selected for the validation of SW-SPH code are shown. One dimensional and two-dimensional simulations of the catastrophic failure of a dam have been considered. Dam 1000 m 1000 m 0v 0m

Figure 5. Stoker’s problem.

4.1 One-dimensional simulations

The first simulations here reported deal with two sim

ple cases for which analytical solutions are available.

At the midpoint of a channel 2000 m long a dam sep

arates two basins with different heights of still water

(Figure 4).

At time t= 0 the dam is instantaneously removed,

then a negative wave moves upstream and a surge

rushes downstream. For the case of a 1 m wide hori

zontal rectangular channel, with negligible resistance,

an exact solution is given by Stoker (1957). This prob

lem, although idealized, is very interesting to test the

shock capturing ability of the method.

We consider the case with η 0m = 10 and η 0v = 1. In

the simulation here presented the initial water mass

upstream of the dam is discretized with 1000 particles

having a constant volume of 10 m 3 /m, placed on a reg

ular grid with a step of 2 m. Water mass downstream

instead is represented by 100 particles having the same

volume but placed on a coarser grid with a step of

20 m. The reference water depth, η 0 , to be used in (11)

is η 0m , the reference smoothing length, h 0 , has been set

1.5 times the upstream particle distance so that about 7

particles interact. Note that with this initialization eq.

(19) givesη i = η 0m upstream andη i = η 0v downstream.

The result, as shown in figure 5, is clearly in

agreement with the exact solution.

The same problem was run considering the initial

tailwater η 0v = 0 (dry bed test case). In this case the

analytical solution is given by Ritter. 0 2 4 6 8 10 12 0 500 1000 1500 2000 Distance (m) W a t e r d e p t h (m) Computed Analytical 50 s 30 10 Figure 6. Ritter's problem. Note than no special treatment of dry areas has been employed. The effect of the "source" term S 0 and S f have been tested simulating dam-break laboratory experiment. Two sets of experimental data, taken from Mignosa et al. (2001), have been used for comparison. The experimental set up is shown in figure 7. The rectangular flume is 1.0 m wide, 0.5 m high and 7.0 m long. The instantaneous dam failure is simulated by means of the sudden removal of the gate. The flow field is characterized by shock propagation, reverse flow and wetting and drying conditions. The experimental conditions of "test A" and "test B" (with and without tailwater depth) are summarized in table 1. In both the test cases the initial condition is set by placing upstream of the dam 225 particles on a regular grid with step of 1 cm. The volume of each particle is 25 cm 3 /cm and the reference smoothing length 1.5 times the grid step. In the simulation of test B (non-zero tailwater depth) 32 more particles are placed downstream of the gate on a regular grid with a step of 5.5 cm.

In figures 7.1 and 7.2 the experimental hydrographs

are compared to the numerical results. The sections

along the flume are set at x= 1.4 m and x= 4.5 m. The

water depth in those sections is recovered by eq. (7).

A good agreement between numerical results and

experimental evidence can be observed.

4.2 Two-dimensional simulations

The first test case of two-dimensional simulations is

the idealized partial dam breach reported in Fennema

et al. (1990). It deals with a partial failure of a dam in

a 200× 200 m basin of simplified geometry depicted

in figure 8. The non-symmetrical breach is 75 m wide

and the dam is 10 m thick. The bottom of the basin is

horizontal and friction losses are neglected (n= 0).

We report the case of initial reservoir depth

η 0m = 10 m and tailwater depth η 0v = 5 m. Wall boundary

Water surface profile computed at time t= 7.16 s. In the simulation the initial water mass upstream the dam is modeled with 750 particles with constant volume of 250 m 3 , placed on a regular grid with step of 5× 5 m. The downstream water mass is instead represented by 216 particles having the same volume but placed on a coarser grid with step 7.05× 7.05 m. The reference water depth, η 0 , to be used in (11) is η 0m , the reference smoothing length, h 0 , has been set 1.5 times the upstream particles initialization grid step. The flow conditions have been computed at time t= 7.16 s and results are shown in figure 9.1 (particle position) and in figure 9.2 (water surface profile). 0 50 100 150 200 X (m) 0 50 100 150 200

y

(m

) PFP SPH

Figure 10. SW-SPH result vs PFP results in terms of water

levels (ranging from 5 m to 9 m with step 0.5 m).

In figure 10 the results are compared to the ones

obtained by the shock-capturing eulerian code PFP

(Braschi & Gallati, 1990). The mesh size of the eulerian simulation is 5 m× 5 m.

After the preliminary tests of the code with simple 1D problems and 2D literature numerical results, a laboratory experiment was decided to get a better understanding of the capabilities of the model.

The scheme and the relevant geometrical data of the experimental setup is reported in figure 11. At the sudden gate opening the reservoir water spreads over the trasparent plane. The boundaries of the plane are plexiglass walls that reflected the flow forming cross shock waves. In order to visualize the characteristics of the flow field the water is colored with methylene blue ink and the plane is lighted from below. By this way it is possible to follow the position of the wave front.

The experiment was shot with a video camera able to record 25 frames per second, fixed 2 m above the plane. Using suitable software it is possible to select from the whole film the frames at given times after the gate opening. Although the evaluation of the water depth can be obtained from the color intensity only a qualitative comparison between experimental evidence and simulation is shown in the following.

Two sets of experiments are reported. For both the

initial water level in the reservoir is of 8 cm and the

plane is initially dry.

In the second experiment a rectangular obstacle

10 cm high is placed in front of the gate as depicted in

figure 12.

The simulation of the flow has been performed mod

eling the initial reservoir mass water by 333 particles

a regular grid with step of 2× 2 cm; η 0m is the initial
water depth in the reservoir, h 0 , has been set 1.5 times
the particles initialization grid step; the Manning
coefficient of n= 0.01 has been assumed. In figures 13 and
14 several computed and recorded flow fields are displayed
at selected times after the opening. In the first and
second column, observed and computed flow fields are
reported respectively. The computed results are represented
by the particle position in the plane. The particle's color
is proportional to water depth associated to it. In the
third column results of the numerical model are displayed
in terms of velocity field: in order to obtain these
pictures, particle velocities are interpolated on a regular
grid using (7). There is an acceptable agreement between
observation and simulation in both the experiments.
Qualitatively, the main depth distribution features are
retained and the shape and velocity of the two-dimensional
hydraulic jumps calculated are in good agreement with the
observed ones. 5 CONCLUSION This paper reports on the
application of the Smoothed Particle Hydrodynamics
technique to Hydraulics in

2D complex problems. It is suited especially to prob

lems with sharp moving fronts since the shock waves

can easily be captured and accurately simulated. The

method is also able to simulate the propagation of flow over dry areas: no special treatment of dry regions is necessary since field values are computed only where the fluid is. More complex situations dealing with inflow and outflow boundary conditions and real world dambreak simulations will be the subject of future studies.

Simulation of flooding caused by an embankment breaking by means of a 2D finite volume numerical model

F. Aureli, A. Maranzoni & P. Mignosa

Dipartimento di Ingegneria Civile, dell'Ambiente, del Territorio & Architettura, Parma, Italy

ABSTRACT: The results of a mathematical simulation of flooding due to the breaking of a railway embankment crossing a river valley are presented. During recent floods, the considered embankment was slightly damaged by piping phenomena. Since two kilometres downstream is located a high risk industrial area the potential flood related with a breaking of the structure would represent an extremely dangerous occurrence. A numerical model was built in order to simulate some catastrophic flooding scenarios. The numerical scheme is based on a finite volume discretization of the 2D shallow water equations. The model was validated performing a simulation of the

October 2000 flood event, with good agreement between computed and observed water depths.Then the flooding

derived by the failure of the embankment was simulated. The results obtained, together with those derived by

the simulation of other possible scenarios, were then utilized in order to design the protection structures for the

industrial area.

1 INTRODUCTION

The flood event occurred in October 2000 in north

ern Italy was a severe test for the embankment system

of several rivers, somewhere causing the formation

of breaks. Whereas the occurring of catastrophic col

lapses can be very dangerous for the environment

and human lives, the identification of the risk derived

by flooding must be evaluated a-priori in order to

organize civil protection plans. At this aim historical

information is essential, but sometimes not enough to

understand all the potential hazards, as for dam-breaks

or levee-breaks never occurred before. In these cases

the risk evaluation can be performed only with the help

of numerical simulations or, more rarely, by means of

physical scale models. In order to give reliable results,

the mathematical models must be capable to describe

the main characteristics of the flooding scenarios such

as inundated areas, water depths, velocities, arrival

times of the wetting fronts and permanence of the water

on the ground.

In this paper the results of mathematical simula

tion of flooding due to the hypothetical break of a

railway embankment crossing the river valley of an

important tributary of the Po river (northern Italy) are

presented. During two severe floods occurred in the

recent past (1993 and especially 2000) the backwater

effect due to the valley constriction gave rise to the

storage of a considerable water volume just upstream

the embankment. This in turn caused high stresses on the structure, which was not designed at this aim, and the beginning of piping phenomena. Since just downstream the railway is located a high risk industrial area, the potential additional flood related with the breaking of the embankment would create an extremely dangerous situation. Due to the impossibility to move in the near future the industrial plants, some catastrophic flooding scenarios were then simulated with a mathematical model in order to obtain design criteria for the protection plans. The mathematical modelling of the flooding scenarios was accomplished by means of a two-dimensional finite volume numerical code, realised by the authors themselves, whose description and main features are explained in another paper presented at this Conference (Aureli et al. 2004a). Thanks to the information acquired during the recent historical event of October 2000, it was also possible to attempt a calibration of the model parameters and to compare to some extent simulated and historical water levels and flooded areas. 2 DESCRIPTION OF THE STUDY AREA In order to reproduce the complex flow field in the area of interest it was necessary to describe the main morphological characteristics of the river, of the flood plains and of the structures crossing the river valley such as motorways, railways, waterways and irrigation

channels (Fig. 1). It was also essential to obtain a

correct representation of the water volume temporar

ily stored upstream the railway embankment during

the floods. At this aim the considered domain was

extended far upstream the motorway that determines

the upper limit of the backwater effects induced by the

railway embankment.

In the meantime the displacement of the upstream

boundary from the area of main interest reduces

the influence of the approximate representation of

Figure 1. Bathymetry of the domain of interest. the inflow boundary condition. For the same reason the outflow boundary was assumed beyond the waterway that constricts the river valley downstream the industrial site. On the lateral sides the inundation is naturally bounded by the morphological step of the river valley, so that also the considered domain was prolonged up to there. Even if the area under investigation is considerably more extended in the longitudinal rather then in the transversal direction, a one-dimensional shallow water model would not be able to represent the complex behaviour of the flow field in this area. The three consecutive constrictions (from upstream to downstream: the motorway, the railway and the waterway), together with the irrigation channel and its intake structures, influence indeed in a determinant way the flow paths during the floods. Transitions from subcritical to supercritical flows are expected through the constrictions, together with the formation of hydraulic jumps downstream. The hypotesised break of the railway would further complicate the situation, inducing the formation of a steep wave (shock) moving downstream towards the industrial area. For all these reasons it was considered necessary to perform the simulations by means of a model based on the 2D shallow water equations written in conservation form and solved with a shock-capturing numerical scheme. The bathymetry of the river and of the floodable region was then described by means of a DEM with a square regular mesh of size 10 m, obtained by an interpolation procedure on the available cartographic maps and river cross sections. The dimension of the grid was chosen as a compromise between the estimated computational time and the satisfactory modeling of the region under study. The main constraints were due to the description of the structures such as river crossings, irrigation channels, bridges and so on. A more flexible mesh, such as a structured non-orthogonal

Cartesian or a non-structured one, would be helpful for a refined description of the main structures crossing the valley, reducing in the meantime the overall number on grid nodes. Nevertheless, the necessity to track the moving fronts and shocks would require a refined mesh almost everywhere. The embankment system of the river and the most important structures located in the domain were described as vertical and insuperable boundaries; a check was carried out at the end of the calculations in order to verify that all the embankments were really never overtopped by the waters during the flood. Since the main object of the simulations was to obtain water depths and velocities on the perimeter of the industrial site for design purposes, the area inside was considered as completely unfloodable. At this aim the interior nodes were excluded from the calculations (blanked in Fig. 1).

3 NUMERICAL MODEL

The adopted numerical code is based on a finite

volumes discretization of the 2D shallow water equa

tions written in integral form:

where A represents the area of the integration cell,

C the cell boundary, n is the outward unit vector

normal to C, while H= (F, G) represents the tensor

of fluxes. The corresponding conservation differential

form of (1) is:

The solution of the homogeneous part of (1) is based

on the Weighted Average Flux (WAF) scheme, where

second order of accuracy both in time and space is

achieved by solving the conventional piece-wise con

stant Riemann problem and averaging it over space

and time (Toro 1992). To avoid spurious oscillations

in the vicinity of high gradients of the solution a TVD

constraint was enforced on the scheme by means of

different well-known limiter functions (Toro 1997).

The solution of the Riemann problem was based on the approximate HLLC solver (Toro 2001), that is a modification of the basic HLL scheme to account for the influence of intermediate waves. A more detailed description of the numerical scheme and of the treatment of the source terms can be found in a related paper presented at this Conference (Aureli et al. 2004a).

4 CALIBRATION OF THE MODEL

The value of the roughness coefficients must account for the energy losses due to distributed and local resistance caused, for example, by the interaction of the flow with obstacles of lower dimensions with respect to the elements of the computational mesh. Also the energy dissipation due to the modification of the riverbed, to trees uprooting and to sediment transport have to be implicitly combined in this coefficients.

Only two homogeneous regions, the riverbed and the floodplains, were identified in the domain, each characterised by a different behaviour with respect to flow resistance phenomena. The two Manning n roughness coefficients were firstly assumed on the basis of literature suggestions and then refined by trials searching for the values that allowed to reproduce at best with the model the maximum water levels observed during the October 2000 flood event. At the inflow boundary a 3000 m 3 /s constant discharge, corresponding to the estimated peak discharge of the October 2000 flood event, was considered. The discharge was assumed entering the domain orthogonally the inflow section and was distributed amongst the nodes unevenly, with a higher specific discharge on the riverbed. Downstream the waterway (Fig. 1), at the outflow section of

the considered domain, a far-field (nonreflective) condition was introduced, whereas at solid boundaries a free-slip condition was imposed. The simulations were extended in time until the maximum differences between the values of the three conserved variables at two consecutive time steps were less than specified tolerances. Then steady-state conditions were considered reached. From the described procedure a value of Manning n= 0.050 s·m −1/3 for the floodplains was identified, while to the river channels was assigned n= 0.033 s·m −1/3 . Figure 2 shows the comparison between computed and observed maximum water depths at some significant points in the neighbourhood of the railway embankment. The good agreement between observed and computed water depths confirms the suitability of the Figure 2. 5 FLOOD FREQUENCY ANALYSIS AND

SYNTHETIC DESIGN HYDROGRAPHS

DERIVATION

A gauged river section is located close upstream

the area of interest, recording water levels almost

continuously from 1925 and with an up-to-date stage

discharge relationship. A reliable flood frequency

analysis can then be performed. From the records a

76 years long annual maximum peak flow (Q 0) series

was extracted.

Log-normal, Gumbel (EV1) and General Extreme

Value (GEV) probability distributions were consid

ered in order to describe Q 0 (T). Parameters estimation

was based on the Method of Moments for the first

two distributions, whereas for the third the method

based on L-moments was adopted. Figure 3 shows, on

Gumbel probability chart, the data sample (Gringorten

plotting position) together with the fitted probabil

ity distributions. The Hosking test (Hosking et al.

1985) on the k = 0 hypothesis with a significance level

α= 5%, k being the exponent of the GEV distribution,

demonstrates that the choice of the GEV distribution

is justified.

From the GEV distribution a peak discharge of

3043 m 3 /s for T = 200 years was derived. This value

is close to the estimated peak discharge of the October

2000 flood event, which is also the maximum value of

the overall historical series. 0 500 1000 1500 2000 2500

Figure 3. Q 0 data sample together with the fitted probability

distributions. In order to evaluate if a steady state solution would be a reasonable choice as initial condition before the hypothesized railway break occurs, Synthetic Design Hydrographs (SDH) were derived. The methodology (Maione et al. 2000a, b; Aureli et al. 2004b) is based on the statistical analysis of recorded flood waves through the construction of the Flow Duration Frequency (FDF) reduction curves of given return period and the determination of the temporal location of the peak value for each duration. The procedure was applied to a 62 years long historical sub-series, since the older strips have been lost. From the recorded flood waves, the annual maximum average discharges for each duration ranging from 0 to 96 hours were extracted and then processed. The resulting SDHs, for return periods ranging from 5 to 200 years, are shown in Figure 4. From the figure it can be observed that the rising limbs of the SDHs are quite gradual, taking about 22 hours from the starting value to the peak discharge. The transient induced by the embankment breaking is surely faster than the potential hydrological stress. For this reason it is justified to assume as initial condition the steady state solution obtained by the model with as inflow discharge the peak value of the 200 years SDH. This in turn substantially coincides with the condition assumed for the calibration of the model. Figure 5 shows the steady state water surface elevations, together with the velocity field (vector map) obtained by the calculations. Figure 6 shows a detail of the Froude values across the railway. The effect induced by the railway constriction is quite evident from the figures: upstream water levels rise up to about one meter below the top of the embankment, whereas downstream a short distance of supercritical flow occurs, abruptly blocked by an impressive -24 -12 0 12 24 36 48 60 72 t (hours) 0 500 1000 1500 2000 2500 3000 3500 Q (m 3 / s) T = 50 T = 20 T = 10 T = 100 T = 200 T = 5 Figure 4. ity field (vector map) before the hypothesized embankment

breaking.

hydraulic jump. An analogous, though less marked,

effect is caused by the downstream waterway constric

tion. Close to the industrial area the steady-state results

reproduce substantially well what happened during the
Figure 6. Froude values across the constriction at steady state (detail 1). October 2000 flood event, when the site was slightly flooded, with water depths of about 0.3÷ 0.8 meters. 6 FLOODING SCENARIO DUE TO THE RAILWAY EMBANKMENT BREAKING The results obtained from the steady-state simulation were then used as hot-start initial condition for the railway breaking scenario. The collapse was assumed to involve a considerable portion of the left side of the embankment, where the most alarming symptoms of piping occurred during the recent historical floods. Together with the railway embankment also the intake structures of the irrigation channel and a portion of the channel itself were assumed to suddenly collapse. A reasonable bathymetry was reconstructed where the structures were originally located. Figures 7 to 10 show details of the computed water surface elevations and flooded areas at different times after the breaking. Due to the considerable water volume stored upstream the railway embankment (about 8.5 · 10 6 m 3), the sudden collapse of the structure induces the formation of a flood wave that in few minutes reaches the industrial area. Then the flow divides into two branches (Fig. 9): one collides with the top side of the area and then proceeds towards the riverbed; the other follows the right side of the industrial plants and then connects to the flooding due to the

backwater effects of the waterways crossing constric

tion. After one hour (Fig. 10) the flow became again

almost steady everywhere. This is also confirmed by

the computed discharge flowing through the original

railway line, shown in Figure 11.

From the figure it can be easily derived that only

a volume of about 2.6 · 10 6 m 3 (out of 8.5 · 10 6 m 3)

was actually released from the storage upstream the

railway, the remaining part being necessary for the

maintenance of the base flow discharge.

Figures 12 and 13 show details of the envelopes of

computed water depths and velocity norm. Figure 13. Envelope of computed velocity norm (detail 2). The maximum of the water depths is reached at the top side of the area, with values of more than two meters. The maximum velocity is attained at the side adjacent to the riverbed with values of about 3 m/s. Considerable velocities of more than 1 m/s are also reached in correspondence of the right side of the industrial area. 7 CONCLUSIONS A mathematical simulation of flooding due to the hypothetical failure of a railway embankment crossing the river valley of an important tributary of the Po river (northern Italy) was presented. Thanks to the information acquired during the

recent historical event of October 2000, it was possible to attempt a calibration of the model parameters and to some extent to compare simulated and observed water levels and flooded areas. Also the historical hydrological information was rich enough to perform a reliable flood frequency analysis and a Synthetic Design Hydrograph derivation. The results of the mathematical model, together with those obtained by the simulation of other catastrophic scenarios, were then utilized to design the protection structures for the industrial plant. In the meantime the railway embankment will be strengthened and a deep diaphragm wall will be realized in order to avoid piping and then reduce failure risks.

Dike-break induced flow: validation of numerical simulations and case study

M. Harms, S. Briechle & J. Köngeter

Institute of Hydraulic Engineering and Water Resources Management, Aachen University, Germany

D. Schwanenberg

WL/delft hydraulics, Delft, The Netherlands

ABSTRACT: A TVD Runge Kutta Discontinuous Galerkin finite element method for two-dimensional depth

averaged shallow water equations is used to simulate dike-break induced flows. This paper presents comparisons

of experimental data obtained by a physical model to results of the numerical simulation. Furthermore, the

numerical method is applied to computations of flood wave propagation initiated by dike-breaks at the River

Rhine. The aim of this case study is to evaluate effects of flood protection improvements, which are intended by

a partitioning of the area at risk into compartments.

1 INTRODUCTION

Recurring events of extreme rainfall resulting in river hazards have shown the disastrous damages that can be caused by floods. Not only the occurrences of 99 dike-breaks at the River Elbe during the flood in August 2002 indicated that flood protection is vulnerable. A Risk Assessment procedure, subdivided into the three stages Risk Analysis, Risk Assessment and Risk Management, was developed for German dams at the Institute of Hydraulic Engineering and Water Resources Management (IWW), Aachen University, by Rettemeier et al. (2000). The basic principle of the approach can be transferred to rivers and dikes.

To assess the risk provoked by floods and potential dike-breaks within the scope of Risk Analysis the potential damage on people and property has to be determined. Thus, objectives that need to be investigated are the identification of inundated areas as well as flow depth and flow velocities of the initiated wave.

Dike-break induced flood waves are characterized by unsteady, rapidly varying flows over non-trivial bathymetry and by propagation on a dry bed. In contrary to dam-break flows there is a constant discharge in the river and the river will not empty like a reservoir.

A physical model, which takes into account the dis

charge in the river, the sudden break of the dike as well

as wave propagation into an area, has been developed

and build at the IWW. Thus, computations can be vali

dated with the measured data of the two-dimensional

wave propagation. Similar tests concerning the pro

pagation of the wave into an area were proceeded

by Kulisch (2003), Fraccarollo & Toro (1995) and Jovanovic & Djordjevic (1995). All of these authors consider dam-breaks, but not dike-breaks. Aureli & Mignosa (2002) present the single investigation also taking into account the river discharge. They perform computations of the induced wave, while taking measurements in the channel. A Runge Kutta Discontinuous Galerkin (RKDG) finite element method has been developed and validated for dam-break flow (Schwanenberg & Harms, 2002). Possessing the ability to simulate unsteady, transcritical flow and wave propagation on a dry bed, it will be applied to dike-break flow. As the numerical method has already been presented in detail the following paragraph will merely give a brief outline. 2 RKDG METHOD FOR SHALLOW WATER FLOW 2.1 Governing equations The mathematical description of a depth-averaged incompressible fluid is given by the shallow water equations in the form where

in which h=water depth; p, q= unit discharge in x

and y-directions; u, v= horizontal flow velocities in

x and y-directions; β ij = correction factor for non

linear momentum flux; g= 9.81 m/s 2 = acceleration

due to gravity; ρ= fluid density; and z b = channel

bed elevation. Bed roughness is approximated by the

empirical Manning formula with Manning’s roughness

coefficient n.

Mild bed slope, constant density and hydrostatic

pressure distribution is assumed deriving these equations from the three-dimensional Navier-Stokes-Equations. As these assumptions limit the applicability of the equations their effects should be considered.

2.2 Numerical method

The presented numerical scheme is based on the RKDG method for hyperbolic equation systems. Detailed introductions to these methods can be found in Cockburn (1999) and Cockburn et al. (2000). Schwanenberg & Köngeter (2000) presented the first implementation of the RKDG method for the shallow water equations and its application to practical problems. The method is divided into three main steps:

- The partial differential equations are decoupled by DG space discretization with a polynomial degree k into a set of ordinary differential equations.
- The ordinary differential equations are integrated in time by a k + 1 order TVD Runge Kutta method.
- A slope limiter is applied on every intermediate time step of the Runge Kutta method introducing a selective amount of dissipation in order to obtain stability at shocks.

Due to its explicit TVD Runge Kutta time integration, the method can be efficiently applied to transient

and transcritical flows. The method was shown to have

sharp representation of shocks. The implementation

of source terms and boundary conditions is straight

forward. For a in depth presentation see Schwanenberg

(2002, 2003, 2004). 3 VALIDATION 3.1 Physical model To validate the applicability of the method to dikebreak flows the flow in a physical model (Fig. 1) is simulated. The model in the Institute’s laboratory consists of a 1 m wide channel with a pneumatically driven gate at one bank and an adjacent propagation area (3.5 m× 4.0 m). The water can fall off freely at the three boundaries of this glass area. Discharge in the channel can be varied from 0 to 390 l/s, while the water level ranges between 30 and 50 cm. The flap gate opens in a minimized time span of less than 0.1 s by rotating upwards. It is intended interfere as little as possible with the flow. Measurements are performed on the propagation area. The water depth is determined by ultrasonic sensors with a measuring frequency of 50 Hz in a dense raster. Furthermore a CCD-camera takes 50 pictures per second from top view, thus the propagation of the wave front is recorded. A detailed description of measuring techniques and the flap gate is given by Briechle & Köngeter (2004). 3.2 Numerical simulations Firstly comparisons of measurements and computations concerning the flow depths on the propagation area are considered. Calculations and measurements are performed on dry bed as well as for a small amount of water on the propagation area. Furthermore, different initial conditions are considered. Secondly the propagation and shape of the computed wave front is compared to evaluations obtained by the CCD-Camera. Figure 2 shows computed and measured water depths over time for three points at different distance, 1300, 2300 and 3300 mm to the channel on the axis perpendicular to the channel. Figure 1. Physical model.

Figure 2. Water depth as function of time for three different initial water depths at three gauges at different distances from

the flap gate on the axis perpendicular to the channel. Discharge in channel Q= 300 l/s.

A constant discharge of Q= 300 l/s is applied.

Results are shown for three different initial flow

depths, computed on dry ground with a Manning value of n= 0.0083 s/m 1/3 .

Computations were performed on an unstructured grid with element sizes of less than 5 cm. The CFL number was set to 0.3.

Flow conditions in the channel in the different ini tial states are characterized by initial flow depth and discharge and can be expressed by Froude numbers.

For an initial water depth of 30 cm arrival times of the wave differ slightly from the measured values at each gauge, while computed water depths are to low after the wave front passes the gauge. Combining a discharge of 300 l/s with a water depth in the chan nel of 30 cm, Froude number before the opening of the flap gate is nearly Fr= 0.6. In case of this very shallow flow with high velocities in the channel, the influence of the flow in the channel on the propagation is overestimated. Propagation is not reproduced well on the axis perpendicular to the channel, as the main flow direction is diverted strongly into the direction of the flow in the channel in the simulations.

Better results can be achieved for an initial depth of h= 40 cm (Fr= 0.38) and h= 50 cm (Fr= 0.27) respectively.Arrival times and flow depth of the propa gating wave are displayed very well. It can be observed

that the wave front at the gauges in 2300 and 3300 mm distance is represented to steep, while measurements indicate a slower rising of the water.

Results in 1300 mm distance from the flap gate are very good for all initial flow depths as regards the maximum flow depth. However, arrival times of the wave front are predicted to early. Possibly, close to the breach vertical components of the flow slow down the velocity in main flow direction, as indicated by the water surface curvature. The vertical momentum increases with initial water depth, therefore the underestimation of the arrival time increases with flow depth as vertical components are neglected in the computation. Thus, differences can be attributed to the assumption of the shallow water approach.

Additionally, in spite of the rapid opening mechanism it can be presumed that a deceleration of the flow is caused by the flap gate in comparison to the simulations, as the gate is not taken into account. This effect might also be enforced for higher initial flow depths, as a larger part of the water body is in contact to the gate.

Some experiments were undertaken without drying the propagation area before the measurement. It is found that the wave is affected by the water film

on the area. Measurements showed that propagation

was decelerated by the water on the area and the front

of the wave is significantly altered. This effect can be

reproduced in the computations by assuming 1 mm of

water on the area. Figure 3. Water depth as function of time for initial water depth of h= 40 cm and discharge of Q= 120 l/s measured on a wet propagation area. Figure 3 indicates that the peak at the wave front can only be displayed, if the thin layer of water on the area is taken into account. Observations during the measurements confirm that the front of the wave is strongly influenced by air entrainment. This explains that the computed water depth does not reach the maximum height of the measurement, as constant density is assumed in the computation. Flow velocities have not jet been determined in the physical model. Computed maximum flow velocities are detected at a distance of 1 m from the flap gate. For an initial water depth of 30 cm the resulting velocity is v max = 2.75 m/s, for 40 cm v max = 3.11 m/s and for 50 cm v max = 3.5 m/s. Secondly the shape of the wave is considered in plan view to compare it to measurements by the CCDCamera.The derivation of the wave front from the symmetrical propagation is affected by flow conditions in the channel. Figure 4 shows a comparison of the wave front computed to results obtained by the CCDCamera for different time steps and a discharge in the channel of 120 l/s (Fr= 0.15) and 300 l/s (Fr= 0.27). The figures indicate that the shape of the wave is reproduced quite well. Propagation on the main axis shows good agreement to the measurement. However, the derivation of the flow in the direction of the discharge in the channel is overestimated by the computation for both discharges as mentioned above. Again a reason could be the vertical momentum, which leads the wave to propagate perpendicular to the channel. Derivation of the wave front increases with discharge in the channel and decreases with an increasing flow depth. Thus is can be found that derivation increases with an increasing Froude number in the channel. The second picture in Figure 4, representing results for higher Froude number in initial state, shows a stronger derivation from the main axis for both computations and measurements. Differences between measurement and computations also increase with an increasing Froude number, as was observed already

Figure 4. Wave front computed and recorded for Q= 120 l/s

and h= 40 cm (Fr= 0.15) and Q= 300 l/s and h= 50 cm (Fr= 0.27).

concerning a discharge of Q= 300 l/s and h= 30 cm resulting in a Froude number Fr= 0.58. Lateral Propagation to the side opposed to the channel's flow direction is not represented very well. The flow in the model is constricted and a steep water surface curvature induces a non-hydrostatic pressure distribution. This effect can not be displayed by computations based on the shallow water approach. Some points of the measurement near the gate indicate a border line between main outflow and water with very strong surface curvatures.

Furthermore, the computed shape of the wave is chubbier and more onion shaped while the recorded one has a clearer apex in the front. Computational results of Aureli & Mignosa (2002) are comparable with the ones presented here. An explanation might be again the neglection of the vertical momentum in the shallow water equations. We conclude that the shown results indicate a satisfying agreement with the measurement. Arrival time and height of the wave are displayed very well. As the physical model is focussed on the initial phase of dike-breaks, the neglection of vertical momentum is noticed. Conditions in the channel with a flow of high Froude numbers (Fr> 0.5) are not computed well. But it can be presumed that in natural rivers Froude numbers are smaller even during floods. For example Froude numbers in the river Rhine are less than Fr= 0.4 during a 500 years flood. 4 APPLICATION 4.1 Flood protection improvement Due to mining activities the left polder area of the Rhine north of Cologne suffers from heavy surface settlements.With a height of up to 15 m the dikes in this region are among the highest in Europe. Though the construction of the dikes is of high standard resulting in a low possibility of failure, the risk

provoked by a dikebreak is high as the potentially flooded area is large. To improve flood protection and reduce the risk, a partitioning of the polder area of 400 km 2 into compartments is considered. Thus, it is intended to diminish the risk by decreasing the probability of flooding of the whole region. Furthermore, evacuation times can be extended for areas, which are not directly affected by a dike-break. In this case the risk provoked by a dike-break is lowered because of a reduction of the potential damage. It is intended to use mainly existing structures like street and railway dam rather than to build a second defense line with the height of the dikes at the river. This case study is a first consideration of the partitioning.The aim is to identify structures, which can be used as borders of the compartments with small effort for construction and at the same time allocate a sufficient volume to detain the water for a certain time. According to information of the German Civil Protection the gained time spans should be more than six hours, to provide sufficient time to evacuate people. Figure 5 shows a part of the partitioned polder area. The whole area under investigation is separated into 19 compartments utilizing primarily highway and railroad embankments as well as natural given steps in the territory. 4.2 Assessment of the effects To evaluate effects of the partitioning of the polder area into compartments on flood protection and the

risk provoked by dike-breaks, different scenarios were

computed for actual and design state. Thus enhance

ment of premonition time spans and reduction of

inundated areas can be determined.

Figure 5. Detail of the polder area partitioned into com

partments. Labels on the lines indicate the required heights.

Compartments are numbered from 1 to 19.

the difference of the inundated areas is 8 km 2 . But, it

has to be taken into account that due to the reduction

of inundation areas in total inside of the compart

ments the water levels might be higher. Compared to

the avoidance of flooding in compartment 5, 14 and 15, this increase of water level can be considered as insignificant.

Analysing the temporal development, it becomes clear that premonition time span for the area inside of compartment 14 is increased from 30 to 50 hours. For the northern area enhancement is even more than 25 hours, while compartment 5 will not be affected by the flood due to partitioning the region.

Another effect is observed considering the arrival time of the flood. In present state the water is spread into the area of three compartments within six hours, while in design state this will take one and a half days.

Considering the maximum water levels that occur during the eight days of propagation, a difference of 23 km 2 concerning inundated areas is determined. Fig ure 7 indicates that the northern part of the area under

Figure 7. Inundation maps of maximum values during eight days of flooding. Present state on the left, design state on

the right. investigation is not affected as a result of partitioning into compartments. Summarizing the investigation yields that the calculation of the scenario proofs the achievement of the required aims. For compartments directly affected by the dike-break induced flood wave or located close to the breach premonition time enhancement is determined to be two to three hours. But for further propagation of the flood wave premonition times are enlarged significantly. Results of a different scenario demonstrate that in that case the water could be kept in the first compartment causing a strong decrease of discharge through the breach and a reduction of inundated

areas of 85%. Thus, based on the performed computations the effect of the partitioning can be assessed as positive. However, it has to be considered that results display conditions of specific scenarios. Computations of dike-breaks at different locations along the river Rhine showed that the outgoing discharge through the breach varies highly in dependence on the territory

directly behind the dike, to flow conditions and to

characteristics of the river.

Furthermore the detailed investigation of damage

potentials caused in present state and in case of

partitioning allow for well-founded recommendations.

5 CONCLUSIONS

A TVD RKDG finite element method for 2D depth

averaged shallow water equations has been applied to

dike-break flows.

Comparisons of numerical simulations to experi

mental investigations concerning dike-break induced

flood wave propagations in a physical model are pre

sented. The aim of the study was the validation of

the numerical method. Computed results show good

agreement to the measured data in term of water level

time series as well as the shape and propagation of the

wave front recorded by a CCD camera. Thus, it could

be proved that the model is capable to reproduce the

main characteristics of dike-break induced flow. Still

computations are limited due to the assumptions of

the shallow water approach, especially concerning the

hydro-static pressure distribution.

These limitations can be overcome using 3D mod

els. But, especially the presented application of the

2D model to dike-break flow at the River Rhine

demonstrate that real-world dike-break flows have to

be performed for large scales, to which 3D mod

els are not applicable. Actually, in natural dike-break

induced flow propagation in horizontal directions

is obviously large compared to 3D effects in the

flow. Thus, for investigations concerning the far field

effects of dike-breaks the shallow water approach is

justifiable.

Performing the case study the model is used to

evaluate the increase of premonition time spans and

the reduction of flooded areas, which is intended by

partitioning the area at risk into compartments. It is

confirmed that an improvement of flood protection is

achieved. At the same time the model is demonstrated

to be a useful tool to deliver input data that is needed

within the scope of risk analysis for dikes.

Surge wave front in a moving reference system

A. Bornschein

Institute of Hydraulic Engineering and Applied
Hydromechanics, Dresden University of Technology, Germany

ABSTRACT: A surge wave is a very unsteady flow. For better observation and measurement an experimental

set-up with a standing surge wave front in a moving reference system was developed. Experimental facilities

and instrumentation are presented. Preliminary tests were conducted in order to confirm that the test results are

similar to measurements of traditional channels.

1 INTRODUCTION

In its simplest form the dam break wave problem was

solved 110 years ago by Ritter (1892) considering a

smooth channel bed without roughness. As Hager &

Lauber (1996) wrote the results of experimental inves

tigations in test channels confirmed this theoretical

solution in the main. One exception is the propagation

of a surge wave front downstream of a broken dam

which is strongly influenced by bed roughness.

Dressler (1952) and Witham (1955) tried to deter

mine the influence of the bed roughness and found

the following equation to determine wave front veloc

ity u F :

where h 0 = depth of water at the dam site before

failure, g= acceleration due to gravity, C=Chezy

roughness parameter and a= coefficient of decreasing

of velocity. This equation means that the roughness reduces the propagation of the flood wave, while the start velocity is Ritter's velocity. But obviously this solution by Dressler does not reflect the actual influence of the bed roughness exactly.

Lauber (1997) conducted dam break wave investi gations in horizontal and sloping channel with smooth bed using advanced measurement techniques. The measured wave front velocities were compared with calculated values based on Dressler's equation. Lauber had to consider unrealistic low values of Chezy rough ness parameter to get satisfactory results.

It seems there is no feasible solution of wave front propagation available. The propagation of the wave front after a certain time due to dam failure is influenced by the bed roughness, bed slope and water surface slope in the front region. Furthermore the knowledge in the field of surge waves is necessary to predict e.g. the inundation area and destruction potential of a flood wave resulting from dam rupture, to determine the effectiveness of surges which occur when flushing sewers and to design irrigation systems with grooves. To find out some rules for the propagation of an assumed triangular shaped wave front on a dry bed Martin & Bollrich (1989) treat the wave front in a moving reference system and found out following equation: where h F = height of the wave front at the boundary between turbulent wave-tip and the following flow being approximately as one-dimensional flow, b= shape parameter of the wave-tip, I= bed slope and n=Manning's roughness parameter. The formula has still to be verified by experimental results. Other theories consider a stepped wave front (Schoklitsch 1950) or a sine curved wave front (Wackernagel 1962). Experimental investigations of dam break waves often dealt with the dam failure as well as the flood wave propagating downstream of the dam (see Fig. 1). The front created by the flood wave was very small and it

was difficult to get detailed measurement results. There is no knowledge available about the velocity distribution in a wave front and about the shear stress caused by a turbulent wave front. An experimental set-up for investigations at the wave front has to create the turbulent front on its own.

2 EXPERIMENTAL FACILITY

The basic idea of an experimental set-up described by Bornschein (1999) is analogous to theoretical deriva tion by Martin & Bollrich (1989) to transform the unsteady flow of a surge into be steady from the observers point of view. The experimental set-up with a conveyer belt as the bed depicts the moving reference system.

Up to now experimental facilities with moving-bed were used especially to investigate air flow, debris flow, open channel flow and large eddy flow as for instance described by Tamburrino & Gulliver 1992.

The model tests on surge wave front are performed in the Hubert-Engels-Laboratory of the Institute of Hydraulic Engineering and Applied Hydromechanics, Dresden University of Technology, Germany (Fig. 3).

The testing flume has glass sides and is 0.4 m high, 0.3 m wide and 10 m long. It is possible to tilt the flume. The bed slope can be varied from 0 to 0.04.

A frequency-controlled motor drives the moving bed, the conveyer belt. The bed being used currently has a smooth surface. A velocity of the conveyer belt

up to 5 m/s can be realized.

Figure 1. Experimental investigations by Estrade (1967) –

dam break wave together with the reservoir outflow.

Figure 2. Technical drawing of the experimental set-up. It is possible to generate waves with different wave heights and different wave velocities. Ultrasonic sensors measure the wave shape. Three sensors were mounted on a mobile monitoring car, which can drive on aluminium tracks on the top of the glass flume along the channel. The position of the car was recorded together with ultrasonic signals. In this way a continuous touchless measurement of water surface was possible. Because of the steep slope of the water surface at the wave front there were hard requirements to ultrasonic sensors to get satisfactory results of wave shape. The flow velocity field of the wave front is measured with a 2D Laser DopplerAnemometer System (Fig. 4). As a light source a 5 W Argon Ion Laser (Innova 70) manufactured by Coherent is used. The light is separated into 2 times 2 colours in the TSI Color Burst. The 4 beams are focused into optical fibres bringing them to a probe containing transmitting/receiving optics. The optical probes are mounted on a 3 dimensional traversing system to reach all measurement points in the flow computer controlled. The emitted light signal is detected and transformed to electrical signals in the TSI Color Link. These raw Figure 3. Laboratory channel with the conveyer belt mechanism. conveyer belt water surface

signals are filtered and processed with the TSI Digital

Burst Correlator IFA 650. The final processing of the

data is done with theTSI Software FIND for Windows.

Hence it was possible to measure the horizontal flow

velocity along the channel as well as the vertical flow

velocity.

3 TEST CONDITIONS

The wave front tests were conducted as follow: a cer tain amount of water was filled into the test flume and the conveyer belt was started. Then the velocity of the belt was adjusted in order to get a steady turbulent wave front near one end of the moving bed. The wave shape (water depth as a function of horizontal coordinate x) and the velocity were measured.

In the context of velocity measurement the vertical distance of measurement volume from bed and from water surface was limited by the distance of the two vertical laser beams. In the optical probe the parallel exit beams from the fibres are focused by a lens into the measurement volume where the beams intersect. In the lens the distance between the two beams is 5 cm. Hence good measurement results are only possible when the point in which the two laser beams meet each other located about 0.5 to 1 cm above the bed or under the water level. Obviously the determination of surface velocity by LDA was not possible.

Furthermore the surface velocity was conducted by measurement of the time and the path of tracer parti cles transported on the water surface. In Figure 5 the surface velocity versus the belt velocity for different bed slopes are shown. In average the surface velocity is

about 10 % of the bed velocity in the moving reference

system.

That means in the nature the water particles of the

water surface travel faster than the wave body. This

depends not clearly from the bed slope. 0 0,1 0,2 0,3 0,4 0,5 0,6 2,0 2,5 3,0 belt velocit y [m/s] s u r f a c e v e l o c i t y [m / s] I = 0 I = 0.01 I = 0.02 I = 0.03 3,5 4,0 4,5 5,0 5,5 6,0 Figure 5. Manning roughness parameter of the smooth conveyer belt. For further comparison of testing results with different surface roughness, Manning roughness parameter of the smooth belt was determined too. For this test series belt velocity was adjusted that a nearly bedparallel water surface was resulted. Since the flow was induced by the moving of the conveyer belt the relevant wetted perimeter was equal to belt wide. Thus the hydraulic radius can be set equal to the water depth. To determine Manning roughness parameter defined by Manning's formula: water depth h, bed slope I B , water surface slope I S and belt velocity as the mean velocity of flow were measured in that test series. In Figure 6 Manning's roughness parameter versus the water depth is shown. There is no significant correlation. The mean value of all test cases is 0.008 and will be used for calculation and comparison with other test results. The measured distribution of the horizontal velocity indicates a very turbulent flow. In Figure 9 an example is shown, measured under the condition of bed slope= 0.01, belt velocity= 2.38 m/s and mean water 0 10 20 30 40 50 60 70 -2,5 -2 -1 -0,5 0,5 horizontal velocity [m/s]

formed to the natural reference system.

depth= 0.065 m. The velocity of the surface was esti

mated due to Figure 5. For better understanding the

belt velocity is displayed in the figure.

To transfer experimental results from moving ref

erence system to nature the Galilean transformation

must be used:

where u n = horizontal velocity in nature, u mrs = hor

izontal velocity measured in the moving reference

system and u b = belt velocity. Transformed data from

Figure 7 are shown in Figure 8. Generally this flow

profile agrees to flow profile of steady flow in a

rectangular open channel.

The measured vertical velocity profile for the same

test case as in Figure 7 is shown in Figure 9. The

vertical velocity has values near zero except for the

region near side wall of the flume.

Hence the main velocity in the case of steady flow

condition in the moving-bed flume is the horizontal

velocity analogous to the steady flow in traditional

channels. -0,075 -0,05 -0,025 0 0,025 0,05 0,075 0,1 0 25 50 75 100 125 150 175 distance from side wall [mm] v e r t i c a l v e l o c i t y [m / s] 5 15 25 35 45 c e n t r e l i n e o f c h a n n e l mm above channel bottom Figure 9. Steady state of wave front in the experimental set-up. Generally the results from the model tests with an moving-bed flume can be transformed and compared with results from traditional flumes. 4 RESULTS OF WAVE FRONT The wave front obtained in the experiment is presented in Figure 10. It possesses a very long and flat shape appropriate to the smooth surface of the moving bed. The water surface is very curly. This is similar to waves in standard flumes like at dam break tests by Bell, Elliot & Chaudry 1992. The slope of the water surface increases until the front where the slope is up to vertical. In traditional dam break experiments with smooth beds the resulting wave front is too small to observe this phenomena. But a steep wave front is observed in channels with a rough bed and in cases of real dam breaks. Measurement results of the wave head shape shown in Figure 2 and confirms the above description of the shape of the wave front.

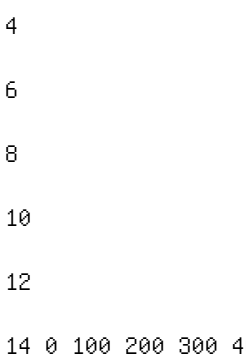

Figure 11. Shape of wave front – dots=measured with ultrasonic sensors, line=mean values (bed slope= 0.01, v bed = 4.24 m/s).

5 CONCLUSIONS

The knowledge in the field of surge waves is neces sary to predict the inundation area and potential of destruction of a flood wave resulting from dam fail ure, to determine effectiveness of surges which occur by flushing of sewers and to design irrigation systems with grooves.

Nevertheless the knowledge about the flow at the wave front and about the propagation of the wave front depending on the bed roughness and turbulence is very limited. A better understanding of these relations is of general importance for the calibration of numer ical models to simulate flood waves resulting from breaching dams.

There are various theories about shape and velocity of the wave front. Previous experimental investigations

consider wave front together with the whole dam break

wave and reservoir outflow.

An experimental set-up was developed basing on

the consideration of the wave front in a moving refer

ence system. Thus the unsteady flow of a surge wave

was converted to a steady flow from the observer’s

point of view.

For further comparison is it important that in the

case that a flow is induced by a moving bed the wetted

perimeter is equal to channel width and the hydraulic

Roll waves evolution in channels

G.F. Maciel

Department of Civil Engineering, São Paulo State
University, Ilha Solteira, São Paulo, Brazil

ABSTRACT: Flows that process under accentuated steep slopes
may develop instabilities called roll waves.

Roll waves can be developed in laminar and in turbulent
streams. The purpose of this article is to analyze the

criteria for the occurrence of roll wave phenomenon in the
case of supercritical and turbulent Newtonian and

non-Newtonian flows from the engineering point of view.
Rewriting the shallow water equations and taking into

account the Bingham fluid behavior and fluid viscosity,
first, the conditions for the development of roll waves

using the stability linear technique are presented; second,
it is presented a numerical simulation performed by

a finite volume technique using Godunov-VanLeer schemes.
Imposing a constant discharge at the upstream of

the high gradient channel and superposing very small

perturbations (with different frequencies and amplitudes),

it was observed that roll waves can be developed more easily for small wavenumbers and for high cohesions

of material.

1 INTRODUCTION

Flows that process under accentuated steep slopes

may develop instabilities. However, the chaotic aspect

present in the nature of these instable phenomena,

seem to tend, at the end of a finite time, to a station

ary flow, more stable, with the appearance of periodic

long waves as a hydraulic jump or “bore waves”. Such

perturbations are called “roll waves”. If, on one hand,

these waves are rare in natural flows, on the other, they

are frequent in artificial canals and in water flowing

from dams.

The proposition of this scientific communication is

to study, from the theoretical standpoint, with numeri

cal appreciation, instability problems in the fluid flow

with rheologic behavior of Bingham fluid type. In par

ticular, it will try to verify the aptitude of the “shallow

water” equations, combined to a “Bingham” rheology,

to “roll waves” propagation and generation in debris

or mudflows. In a first part, the conditions of exis

tence of “roll waves” and formation criteria, either in

Newtonian fluids (clean water) or in non-Newtonian

fluids (“debris flow” case) will be analytically verified;

in a second part, such instabilities would be numeri

cally generated. The equation system used is a mod

ified shallow water type with and without diffusion

terms. The numeric modeling proposed is the finite

volume type where the schemes Godunov-VanLeer

(1981) (compatible to the hyperbolic non-linear sys

tems) are applied. 2 THEORETICAL MODELLING THROUGH “SHALLOW WATER” EQUATIONS - CONSERVATIVE FORM “Shallow water” equations with shock used here are obtained from the classic equations of fluid mechanics to which a representative behavior law of a Bingham fluid rheology is added, such as τ= τ c +μ. (du/dy) if τ > τ c and du/dy= 0 se τ < τ c . τ c represents the critic tension of shearing or initial stress (yield value), μ the dynamic viscosity and du/dy the velocity gradient (shear rate). “Shallow water” system consists of a mass conservation equation (1), a momentum conservation equation (2) and, in this case, two relatives to the hydraulic jump (3 and 4).

In these equations “h” is the flow depth; “h 0 ” is the

uniform flow depth; “u” is the vertical average veloc

ity; “w” is the propagation velocity of the front flow

(celerity); “C h ” is Chézy coefficient; “θ” the canal

declivity; “ρ” the specific mass of the fluid and “α”

the velocity profile coefficient (α= 1, by simplifica

tion). The Bingham Number considered is this article

is high, in order that critical stress dominates largely

over viscosity effect.

2.1 Existence conditions of “roll waves” in the new Bingham fluid rheology, without viscous term

The proposal of this item is to determine the neces

sary and sufficient conditions to the generation of “roll

waves" as the solution of "shallow water" equations in

a Bingham fluid rheology without the diffusion term.

At first, the interest variables and thus the work scales

should be defined:

in which √ g · h 0 · cos(θ) is the propagation speed of

the gravitational waves. Introducing the dimensionless

variables in the equations (1)-(4), and disregarding the

specific mass variations, the following equations are

obtained:

The determination of the "roll waves" formation

criterion, demands, first of all, a solution to the free

surface equation. First, the equations (5) and (6)

are rewritten in a moving system of co-ordinates.

By hypothesis ζ=X-W.T, where W represents the

dimensionless velocity of the front flow propaga

tion (celerity). Starting from these presuppositions, we obtain two linear equations with two incognitos (U ′ and H ′). This system resolution will provide two differentials equations with U ′ and H ′ : The relation between (8) and (9) allow to verify that the specific discharge is a constant as described below: If we apply (10b) in the expression of H ′ (equation 8), an equation non-linear of 1st order will be obtained, as shown in equation (11): The resolution of (11) will provide us the wished profile of the free surface. However, it is verified that there is no solution to this periodic equation. Thus, the proposal would be to try to "build" periodic solutions from continued intercalated solutions by hydraulic jumps. For this, it is necessary to find continuous solutions presenting the property in which, in a determined section, the flow is supercritical and, in a posterior one, subcritical. By continuity, there should exist an abscissa point ζ 0 , a depth point H 0 , a speed point U 0 , where the Froude number is equal to the unity (critic flow).Thus,

W-U 0 = √ H 0 .To this point, especially, the equation denomination (11) is null, which means a discontinuity, except for the case in which the numerator is also null. This critical point is necessarily different of that where the jump occurs, in a way that is only possible to construct the “roll waves” when the numerator and the denominator concomitantly null themselves. Thus:

Substituting (10b) in (11), and after some mathe

matical developments, the differential equation to the

free surface in the continuous interval is obtained:

Finally, in order to generate “roll waves”, start

ing from the equation (12), it is necessary that

∂H/∂ζH =H 0 > 0, implicates in:

2.2 Discussing the theoretical results, without diffusion

The inequality (13) defines a dominion into which

“roll waves” can be formed. Such results are illus

trated in the Figure 1. It is observed that for an addition

of the Bingham term (cohesion effect or critic ten

sion τ c), “roll waves” can be developed easily, i.e., the

increase of this parameter would favour the develop

ment of these disturbances. This conclusion agrees,

for example, with the experimental observations of

Takahashi (1990), who generates “roll waves” in lab

oratory to Froude numbers F< 2. If the fluid cohesion

C * is null, the inequality (13) is given by β< 1/4 ⁼

Figure 1. Dominion of existence of “roll waves”. of linear stability. In order to do that, resource will be made to the “shallow water system” (equations (1) and (2)). Adding the diffusion term ∂/∂x(hu∂u/∂x to the equation (2), throughout the current, in which “ν” represents the average kinematics viscosity; the quantity of movement equation becomes: Thus, the second member of the equation (14) takes into consideration four effects: the weight force, represented by the gravity, the shearing due to the Bingham fluid modeling, turbulent dissipation through Chézy coefficient and, finally, the viscous dissipation represented by the term in “ν”, adapted to the “shallow water” system. The parameters that may at times evidence the probable instabilities in the flow curve pass necessarily by a process of system adimensionalization. Taking the uniform flow as a basis in the adimensionalization process, and applying the characteristic scales, such as x=L · x ′ , h= h n · h ′ to lengths, u= u n · u ′ to velocities and C∗= τc/ρ · g · h n · sin(θ) to tensions. Where L represents the wave length and n an index that characterizes the normal or uniform regime, it is obtained (omitting the character (′)): with: Concerning the study of linear stability, it is admitted that heights and velocities are submitted to small perturbations, such as: u= 1+ uˆ with uˆ 1 and h= 1+ hˆ with hˆ 1. Introducing the equation (15) in (16) and disregarding the second order terms, the equation system of the perturbed quantities h and u is obtained. Finally, omitting the notation (∧):

The equation (17) can be inserted in (18), allowing

the elimination of “u” and obtain an equation that only

takes into consideration the variable “h”:

With the equation (19), the development crite

ria of instabilities of wave number k and of fre

quency w are researched. The solutions of the form

$h(x, t)=H(k) \cdot e^{(ikx-\omega t)}$ where $w=w_r + i \cdot w_i$, are

interesting to be obtained, observing that $w_r \geq 0$ in

order to assure stability. Introducing h(x, t) in the

equation (19), an equation of order 2 with complex

coefficients is obtained. From this point, the real and

the imaginary parts are separated, thus creating two

other equations (one to w_r and another to w_i), which

allows the obtaining of polynomial $P(w_r)$, having as

only incognito w_r. Here, it is interesting to discuss the

existence and the nature of the root signals of $P(w_r)$.

It is known that stability will only occur if the roots

of $P(w_r)$ are positive or null. After some mathemat

ical developments, it is demonstrated that $P(w_r)$ is a

strictly monotonous function, decreasing in the inter

val $]-\infty; 0]$; thus, it is concluded that the condition

needed and enough that the roots of $P(w_r)$ are positive

is that P(0) is positive ($P(0) > 0$). After some mathe

matical developments, the critic Froude number F_c is

obtained: Figure 2. Critic Froude in function of the number k of waves. Figure 3. Critic Froude in function of Reynolds’ number. 2.4 Discussing the theoretical results, with diffusion From the previous results, some guiding formation criteria and the development of “roll waves” in

function of the physic parameters can be illustrated. The following figures show the influence of the Reynolds' number Re and of the wave number k in function of the critic Froude number F c for various cohesion values C∗ (Bingham effect). The Figure 2 shows the influence of the number of waves (wavelength) over critic Froude for two fixed parameters, ζ= σ/R e = 0.05 and α= 1.00. It can be deduced from the Figure 2 that roll waves tend to develop more easily or more quickly to a scenery of small wave numbers and high values of critic tension of Bingham (cohesion effect C∗). On one hand, it could be asserted that an increase in the cohesion value would guide or favor the appearance of instabilities of roll waves; on the other, long waves would be the first to destabilize. Figure 3 shows the influence of the adimensional rigidity C∗ over the Froude number as a function of the Reynolds' number. It can be observed that in the same way that in the result illustrated in the Figure 2, an increase in the fluid cohesion would cause the precocious appearance of roll waves, to fixed Froude and Reynolds numbers.

Figure 4. Roll waves amplitudes generated versus longitu

dinal distances (sinusoidal perturbation ofT= 3. 14 s; C∗= 0

and 1% of discharge).

3 VALIDATION TESTS – NUMERIC RESULTS AND DISCUSSIONS

The purpose of this paragraph is to present some

results of numeric order in generating roll waves in

Newtonian and non-Newtonian fluids. The simula

tion program developed had its theoretical formulation

in the hyperbolic non-linear systems and its deriva

tions, notedly the resolution of the Riemman problems

(Vila, 1985). The numeric simulations were executed

from VanLeer numeric schemes (second order in

time and space) and effectuated in rectangular sec

tion canal of 1000 m length (with increment of space

x= 1.00 m) and significant slope of 30%. Work

ing with flow regimes preferentially turbulent and supercritical, two upstream limit conditions could be fixed: discharge of 800 l/s/m and depth of 0.15 m. On this discharge, small perturbations (of per cent order) were imposed, so as to generate stable roll waves to the canal downstream, as illustrated by the diagrams below.

A first series of tests were carried out, allowing a more global assessment of the phenomenon, mainly concerning the initial conditions of the perturbation imposed, as described below:

(a) an upstream perturbation on the discharge, sinu soidal perturbation type, was capable of generating well defined roll waves (Figure 4);

(b) a random perturbation was not able of generating well defined roll waves, i.e., with a preferential marked frequency; however, it generated a puls ing free surface, with chaotic aspects, as shown in Figure 5.

Concerning the amplitude of the imposed perturba tion (sinusoidal perturbation), the results show that:

(a) to a given frequency, the perturbation amplitude should not influence over the amplitude of the

generated roll wave; Figure 5. Pulsing surface from random perturbation versus longitudinal distances. Figure 6. Roll waves amplitude generated versus longitudinal distances

(10% discharge perturbation (C*= 0). Figure 7. Roll waves amplitude generated versus longitudinal distances (50% discharge perturbation (C*= 0). (b) however, a higher or a lower perturbation amplitude should anticipate or postpone the appearance of the roll wave, as if perturbing the base flow without altering the amplitude of the generated roll wave. See Figures 6 and 7. Concerning the wave length of the imposed perturbation, the numeric tests show that the generated roll wave has the same length. A small perturbation of T= 3.14 s generated a roll wave of the same

Figure 8. Detail of the roll wave illustrated in Figure 6.

Figure 9. Generation dominions of roll waves in function

of the canal declivity and Bingham effects.

period (with respective wave length of 25 m). Figure 8

illustrates this result.

A second series of tests were performed, taking into

consideration the new rheology and its implication

over the generation and characteristics of the produced

waves. Various tests were carried out, allowing the

establishment of a border or dominion of roll waves

formation in function of the parameters being used:

β taking into consideration the canal declivity and its

resistance; Bingham tension X=C * (1-β)/W * W

(Figure 9).

For this case we could certify that for constant β,

the Bingham tension effect seems not to influence, in

a significant way, the period or the wave length, thus

reconfirming the same conclusions for a newtonian

fluid. On the other hand, when taking into considera

tion the cohesive effect (C*), to a given amplitude of

perturbation, the roll waves appear earlier and present

higher height values. Figures 10 and 11 illustrate these

results.

A third series of tests consisted in verifying the

sensibility of our system nonlinear when submitted to

simultaneous small perturbations and frequencies and

amplitude different of h(x, t)=H 0 e (kx-w(t)t) , where k

is the number of waves and w(t) are the frequencies.

The diagram below illustrates some results for various

configurations: Figures 12, 13 (for Newtonian fluids)

and Figures 14, 15 (non-Newtonian fluids). Figure 10. Roll waves with T perturbation of 3.14 s (C*= 0.10). Figure 11. Roll waves with T perturbation of 3.14 s (C*= 0.20). Figure 12. Roll waves with T perturbation= 3.14 s and different amplitudes (C*= 0). From these results, some comments are in order: (a) the perturbation amplitude does not intervene in the generated roll wave amplitude; (b) the generated downstream roll wave presents the wave period or length regarding the bigger wave length of the different perturbations imposed upstream, after passing and capturing other frequencies (lower wavelengths). Another analysis which could be made, confirming such results, is related to the fact that long waves (big wavelengths)

Figure 13. Roll waves with T perturbation= 1.00s, 1.57s

and 3.14s and constant amplitudes (C*= 0).

Figure 14. Roll waves with T perturbation= 1.00 s, 1.57 s

and 3.14 s and different amplitudes (C*= 0.2).

Figure 15. Roll waves with T perturbation= 1.00 s, 1.57 s

and 3.14 s and constant amplitudes (C*= 0.2).

are almost always the first to destabilize, as illus

trated in Figure 2;

(c) to the new Bingham rheology, based in Figures 10,

11, it is proved that the tendencies are the same

shown for the Newtonian fluid, i.e., the roll waves

appear earlier and with higher height values.

Physical model tests for dike-break induced, two-dimensional flood wave propagation

S. Briechle, A. Joeppen & J. Köngeter

Institute of Hydraulic Engineering and Water Resources Management, Aachen University, Germany

ABSTRACT: There is a lack of knowledge about the properties of a flood wave due to dike break and failure of (mobile) flood protection walls, on which a prediction of the implicated risk could be based. Fore this reason a physical model, which takes into account the special boundary conditions of such an incident, was built and measurements were undertaken. The results of a variation of initial water depth and discharge in the river and the effect of a thin water film on the propagation area are presented and discussed.

1 MOTIVATION AND AIMS

Dikes and (mobile) flood protection walls defend areas used by man from flooding. In case of failure how ever, the resulting flood wave implicates an extra risk to people and goods in the near field of the breach

because of the strong dynamic forces. At the moment it is hard to assess this risk. Due to the rareness and dangerousness of such failures, data from real-world incidents are insufficient to base a prediction of the flood wave propagation on these and there are no ana lytical solutions for this problem. Attempts to predict the wave numerically are made frequently, but produce uncertain results: Assumptions and simplifications to make the problem computable usually do not repro duce all the complex effects of roughness, turbulence, flow inhomogeneities (e.g. air entrainment) and verti cal momentum at places of strong surface slope (e.g. in the near field of the breach or at the wave front). Furthermore validation examples are mostly unavail able. The extend of deviation of the calculation results from the reality is therefore not known unerringly and it is not easy to ascertain how to improve numerical models best.

For this reason experiments are conducted in a phys ical model. Data of the flood wave propagation are gathered, which later can be used for the validation and improvement of numerical models. Furthermore insight into the wave is gained, especially concerning flow processes, effects of systematically varied param eters, scalability of the results to other dimensions

and as a basis for a simplified projection of the flood

wave propagation without an expensive numerical

calculation. 2 PROBLEM DEFINITION 2.1 Comparison of damand dike-break For the dam-break case there can be found several detailed investigations in literature, Hager & Lauber (1996) give a good review. Most physical investigations took place in flumes and therefore reduced the problem to one dimension – propagation takes place only along the flume, lateral propagation is not considered –, in addition breach and reservoir have the same width. Only few investigations allow for a propagation into an area, combined with a breach width smaller than the width of the reservoir. Most recent example is Kulisch (2003), other model tests were conducted by Jovanovic´ & Djordjevic´ (1995), Fraccarollo &Toro (1995), Naaim & Brugnot (1994),Tingsanchali & Rattanapitikon (1993) and Memos et al. (1983). However, those findings are not directly transferable to a wave resulting from the failure of a flood protection structure on a river. Figure 1 depicts the Figure 1. Comparison of flood wave propagation caused by damand by dike-break, Q in = discharge into reservoir/river respectively, Q b = discharge through breach, h b =water depth in breach, v b = velocity in breach.

other two mayor differences: Compared to the reser

voir of a dam, in which the water depth converges

to zero with time, the discharge Q in in a river can

not be neglected – the river bed will not empty com

pletely, but after a certain transitional period a steady

state condition will be reached with constant water

depth h B in the breach. Additionally in a river the

velocity component parallel to the protection structure

has to be considered, since it will deform the wave

asymmetrically. The only physical model known to

the authors, which accounts for the river flow apart

from there own can be found in Aureli & Mignosa

(2002).

2.2 Delimitation of this investigation

A complete, instantaneous failure is assumed with the chosen mechanism (see section 3.1). A real dike or (mobile) flood protection wall will probably not fail in this idealized way. However, this assumption seems justifiable due to the following reasons:

- Analytical solutions for the dam-break problem and most numerical simulations start from a vertical water front at the breach section. To be able to compare our results with those calculations this idealized scenario seems most appropriate.
- At present knowledge on the various failure mech anisms of dikes and (mobile) flood protection walls and their interaction with the flow is poor, resulting in high uncertainties. To reduce these for this inves tigation, the failure mechanisms were neglected for the time being.
- It is considered a well defined worst case scenario which corresponds to an instantaneous and total failure at starting time giving the highest factor of safety for risk considerations.

The two-dimensional wave propagation is investigated in the near field of the breach, where the dynamic forces are crucial with respect to the later use of the

results in risk assessment procedures. Also in this area (i.e. near the breach) the vertical momentum is likely to become important for the flow process.

The unsteady state immediately after the failure is investigated.Additionally and in contrast to past inves tigations, the steady state case, reached after a certain time span due to the constant discharge in the river as described above, is examined.

There is no fixed scaling factor applied. Consider ing initial water depth before break it ranges between nearly 1:1, as would be applicable for small mobile flood protection walls in Germany, to up to 1:30 and more, for example for dikes in the Lower Rhine Area in Germany of up to 15 m height. Therefore scalability is of particular interest. 3 EXPERIMENTAL SETUP AND MEASURING TECHNIQUES 3.1 Physical model To satisfy the needs described above a physical model was built at the Institute of Hydraulic Engineering and Water Resources Management (IWW) at Aachen University, which takes into account the special boundary conditions of the dike-break problem. A channel, 1.0 m wide and representing the river, is joined to an area (3.5 m× 4.0 m), on which the propagation of the flood wave can be measured (see fig. 2). Channel and area are separated by the channel wall, i.e. the dike or flood protection wall, in which a pneumatically driven gate is installed for simulation of the breach (see below). The water is allowed to fall freely off the other three boundaries of the area. The floor of the propagation area is made from glass, not only to minimize roughness, but to observe the wave and take measurements from below as well. In this physical model the following parameters can be varied to study their effect on the flood wave propagation: The initial water depth can be risen to up to 50 cm by adjusting a weir at the end of the channel, the discharge in the channel can be set from Q in = 0 to 390

l/s and the breach width can be chosen to 30, 50 or 70 cm, rectangular in shape. The area is horizontal and can be covered with different materials to study roughness effects. The flap initializes the flood wave propagation by opening in a minimized time span of less than 0.1 s. The movement of the flap is illustrated in figure 3. The design aimed at the immediate clearance of the entire vertical water front in the breach. This distinguishes the mechanism from the gates used in the past in damand dike-break experiments, were the wave propagation was usually initialized by lifting a sliding panel. However, in that case the foot of the wave is Figure 2. Physical model.

released first, the whole front only after a short delay.

This problem is eliminated by the new flap mechanism,

but a pull could be exerted on the water body by the

horizontal component of its movement. This is how

ever reduced by the hinges on top, which allow the flap

to swing. The effect could be shown in comparison to

a flap which was fixed to the steel framework.

3.2 Measuring techniques

The two-dimensional measuring arrangement is

demanding. Strong spatial and temporal changes of

the propagating wave, air entrainment and piling up of

Figure 3. Opening mechanism.

Figure 4. Coordinate system. water (if the measuring technique is intrusive) entail manifold problems. The wave is difficult to access on the propagation area and all data have to be gathered in two dimensions, which results in a great amount of data. The water depth is measured by ultrasonic sensors in a dense raster on the propagation area. The measuring locations are the intersection points of the raster lines in figure 4. The sensors have a measuring frequency of 50 Hz and are optimized for steep wave fronts. They are not influenced by the vertical momentum of the wave, like pressure gauges installed in the floor would be. Our experience on the physical model indicates that the error is usually less than 2 mm.

Unfortunately measurement is not possible in the range of flap movement up to approximately 800 mm distance from the breach. However, in the breach itself the water depth can be determined. Complementary a CCD-camera was installed, recording the whole flood wave from top with a spatial resolution of 756× 550 pixels (in gray scales), again giving results with a frequency of 50 Hz after de-interlacing of the recorded images. Digital image processing is used to adjust distortion, for automated wave front localization and for post-processing with respect to front velocities, asymmetry etc. When a thin water film remains on the propagation area between the experiments, the entrained air can be used as white contrast for automated digital image processing of the images (see section 4). To detect the wave front in the dried case, the water must be colored to increase contrast, those images can not yet be presented. Both measuring devices are triggered with the opening mechanism to bear relation to the start of the opening process. Additionally the wave is recorded by high-speed camera or camcorder to gain an insight into details as the need arises. 3.3 Measuring program The measuring campaign is still under way. Different boundary conditions, namely initial water depth, discharge in the channel, breach width and roughness materials on the propagation area will be systematically tested to be able to quantify their effects. In this paper combinations of Q in = 300 l/s discharge in the river and initial water depth of h i = 30 to 50 cm are presented. The breach width was 0.5 m and the floor of the propagation area was plain glass. 4 RESULTS 4.1 Effect of initial water depth in the channel Figure 5 shows water depth over time on the main axis for a variety of initial water depths at three different distances from the flap. As a first attempt the data

Figure 5. Non-dimensional water depth for five different initial water depths on the main axis at three distances from the

flap. Discharge in channel Q in = 300 l/s, the propagation area was dried before every experiment.

was scaled by applying Froude’s law. For this pur

pose the model is considered superelevated. In the

horizontal directions x and y the scale basis is set to

L basis = 0.50 m (breach width). This width does not

change with the modification of the initial water depth, therefore the horizontal scaling factor L equals 1.0. The same would hold for the distances of the sensors from the breach in y direction. As a scale basis in verti cal direction the initial water depth of H basis = 0.50 m is chosen, giving different vertical scale factors H for different initial water depths. Based on Kobus (1978) the following equations can be derived for the superelevation in this case:

where n= superelevation factor, T = time scaling fac tor.

Table 1 assembles the results of the equations (1) to (4) for the different initial water depths.

With these values and the following equation (5) the data for figure 5 were obtained:

where h∗ and t∗ are the scaled values for the measured water depth and time respectively.

At position 800 mm the sensors failed for higher initial water depth, presumably due to the extreme steepness of the front in this place. However, the time the sensor failure occurs can be assumed to be the arrival time.

If the waves were scalable this way, all lines in the graphs should coincide. The water depth h there fore seems to be scalable reasonably well within the

0.35 1.429 0.7 0.837

0.30 1.667 0.6 0.775 proximity of the maximum. Differences can be found in a little “step” in the rise before the maximum – the step is lower for lower initial water depths. After the maximum the water depth reduces stronger and fluctuation increases with reduced initial water depth. The reduction in depth is explicable by the fact that the discharge in the channel was not scaled as well, but stayed at 300 l/s and the weir at the outflow of the channel was adjusted accordingly to obtain the different initial water depths and was fixed during the experiments. Regarding the arrival time of the wave, at position 800 mm the wave with the lowest initial water depth arrives first, at position 1500 mm the arrival times are nearly identical and at 3300 mm the relation is conversed and the wave with the highest initial water depth arrives first. An explanation for the growing deviation of the measured values with decreasing initial water depth could be, that the simple superelevation rules are only applicable in cases in which the effects of vertical velocity components can be neglected. This is not the case especially near the breach, where all the kinetic energy is derived from the potential difference and the water surface is strongly inclined – this could explain the overestimation of acceleration especially for the lower initial water depth. Additionally a discrepancy of roughness effects can develop – this could be an explanation for the underestimation of the wave velocity in the longer run, where the water depths for the lower initial water depth is less and roughness effects are stronger. 4.2 Effect of a thin water film If a thin water

film remains between two tests, i.e. the water drains off over the three free boundaries of the propagation area but it is not dried explicitly, the wave front is significantly altered. Figure 6 shows the differences between the two cases “thin water film” and “completely dried” for a discharge of 300 l/s in the channel and an initial water depth of 50 cm. Near the flap the two cases are similar, between 1300 and 1700 mm distance however, a difference starts to appear: in the “water film” case the tip of the wave starts to built up a high peak whereas the “dried” case flattens more and more. The envelope of both cases is adumbrated in the figure for orientation. Parallely the arrival time of the wave front at the sensor is increased in the “water film” case compared to the “dried” case, i.e. the velocity of the wave front slowed down by the water film. The building up of the peak could be due to piling up of the water in the film in front of the strong growing circumference of the wave. However, this can not be the full explanation, since the peak flattens down again after a maximum at about 2500 mm distance from the flap. In the photographs in figure 7, recorded

Figure 6. Comparison of the cases “thin water film” and “dried” at six different distances from the flap. Water depth on the

main axis over time for intitial water depth h i = 50 cm and discharge in channel Q in = 300 l/s.

by the CCD-camera, strong air entrainment can be

perceived as a white band at the wave front, which

indicates strong turbulence and roughness effects. The

white band is completely absent in the case of a dried

propagation area.

A similar peak can be found in Stansby et al. (1998)

with a ratio of 0.1 between the water depth on the prop

agation area and in the reservoir before dam-break.

Using a camera, recording through the sides of their

flume they observed a “mushroom” shaped wave front.

4.3 Effect of discharge in the channel

In figure 5 the water depth seems to converge to a constant final value with time. This quasi steady state however lasts only for a short time, since when the negative surge is reflected at the ends of the channel, it causes the water level to drop in progressive stages. In case of higher discharge in the river, the decrease in water level is more even, i.e. the surge reflection is less influential.

Figure 8 shows the position of the wave front with an interval of Δt= 0.02 s for the cases of no discharge in the channel and, for comparison, with 300 l/s. The sporadic interruptions of the lines at small y-values are caused by the moving flap. The propagation area was not dried, i.e. the thin water film remained between the experiments and air entrainment made the wave visible (see section 3.2). In the case of no discharge in the top part of the figure, the wave propagation is symmetric and onion shaped. In the bottom part of the figure the trajectory of the wave tips were added. The derivation from the main axis is relatively small. Therefore in the preceding sections the main axis only was considered the water depth discussions. The deviation of the wave tip is defined by an interaction of initial water depth and the discharge in the channel.The effect of initial water depth and discharge can be combined in the Froude number of the channel before break: in which the numerator with the velocity v represents the momentum resulting from the discharge parallel to the channel and the denominator with water depth h and gravitational constant g represents the momentum from gravitation. The result is shown in figure 9, in which the data points coincide reasonable well with a trend line.The angle of deviation is greater with greater discharge, i.e. velocity in the channel. Furthermore the deviation is greater for lower initial water depth, i.e. lower velocities of the wave front propagation.

Figure 7. CCD-camera recordings at five different time steps with an interval of Δt= 0.2 s. Initial water depth h i = 50 cm, discharge in channel Q in = 300 l/s. Figure 8. Position of the wave front with an interval of Δt= 0.02 s. Initial water depth h i = 50 cm, discharge in channel Q in = 0 l/s (top) and 300 l/s (bottom). In the bottom part of the figure the trajectory of the wave tips were added. The propagation area was not dried, i.e. covered with a thin water film. Figure 9. Deviation angle of the wave tip over Froude number before breach. For every discharge (except 300 l/s) the three initial water depths (30, 40 and 50 cm) are plotted, the data points with the smallest angle corresponds to the highest initial water depth.

5 CONCLUSIONS AND FUTURE WORK

There are many open questions concerning the flood wave propagation following a dike-break or the failure of a (mobile) flood protection wall.This paper presents first results of a systematic investigation of the influ ence factors and thereby starts to answer some of those questions.

The analysis of the data shows, that the water depth of the propagating wave is already scalable with respect to the initial water depth by easy means, but there are still some deviations which have to be inves tigated further. This holds especially in the case of the arrival time, which implies the velocity of the wave front.

A thin water film, which remains when the propa gation area is not dried explicitly between the experi ments, alters the shape of the wave front significantly

by building up a prominent peak and slowing down the

wave front velocity.

The sideways deviation of the wave tip position from

the main axis is determined by an interaction of initial

water depth and the discharge in the channel and can be

estimated reasonably well by using the Froude number

of the channel before failure.

In the future the physical model tests will be sys

tematically completed, to gain more insight into the

flow processes of the flood wave, to be able to quan

tify the influence factors and to assure accurate scaling

of the results to other dimensions.

ABSTRACT: A spatial linear stability analysis of the one-dimensional St. Venant flow model, accounting for

the dispersive effects, is carried out in the present paper. The theoretical investigation allows to discuss about the

influence of channel length on roll-waves occurrence. In order to provide a rigorous justification for selecting

the spatial stability theory, a preliminary proof of the convective nature of the flow instability is furthermore

performed. The results of the spatial analysis show a non-negligible influence of the disturbance frequency

on the perturbation spatial growth rate. As a consequence the semi-empirical criteria commonly employed for

predicting roll-waves occurrence, which do not take into account the frequency effects, may lead to overestimate

the minimum channel length above which the phenomenon is not perceivable.

1 INTRODUCTION

High velocity flows in steep channels may exhibit surface instabilities, perceivable as a series of water waves. As these waves propagate downstream they increase in amplitude and eventually break forming hydraulic bores. The series of waves just described are the so called “roll waves” and occur usually in man-made channels, such as draining systems and dam spill-ways. Generally, roll-waves presence is undesir able since they may determine a water overflow from the channel sides and excessive intermittency at the outlet. In studying such a phenomenon, two basic issues arise:

- identifying the necessary conditions under which roll-waves appear;
- predicting roll-waves evolution along the channel.

Only the former question will be addressed herein. From the theoretical point of view, the generation process of roll-waves has been thoroughly and deeply investigated. In what follows we will restrict the dis cussion on the analyses performed with reference to the linearized one-dimensional flow model (St Venant equations) in which the field variables, mean veloc ity and flow depth, are assumed to be smooth. Under

such assumptions roll-waves generation process has been fruitfully interpreted in terms of instability of the linearized flow model. Many temporal linear stability analyses have been performed (Brock, 1970; Berlamont, 1976; Ponce & Simon, 1977; Berlamont & Vanderstappen, 1981) in order to individuate the critical values of relevant dimensionless – Reynolds and Froude – numbers corresponding to the appearance of roll-waves. For instance, assuming the channel to be sufficiently wide and expressing the bottom shear stress as a quadratic function of the mean velocity, a critical value of the Froude number, F rc = 2, below which roll waves cannot occur, has been found (Brock, 1970). Furthermore all conditions of flow characterized by F r >F rc are unstable, independently of the perturbation wavelength values. Several experiments (see for instance Brock, 1969) confirmed the absence of roll-waves for F r <F rc , while their presence was not always detected for F r >F rc . In contrast with the temporal analysis and to take into account the developing character of roll-waves, spatial linear stability analyses have been performed, starting from the hyperbolic character of the St Venant equations (Vedernikov, 1945, 1946; Liggett, 1975; Julien & Hartley, 1986). The point-wise perturbation is assumed to propagate downstream with the celerity of the faster shallow-water wave, according to the hyperbolic wave theory. In terms of stability region

the results of the temporal analysis are essentially

confirmed, despite the strong different space-time

evolution of the perturbation.

Whether the temporal or the spatial technique is

more appropriate to investigate the instability of St

Venant flow model depends on the nature, Convective

or Absolute, of the instability (Huerre & Monkewitz,

1990). An instability is defined as Convective if a

localized initial small perturbation, growing in time,

is swept away from the source only in one direc

tion, whereas the instability is Absolute if it spreads

in all directions. Only when the instability is Con
vective, spatial analysis may describe fruitfully its
evolution.

The definition of the instability nature allows to
verify the theoretical assumptions embodied in some
semi-empirical criteria defining the minimum chan
nel length below which the roll-waves presence is not
perceivable, even in linearly unstable conditions of
flow. These criteria, tested and calibrated using many
available experimental data, start from the space-time
evolution of perturbations resulting from the spatial
linear hyperbolic analysis.

Montuori (1961, 1963), and later Liggett (1975),
proposed to relate the critical Froude number value
upon the channel length L; for sufficiently small val
ues of L no roll-waves appear. Considering the process
as Reynolds independent, the critical Froude number
is expressed as a monotone decreasing function of the
channel length whose value, for sufficiently large L, is
F rc . Similar conclusions have been drawn by Julien &
Hartley (1986) who studied roll waves formation pro
cess in highly viscous mud-flows observable in steep
mountain channels. It is worth of note that the above
semi-empirical criteria share some similarities with the
e n -method, originally proposed by Van Ingen (1956)

and by Smith & Gamberoni (1956), commonly used to

give an engineering prediction of the boundary layers

transition location.

In the present paper the convective nature of the

instability is preliminarily proved by examining the

linear impulse response of a given uniform base flow.

Following the Briggs criterion (Briggs, 1964), an anal

ysis concerning the behaviour of the spatial branches

associated with the dispersion equation is carried out in

the complex k andω planes, whereω and k are the com

plex pulsation and wave-number of the disturbance,

respectively.

Furthermore a spatial linear stability analysis in

terms of flow response to a point-wise time peri

odic perturbation is performed. The analysis naturally

accounts for dispersive effects. The strict dependence

on the source frequency of the perturbation spatial

growth rate, whose expression constitutes the the

oretical starting point of some criteria commonly

employed in hydraulic engineering applications, is

finally discussed. 2 GOVERNING EQUATIONS The system under investigation is an incompressible fluid flowing in a broad rectangular channel without inflow or outflow with a non-erodible plane sloping bed. The one-dimensional equations governing the motion are the well-known St. Venant equations: in which x= streamwise coordinate, t= time variable, g= gravity, ρ=water density, u= depth-averaged velocity, h= depth of the water surface, S 0 = bed slope, τ b = bed shear stress. Starting from a steady uniform flow u= u 0 , h= h 0 , the base state is perturbed

by an infinitesimal fluctuation, so that u= u 0 + u ′ , h= h 0 + h ′ , τ b = τ b0 + τ ′ b . The substitution of the perturbed variables in equations (1)-(2) leads, after the linearization, to the following problem: Expressing the bed shear stress in terms of bulk velocity square as τ b = ρC f u 2 and assuming a constant value of the friction coefficient (C f =C f 0) equation (3) becomes: Considering the following non-dimensional variables: equations (5)-(4) can be rewritten in dimensionless form as

where F r = u 0 /(gh 0) 1/2 denotes the unperturbed

Froude number.

The first order system (7)-(8) can be easily refor

mulated only in terms of depth and it reads:

As the classical linear stability theory prescribes, the

perturbation h˜ ′ is decomposed into elementary waves

like exp i(kx˜-ωt˜), with the complex wave number

k = k r + ik i and the complex frequency ω=ω r + iω i .

The substitution of such perturbation into equation (9)

leads to the quadratic dispersion equation:

In performing a spatial stability analysis the fre

quency ω has to be considered real and the instability

is related to the occurrence of complex wave num

bers k , roots of equation (10), characterized by positive

imaginary part. On the other hand, in a temporal sta

bility analysis, the wave-number k is assumed to be

real and the unstable conditions are related to the exis

tence of complex frequenciesω, roots of equation (10),

characterized by negative imaginary part. Performed

linear temporal stability analyses (Brock, 1970; Ponce

& Simons, 1977) have shown that the flow model (9) is unstable when the Froude number exceeds the limit value 2, independently on the of the perturbation wave-length value.

In order to ascertain which of the two techniques is the most appropriate to describe an unstable pro cess, a study about instability nature can be performed. As mentioned before, instabilities have been distin guished between Convective and Absolute (Huerre & Monkewitz, 1990). In the Convective instability an initial disturbance, localized in space, is swept away from the source leaving the flow domain unperturbed as time tends to infinity. By contrast, the instability is classified as Absolute, if a preferential direction of propagation does not exist. In this case the dis turbance spreads both in downstream and upstream directions contaminating the whole domain as time tends to infinity.

A spatial analysis leads to a well posed problem only when the instability is of convective type. Contri butions to the theoretical foundations underlying these notions have been brought out in studies concerning plasma (Bers, 1975) and hydrodynamic (see the review of Huerre & Monkewitz, 1990) stability. In a morpho dynamic context the nature of bar formation process

has been investigated recently by Federici & Seminara

(2003). 3 STUDY OF INSTABILITY NATURE The nature of instability of the linearized St. Venant flow model can be ascertained by studying the impulsive response of equation (9).The usual approach leads to investigate the asymptotic time behavior of the solution (Green's function) of the following initial value problem: where δ= the Dirac delta function. The spatial domain is assumed to be unbounded and homogeneous initial conditions are prescribed. Following Huerre & Monkewitz (1990), the base flow is classified as linearly unstable if there exists a ray x˜/t˜= cost along which A linear unstable condition of flow is convective if, along ray x˜/t˜ = 0, it occurs whereas it is absolutely unstable when, along the ray x˜/t˜= 0, The asymptotic behavior of the Green's function (12)-(14) can be analyzed representing G(x˜, t˜) as double Fourier integral in the complex ω and k planes in which D(k ,ω, F r)= the dispersion operator given by equation (10). The contours B and C are placed in the region of absolute convergence of G(x˜, t˜). The application of the steepest descend method to equation (15) allows to analyze the asymptotic conditions (12)-(14) only through the study of both temporalω(k) and spatial k(ω) branches of the dispersion relation D(k ,ω, F r) in the complex ω and k planes (Briggs, 1964; Huerre & Monkewitz, 1990). It can be shown (Huerre & Monkewitz, 1990) that condition (12) is not fulfilled, i.e. linearly stable conditions of flow occur, if, for all k = k r and for all temporal

branches ω(k r), ω i (k r)< 0. Therefore, the presence of

linearly unstable conditions of flow will be detected if

the maximum value ω max i of ω i (k r) is positive definite.

The simple structure of the dispersion equation (10)

allows to deduce in an analytic form the temporal

branches ω(k)

Setting k = k r in the right hand side of expres

sion (16), it follows that, according to previous results

(Brock, 1970), linearly unstable conditions of flow are

permitted only when the Froude number exceeds the

limit value F rc = 2.

In order to ascertain the nature of unstable con

ditions of flow, occurring when F r >F rc , a careful

study of the spatial branches is required. Briggs (1964)

proved that the absolute character of the instability can

be defined looking for the complex frequencies ω 0

for which two (or more) spatial branches k(ω) merge

(pinch-type singularities). The positive definiteness of

ω 0 i is the necessary condition for the absolute character

of the instability. The sufficient condition comes from

the analysis, for large enough ω values, i.e. ω i >ω max i ,

of the spatial branches k(ω) that coalesce for ω=ω 0 .

The instability will be of absolute type if forω i >ω max i

at least two of such branches are placed on opposite

sides of the real k-axis.

The study of the branches location, in condition of

spatial evanescence ω i >ω max i , ensures that the insta

bility, corresponding to the pinch, will appear as two

waves, propagating in opposite directions, without

any discontinuity at the origin of the spatial coordi

nates. The time growth of these waves, that behave

as only one wave (normal mode), will lead to the

contamination of the whole domain as time tends to

infinity.

Since the spatial branches merging points corre

spond to the saddle points of the temporal branches

ω(k) (Huerre & Monkewitz, 1990), the necessary

condition of the Briggs criterion can be analyzed alter

natively looking for the complex wave number k 0 such

that ∂ω/∂k = 0, i.e. ω 0 =ω(k 0).

The last technique is the most useful when many

spatial branches are present. The above procedures

may be applied only when pinch-type singularities

occur at finite values of k 0 . If such an instance does

not occur the singularities will be defined as essential

and the Brigg's criterion cannot be straightforwardly

applied. In this case, a direct numerical evaluation of

G(x˜, t˜) is needed (Park & Huerre, 1988).

In the St. Venant flow model (9) only two spatial

branches exist whose merging points are given by The inspection of (18) and of (17) with ω=ω 0 allows to conclude that the instability of the St. Venant flow model has a convective nature, since only finite pinch-type singularities characterized by negative imaginary part exist, for F r > 2. 4 RESPONSE TO A POINT-WISE TIME-PERIODIC DISTURBANCE The absence of absolute instabilities suggests analysing roll-waves generation process by linear spatial analysis. In this context, considering the dispersive effects, the time-asymptotic response of the flow model to a point-wise external source oscillating with a prescribed frequency is studied. The dimensionless pulsation of the oscillation is denoted as ω e = 2πf e /S 0 , being f e = h 0 /(u 0 T e) the source frequency and T e its dimensional period. The time asymptotic response of the flow model can be studied by investigating the time asymptotic behavior of the solution (Green's function) of the following problem: in which the flow domain is assumed to be unbounded and δ= the Dirac delta function. As in the pulse case, the solution of problem (19) can be described as double Fourier integral in

the complex ω and k planes. being D(k ,ω, F r)= the dispersion operator given by (10). In unstable condition of flow (F r >F rc), the time asymptotic behavior of relation (20) can be written

as a superposition of two waves traveling both in the

downstream direction (Bers, 1975):

where u(x˜)= the unit-step function, k l (ω e) with

l= 1, 2 are the two spatial branches, obtained setting

ω=ω e in expression (17)

and finally

4.1 Spatial grow rate

Independently of the ω e value, the inspection of (22)

leads to recognize the existence of only one spatially

excited wave (k i (ω e)< 0); the other one is spatial

evanescent. A graphical evidence of such findings is

given in Figure 1 in which the imaginary part of the

two spatial branches k(ω e) for F r = 2.5 is showed.

Let focus the attention on the primary excited wave.

Equation (22) indicates that, for a constant Froude

number value, the imaginary part of the wave-number,

i.e. the spatial grow rate, is a bounded monotone

function ofω e or, equivalently, of the source frequency

Figure 1. Imaginary part of the wave number: solid line

unstable wave, k 1 ; dashed line evanescent wave, k 2 . -

F r = 2.5. f e , for a fixed bed slope. Independently of the Froude number, very small values of the frequency lead to a vanishing spatial growth rate. On the other hand, the limit process for very high frequencies (f e →∞), furnishes the minimum asymptotic value of the k i , i.e. maximum

spatial grow rate, that reads 4.2 Propagation phase speed The analysis of propagation phase speed c=ω e /k r (ω e) suggests that the excited waves is the primary one (faster) while the evanescent one is the secondary one (slower). In Figure 2 the propagation phase speed of both waves versus ω e is depicted for F r = 2.5. The diagram reveals that the c value of both waves is not constant and strongly depends on the value of the source pulsation. Similar results have been derived by Supino (1960) in studying the evolution of small waves in hydraulic channel, starting from the linearized St. Venant flow model. For fixed value of the bed channel, the propagation phase speed is a monotone function of the dimensionless source frequency f e and decreases as the frequency increase, tending to the asymptotic value 1+ 1/F r , which represents its minimum value. The maximum celerity value occurs at f e = 0 and it is 1.5, independently of the Froude number. 4.3 Distance for roll waves formation Spatial growth rates, formally equivalent to the asymptotic value (24), have been deduced from previous Figure 2. Phase speed: solid line unstable wave, c 1 ; dashed line evanescent wave, c 2 . - F r = 2.5.

linear analyses that do not consider the dispersive

effects (Vedernikov, 1945, 1946; Liggett, 1975). More

over, these growth rate expressions have constituted

the theoretical justification to semi-empirical cri

teria for predicting the presence of the roll-waves

(Montuori, 1961; Julien & Hartley, 1986).

In particular, Montuori (1961, 1963) related the

formation of the roll-waves not only to the Froude

number but also to the channel length L. Starting

from the results of the spatial linear analysis of

Vedernikov (1945, 1946), the author introduced a func

tional dependence of the critical Froude number value

upon the non-dimensional channel length, LS 0 /h 0 ,

that, as far as wide rectangular channels are concerned,

may be rewritten as follows:

The amplification factor ε= 10 −4 appearing in (25)

has been calibrated starting from numerous field data

collected in Europe and in Russia. The curve defined

by equation (25) individuates two disjoint regions, in

the LS 0 /h 0 − F r plane. Roll-waves formation is inhib

ited in flow conditions characterized by LS 0 /h 0 − F r

pairs laying below the curve.

Figures (3) and (4) depict the deviation of the cal

culated spatial growth rate from its asymptotic value

(α= k i /k min i) versus the frequency f e , for two different

channel bed slope values (S 0 = 0.01 and S 0 = 0.30). In

each figure three different values of the Froude number

(F r = 2.5, F r = 5 and F r = 7.5) have been considered.

In the S 0 = 0.01 case (Fig. 3) only for very low fre

quency values (T e > 500 h 0 /u 0) substantial deviations

from the asymptotic value can be detected. In contrast,

for higher bed channel slope value (Fig. 4) consider

able differences appear in a broader frequency range.

Independently of the bed channel slope, the deviations

reduce when the Froude number is increased, even

though the Froude number effect appears to be less

significant.

From the above results it follows that the spatial evo

lution of the perturbation, according to the dispersion

effects in a linear approximation context, is gov

erned by three dimensionless parameters xS 0 /h 0 , F r ,

f e /S 0 . Therefore the conventional approaches employ

ing only two parameters xS 0 /h 0 , F r (Zanuttigh &

Lamberti, 2003, 2004; and Montuori, 2004) require

an additional constrain on the minimum value of the

physical disturbance frequency. We whish to stress

that such a lower bound may be particularly severe

in presence of channels with huge bed slope (Fig. 4).

Furthermore, neglecting the frequency effects leads

to overestimate the spatial growth of the disturbance.

This final remark provides a theoretical justification

for the experimentally ascertained underestimation of

the minimum channel length above which equation Figure 3. Spatial grow rate α= k i /k min i versus the dimensionless frequency f e , - S 0 = 0.01. Figure 4. Spatial grow rate α= k i /k min i versus the dimensionless frequency f e , - S 0 = 0.3. (25) predicts the presence of roll-waves (Montuori, 1961). As a matter of fact Figure 4 clearly shows that for large bed slopes the amplification factor is considerably reduced compared to its asymptotic value, in large range of dimensionless frequencies f e .Therefore equation (25) would correctly account for the above quoted experimental evidences, provided k min i is replaced by the correct spatial growth rate of the unstable wave given in (22) and the frequency of the disturbance is not excessively large.Which is the appropriate disturbance

frequency value is still, as far as the authors are

aware, an open question and requires properly design

experiments or direct numerical simulations.

5 CONCLUSION

In the present paper, the convective instability property of the one-dimensional linearized flow model has been preliminarily demonstrated. The Briggs criterion, con cerning the analysis of the branch-point singularities of the dispersion relation, has been applied. Starting from the ascertained convective character of the insta bility a spatial linear stability analysis, which naturally accounts for the dispersive effects, has been carried out. Results showed that, in unstable condition of flow, a point-wise temporal oscillating perturbation gener ates two waves, both propagating in the downstream direction. The primary is spatially growing, the sec ondary is spatially evanescent. The spatial growth rate of the unstable wave strongly depends on the frequency of the disturbance, particularly as far as high bed slope channels are concerned. It follows that the descrip tion of the spatial evolution of the perturbation only through the Froude number and the non-dimensional distance, commonly assumed in hydraulic engineering criteria, may lead to overestimate the spatial amplifi cation of the perturbation, depending on the temporal frequency of the disturbance and on the bed slope of the channel.

ABSTRACT: Among the damaging consequences of a dam-break flow on the downstream valley, the mor

phological changes due to the heavy transport of sediments are not the least. The rapid flow has an important

erosive power and a high transport capacity. Besides scouring of the river bed, erosion of the banks can drastically

increase the river width and hence completely reshape the valley. Simplified dam-break experiments have been

undertaken to investigate this problem at the laboratory scale. They were conducted in an asymmetric horizontal

channel with a single bank on one side and a glass side-wall on the opposite side, allowing visual observation of

the flow features. The bed and the banks are made of uniform sand. By means of those simplified experiments

it was possible to reproduce qualitatively the main features of real events such as the important enlargement of

the valley due to the failure of the banks and the deposition of the material eroded from the banks. The major

difficulty with such experiments is to obtain reliable data of the rapid evolution of the system. This concerns the

water profile, the bed profile and the shape of the cross sections. Indeed, using intrusive probes in rapid flows

over movable bed and banks heavily disturbs the system and modifies considerably the results (for example:

scouring around a level probe). Furthermore, it provides only a one-point measurement, hence making it unfea

sible to obtain a wide set of data given the amount of work required for test preparation. As an alternative we

resort to imaging techniques for the non-intrusive characterisation of the flow features over the full coverage of

the digital images. The present work relies on an original imaging technique based on laser-sheet technology to

track the evolution in time of the whole cross-sectional profiles, both above and below water.

1 INTRODUCTION

Erosion of the bed and banks of a river is usually a long

term and never-ending process that slowly induces

geomorphic changes to a valley. In some extreme

cases, rapid and important geomorphic changes may

occur after a catastrophic event such as a dam or dike

break. The debris-flow like rheology of the wave in the

early stages of the dam-break flow evolves to intense

bedand suspended-load transport with a particularly

high concentration. This flow is highly transient and

invades parts of the valley that were probably never

inundated in the past.The geological equilibrium of the

banks is ruined and dramatic morphological changes

can be expected.

In July 1996, the heavy rainfall in the Saguenay

region of Quebec induced severe floods in many

rivers and a dike-break on the lake Ha!Ha! (Brooks

& Lawrence, 1999). The flood wave completely

reshaped the alluvial valley and the river Ha!Ha! bed (Fig. 1), with successive reaches of intense erosion and deposition, and an overall increase in channel width that reached 700% in some locations. In the last years, a number of authors have studied the problem of rapid geomorphic changes induced by a dam-break flow. The problem was first tackled from a 1D perspective with laboratory experiments in idealised conditions and with artificial sediment analogues (see e.g. Capart & Young, 1998, Fraccarollo et al., 2003). In order to get closer to natural valleys, an attempt is now made to investigate the impact of dam-break flows on lateral erosion of the valley flanks. Small-scale laboratory experiments proved to be able to reproduce quite well the behavior observed in real events, at least with non-cohesive material. Recently, experiments were carried out in a half-channel (Spinewine et al., 2002) and imaged in such a way to obtain the time evolution of the water and bed level. The key problem with such flows is to obtain reliable data without perturbing the flow. Intrusive measuring

Figure 1. Geomorphic changes induced by the lake Ha!Ha!

dam-break in July 1996.

techniques can modify the results significantly. For example, local scouring around a bed level probe may completely alter the bed evolution.

As an alternative to intrusive measurements, this paper presents an original non-intrusive imaging technique based on laser-sheet technology. The rapid evolution of a whole cross-section is tracked during the dam-break experiment, both below and above the water surface.

The experiment presented in this paper is used in the benchmarking program of the IMPACT European project (le Grelle & Zech, 2003). This research project addresses the assessment and reduction of risks from extreme flooding caused by natural events or by the failure of dams and flood defense structures.

2 EXPERIMENT DESCRIPTION

2.1 Experimental set-up

Dam-break flow experiments in an erodible channel were carried out at the Civil Engineering Laboratory of the Université catholique de Louvain. The experimental set-up is sketched in Figure 2. It consists in a half-width channel with a single erodible bank. The total length is about 3 m.The initial shape of the section is prepared by profiling compacted sand as defined in Figure 3a, where the banks make an angle of 50 ◦ with

the bed. In the longitudinal direction, the bed and the

bank crest are initially horizontal (Fig. 3b). rigid bank Gate erodible channel Figure 2. Experimental set-up. (a) (b) 150 h 0 150 134 160 80 50° 211 Gate Figure 3. Initial conditions, (a) cross-section and (b) elevation (dimensions in millimeters). The erodible bed is initially fully saturated while the banks are only partially saturated with water. The important drainage capacity of the sand used in the experiment makes it impossible to maintain the banks in a fully saturated state. The reservoir upstream from the gate is filled up to 15 cm. In the reservoir, the banks are rigid and no erosion is thus possible. The sediments consist in uniform sand with the following characteristics: a median diameter of 1.8 mm, a unit mass of 2615 kg/m 3 , a lose bed porosity of 40.5% and a permeability of 1.5 cm/s. The experimental set-up used here is similar to the set-up used by Spinewine et al. (2002). These authors performed geostatic bank failure experiments to define a stable initial bank slope for the humid sand and to measure the angles of repose of the sand after a bank failure. Their observation is reproduced in 85° 37°

Figure 4. Angles of repose after a bank failure, from the

geostatic experiments by Spinewine et al. (2002).

Figure 5. Bank erosion resulting from intermittent block

failure.

Figure 4: the angle of the bank is 85 ◦ above the water

level and 37 ◦ under water.

2.2 General flow description

The experience is launched by suddenly raising the

gate. This releases a dam-break wave which rapidly

propagates down the channel and triggers a series of

bank failures. The water does not fill the channel up

to the top of the embankments and the flow can thus

not erode them only by bedload transport. In fact, the

rapid erosive flow attacks the toe of the banks with the

consequence that they become steeper near the bed and thus destabilized. Bank erosion then occurs in fact as a series of intermittent block failures (Fig. 5) that feed the flow with an important quantity of sediments.

The channel enlargement due to bank failures is the most important in the immediate vicinity of the dam. The water depth there is greater and the flow shows a two-dimensional expansion from the reservoir into the channel.

After about 10 s, most of the geomorphic action has occurred. Only light bedload transport can be observed and the banks are no longer affected. 3 LASER MEASUREMENT TECHNIQUE The overall principle of the method is to use a laser light sheet to enlighten a given cross-section, to localise the trace of the imprinted laser line onto digital images of a remote camera through the transparent side-wall, and to project the line back in 3D space using distinct projective transforms for the immerged and emerged portions. The method is detailed somewhat further in the next sections. However, a detailed description of the camera calibration method and specific projective transforms goes beyond the scope of the present paper whose objective is to focus on the results of the method. We refer the interested reader to Spinewine et al. (2003) for more details. The companion paper in this conference (Spinewine et al., 2004) applies a similar technique to dike breaching experiments for tracking the evolution of the breach geometry as a function of time. 3.1 Set-up A laser light sheet is used to enlighten a crosssection through the channel side-wall. The flume, the laser-sheet and the camera are sketched in Figure 6. Illumination from above through the water surface would induce uncontrolled refraction effects at the air/water interface. Orthogonal illumination through the side-wall, on the contrary, avoids such alterations. The trace of the laser light sheet imprinted on the cross-section (Fig. 7) is imaged with a digital camera located more upstream at the same height as the laser source. An example of a resulting image is shown

in Figure 8. Two portions of the line are visible on the figure: one profile for the dry bank above water, and one for the submerged part of the bank. The transition between both curves generally escapes to observation. This explains why the resulting profiles shown in further figures present an interruption around the location of the water surface. 3.2 Treatment of the images After the experiment, a series of images of type of Figure 8 are obtained. On each image, the pixel coordinates corresponding to the trace of the laser are identified using an automated algorithm. Those pixel coordinates are then projected in 3D space using separate geometrical transformations for the above-water and under-water profiles: indeed, the differing refractive conditions need to be accounted for through separate calibration procedures (Fig. 9). Both profiles are merged together to yield the shape of the full cross-section in a given instant. Details about geometrical transformations can be found in Spinewine et al. (2003). The results were found to be surprisingly reproducible, even though the bank erosion mechanism

Figure 6. Set-up for the laser-sheet measuring technique.

Figure 7. Trace of the laser sheet on the channel.

through intermittent block failures is quite stochastic.

Three runs were carried out for each cross-section. An

example of the reproducibility (three different runs,

same section, same time) is shown in Figure 10.

4 EXPERIMENTAL RESULTS

The experiment was carried out several times to mea

sure the evolution in time of 8 cross-sections located at

0.25 m, 0.50 m, 0.75 m, 0.95 m, 1.25 m, 1.5 m, 1.75 m

and 2.25 m from the gate, respectively (Fig. 11). Those

measurements allow to investigate in detail the pro

cesses of bank failure and subsequent deposition of

the failed material over the channel bed.

The evolution of cross-section S2 located 0.50 m

downstream from the gate is shown in Figure 12. The Figure 8. Sample image obtained during the experiment. Figure 9. Calibration of above-water and under-water situations. Y Z Figure 10. Reproducibility of the experiment – Crosssection at x= 2.25 m after 5 s. rapid rise of the water level following the dam-break induces rapid and important bank failures. After 2 s (Fig. 12b), the water has reached the section and a block failure occurred. The shape of the cross-section indicates deposited sediments at the toe of the bank. After 5 s (Fig. 12c), the cross-section has already evolved towards the final shape, with the bank making an angle of 37 ∘ with the bed, corresponding to the angle of repose under water. The portion of the bank with a steep slope could not be measured on this image. The flow at this stage is highly transient and the rapid moving water surface induces perturbing reflection effects on these images.

Evolution of section S8 (x= 2.25 m) – (a) t= 1 s, (b) t= 5 s, (c) t= 10 s, and (d) t= 15 s. Figure 13 shows the evolution of section S8 located 2.25 m downstream from the dam. The erosion of the bank is more progressive. At t= 5 s (Fig. 13b), only the lower part of the bank failed due to the arrival of the dam-break wave. Then, after t= 10 s (Fig. 13c), erosion at the toe of the bank has induced a new failure but the crest of the bank is still not reached. After 15 s (Fig. 13d), the width of the

valley has increased as a consequence of further failures of the bank. 5 CONCLUSION For accurately measuring rapid transient flows involving significant geomorphic aspects, it is important to

use non-intrusive techniques. Using a laser sheet to

enlighten a cross-section of the channel, it was possi

ble to obtain an accurate description of the evolution of

this cross-section, both above and under the water sur

face. Combining this technique with bed elevation and

water surface measurements obtained by imaging the

flow through the side wall of the channel (Spinewine

et al., 2002) yields a valuable characterization of the

experiment. This then allows a refined analysis of the

ongoing processes.

The bank erosion is driven by a succession of block

failures slumping into the water.This feature, observed

in the experiments, also appears on the measured pro

files. Despite the discrete character of the bank failure

mechanism, the measured profiles show a very good

reproducibility of the experiment.

ABSTRACT: We present results from a series of laboratory experiments simulating the breaching of a coarse

sand dike by overtopping. The focus is set on a range of measuring systems used to gather as much information

as possible on the evolution of flow parameters and breach geometry during the tests. In particular, we present

an original non intrusive technique involving a sweeping laser light sheet system combined with digital imaging

algorithms, whose objective is to obtain full digital terrain models of the evolving breach topography. Results are

emphasized, and some degree of interpretation is performed in light of other observations and breach modelling

frameworks found in the literature.

1 INTRODUCTION

Understanding and preventing the occurrence and

development of breaches in dams and/or river dikes has

recently attracted widespread interest from both the

research community and the civil society. The proba

ble increase in the occurrence of extreme hydrological

events resulting from climate changes, combined with

the increased industrialization of river valleys, has

brought the expected human and economic conse

quences in case of dike breaches to a critical point

at many dams and along large portions of embanked

low-land rivers.

However, the development of numerical models for

the prediction of breach formation and development is

still in the early stage (Wahl, 1998; Singh, 1996). Most

available models do rely on crude assumptions for

the flow (uniform, gradually varied), breach discharge

(weir formulas), cross-section (rectangular, triangu

lar, etc.) and erosion rates (lateral, vertical). Breach

width and peak outflow, two utmost important param

eters for risk analysis studies, are often derived from

semi-empirical relations calibrated against a limited

number of data sets (Morris and Hassan, 2002). How

such relations are linked to dike characteristics and soil

properties remains unclear, and estimation of the asso

ciated uncertainty in terms of parameter sensitivity is

somehow left over to the rule of thumb.

This comes in contrast with an integrated frame

work of governing equations able to grasp the under

lying mechanisms of the coupling between flow dynamics, breach erosion, sediment transport and lateral bank failures in a unified description. Since recently, such physically-based models try to start from scratch, and to build up evolution equations that do not rely on a-priori assumptions on discharge, breach geometry and erosion rates (see e.g. Froehlich, 2002). Breach models in general, and

the latter class of models in particular, are still facing the lack of reliable data sets for validation. Real failures are not scarce in recent history, but are often poorly documented. At a different scale, laboratory experiments offer the advantage to control more precisely dike characteristics and to force failure mode (Benoist, 1989; Kulisch, 1994). They also allow the continuous observation of the breach growth process during the whole duration of breach formation and development. However, the measurements performed have, to the knowledge of the authors, mostly been restricted to global parameters such as e.g. discharge and crest width. The focus of the present paper is precisely set on such measuring techniques. We present results of an experimental campaign of breaching tests in a homogeneous coarse sand dike (Delobbe and Elslander, 2002). A range of measuring systems has been used and cross-validated, with the intention to gain as much information as possible on the evolution of discharges, water levels, and breach geometry. In particular, we present in more details a novel digital imaging technique whose objective is to track the evolution of the entire dike topography as a function of time. The method relies on a sweeping laser light sheet

to visualize breach cross-sections, and on 3D pro

jective transforms to merge individual profiles and

reconstruct the whole breach topography.

The remainder of the paper is structured as follows:

in the next section we present the experimental set-up,

including sediment characteristics and initial breach

geometry. Section 3 focuses on the various measuring

systems, and present in more details the original imag

ing technique developed for tracking the evolution of

breach topography. Results are presented in section 4,

preceding some concluding remarks.

2 EXPERIMENTAL SET-UP

2.1 The flume

Breaching tests were undertaken in a fixed horizontal flume with a length of 36 m and a width of 3.6 m, as illustrated in Figure 1.The dike was constructed across the flume with a crest length of 2.4 m, the remainder of the flume width being taken over by fixed abut ments on both sides. The dike crest is at 15 m from the upstream end of the flume, this length provid ing sufficient volume for acting as upstream storage reservoir.

The upstream part is separated in two parts (indi cated as 1 and 2 in Fig. 1) by a large gate. This has two advantages: at first, it allows to store the volume of water in the upper part, keeping the rest of the flume dry for building the dike. Secondly, the level in this upper reach is chosen in such a way that after grad ual opening of the intermediate gate the level attained at the upstream side of the dike is at the desired height. Adequate operation of the gate allows to fill the upstream part of the dike relatively fast, and hence avoid other modes of failure such as piping or seepage through the embankment.

Water in the downstream part of the flume dis charges freely in a lower reservoir at the downstream end, and the length of the lower reach is long enough to ensure that the downstream boundary condition does

not affect the flow conditions in the breach over the

entire duration of the test.

Upstream Downstream Dike Gate

Figure 1. Plane view and elevation of the flume, indicating

dike location and upstream gate position. 2.2 Dike geometry
The dike itself is built onto the rigid bottom of the flume. It has a length of 2.4 m, a crest width of 35 cm, and upstream and downstream slopes of 1:2 and 1:3 respectively. The height of the dike is 37 cm. In a second series of tests, the whole geometry was raised by 10 cm to provide a uniform layer of the same loose material below and downstream of the dike, in order to investigate the potential effect of the creation of a scour hole on the outflow and breach development. Failure by overtopping was enforced by digging an initial pilot channel in the middle of the dike. This initial breach has a trapezoidal cross-section, with a crest width of 19 cm, bottom width of 5 cm, height of 7 cm and slope angles of 45 ∘ . The overall dike geometry is represented in Figure 2. 2.3 Dike material
The type of sediments used as dike material and bottom layer is crushed coarse sand with grain sizes uniformly distributed in the range 1 to 2 mm. A range of standard tests (Vane test, Casagrande, Proctor) were performed to measure soil properties such as density, void ratio, friction angle, residual cohesion, permeability. Results are summarized in Table 1. Dike stability and seepage flow were simulated with a Finite Element commercial geotechnical package (Geo-Slope). Results, illustrated in Figure 3, were 7 19 5 45° 47 35 200 1 2 3 1 a b Figure 2. faced with experimental data of a preliminary seep

age test. Measured (1.43 l/s) and simulated (2.39 l/s)

seeping discharges were close to each other, giving

confidence in the soil properties obtained from the

various geotechnical tests.

To ensure dike homogeneity and reproducibility of

the test, the dike was built in successive layers of 10 cm.

Each layer was compacted with a given number of

strokes with a mass of 10 kg falling onto a steel plate

of 35× 25 cm. In-situ soil samples were taken to ver

ify that the same desired degree of compaction was

reached. The bottom layer used in the second series of

tests was compacted in a similar way.

2.4 Mode of operation

Tests were initiated by gradually opening the upstream

gate and filling the whole upstream part of the dike up

to the desired height, i.e. 2 cm below the dike crest level

Figure 3. Modelling of the seepage curve and out

flow through the dike, using a finite-element geotechnical

software. a b c d

Figure 4. Four stages of breach development: (a) initiation; (b) erosion along the downstream slope; (c) lateral migration;

(d) equilibrium stage. or 5 cm above the bottom of the initial pilot channel. This smooth filling phase lasts 1.5 minute, in order to avoid water waves reflecting on the upstream slope of the dike and threatening its stability. The breach then develops in time, and its geometry evolves to an equilibrium as the level in the reservoir decreases. Indeed, no inflow is added to the reservoir during the test. 11 tests were performed in total, 5 identical tests with the dike onto the rigid bottom (tests numbered C1 to C5) and 6 identical tests with a loose layer of sand below and downstream of the dike (tests D1 to D6). Figure 4 illustrates four characteristic stages of breach development, ranging from initiation to equilibrium. 3 MEASURING SYSTEMS A range of measuring systems were used during the first and second series of tests, in order to gain as much information as possible on the evolution of breach geometry, water levels, discharges and flow velocities. Those include both intrusive and non-intrusive, and point-wise or full coverage measurements. Not all the devices were used simultaneously. However cross-validation between successive tests confirmed an acceptable degree of reproducibility.

The following system of coordinates is used through

out the remainder of the paper: x-, yand z-axis are

respectively taken along the longitudinal, transverse

and vertical directions, and the origin is placed in

the middle of the flume at the upstream side of the

dike crest, and at the bottom level of the flume.

3.1 Standard measurements

Rather standard measurements are listed first:

- a series of two-wires resistive probes were placed

along the flume axis in the upstream reservoir to

measure the evolution of water levels. Discharge

through the breach was estimated from those water

level measurements;

- surface velocities in the breach were obtained

through tracking small floating tracer particles with a fast digital camera placed at the vertical of the dike breach, 2.5 m above the flume (see Fig. 5). Tracers were expanded polystyrene particles with a diameter of approximately 3 mm, and delivered from a vibrated silo in the reservoir. Custom parti cle identification and tracking algorithms (Capart et al., 2002; Spinewine et al., 2003) delivered the horizontal component of surface velocities;

- the breach width at various locations was manu ally deduced from the same images of the camera located above the dike crest;

- point measurements of water and bed elevations in the breach were obtained with a level profiler probe, used alternatively for the bed and water levels. The probe was located in the axis of symmetry along the downstream slope at x = 59 cm;

- the evolution of bed and water profiles along the thalweg were obtained by imaging a thin calibrated checker-board panel buried in the middle of the

Figure 5. Vertical image and floating tracers used to derive velocity measurements. breach (see Fig. 6); the perturbation created by this panel was negligibly small, as verified by comparing the results with the point measurements performed independently on a test where this panel was absent. 3.2 Sweeping laser topography A more original technique was developed with the objective to reconstruct the entire topography of the breach using a

non-intrusive imaging technique. The principle is to use a laser light sheet to illuminate a particular cross-section of the breach, capture the line imprinted on the dike onto digital images of a remote camera, and ultimately project it in 3D space with appropriate camera calibration. A similar principle was used in a companion paper (Le Grelle et al., 2004) for tracking bank failure events with a fixed laser line. Here, the ambition is to survey the whole dike by sweeping successive cross-sections with an oscillating laser line. The procedure (see Fig. 7) is described in more details here below. A laser is placed horizontally at the vertical of the dike crest (approximate position x = 0.55 m, y = 0, z = 2.50 m), and passes through a cylindrical prism to Figure 6. Thin checkerboard panel buried along the breach centreline to visualise water and bed profiles. LASER CAMERA MIRROR Sweeping movement Figure 7. Sketch of the laser surveying technique used for reconstruction of the breach topography.

produce a thin light sheet. The laser used is a red diode

laser with 12 mW output power, and the light sheet has

an opening angle of 39.3 ◦ .

The light sheet is reflected towards the dike using an

oscillating mirror, adjusted in order to sweep the dike

from the upstream slope to about 1 m below the down

stream toe. The sweeping cycle takes about 5 seconds,

which is small enough compared to the speed of breach

evolution to be assumed as quasi instantaneous.

A remote camera is placed more downstream (app

roximate position x = 4.4 m, y = 0, z = 2.45 m) and

oriented to cover the whole range of sweeping laser

lines. The camera is a Dalsa CAD4 operating at 40

frames per second for a resolution of 1024 × 1024

pixels × 256 grey scales. Given the covered field of

view, one pixel represents less than 2 mm in reality.

The images are recorded and processed offline. The contrasted line is automatically detected on the images using a series of filters, following tightly the procedure described in Capart et al. (2002).

The line, expressed as pixel coordinates, must now be projected in 3D space and world coordinates. This requires to know the position (or equation) of the laser light sheet. The latter is derived from two reference points of the laser line printed on two thin rods fixed above the dike. The procedure also requires a camera calibration transform, from which each pixel may be associated with a 3D ray originating from the camera focal point. Those rays are then intersected with the known plane of the laser light sheet to obtain the 3D position of the line. A detailed description is beyond the scope of the present paper. Nevertheless, we refer the interested reader to Spinewine et al. (2003) where details of camera calibration and projective transforms may be found.

Relying on the above assumption that the sweeping speed of the laser is an order of magnitude faster than the speed of evolution of the breach, the images cor responding to one sweeping cycle are then assembled into a single set of 3D data, from which a digital ter rain model of the entire dike may be obtained through

standard interpolation techniques.

The advantage of the method is that all the required geometrical information is implicitly encapsulated in the images, and that it is not required to manually mea sure the respective positions of the mirror, laser lines and camera. The method overall is relatively simple to implement and provides an unprecedented degree of details in the results.

However, it has an advantage that turns out to be a drawback too. Since the laser light passes through the water surface, what is seen from the camera is the line printed onto the sediment bed. On the one hand, this allows to have a detailed perception of the underwater bed geometry and slope angles. On the other hand, the underwater portion of the laser line undergoes alter

ation at the water surface due to the difference in LASER CAMERA 1 2 AIR WATER Figure 8. The vertical error due to differing refractive indexes in the air and water regions. Point 2 is actually measured on the image, whereas point 1 is the true position of the bed interface. Note that angles and refractive error is here extremely exaggerated for illustration purposes. refractive index of air and water. This is illustrated in Figure 8. Consequently the measured bed level has an error proportional to the water depth and slope of the water profile. While it may not be impossible to account for those refractive effects, this goes beyond the scope of the paper, and would require a measure of the water depth and longitudinal slope of the water profile. As an alternative, what we performed at least is an estimation of an upper bound for the associated error. In the worse conditions corresponding to maximal water depth and inclination of the water profile, the vertical error has been estimated to be in the order of 30 mm. Provided that it constitutes an extreme case, this is small but may not

be considered as negligible. On the contrary, measurements along the emerged flanks of the breach are not altered by this error, and the accuracy in this region is mainly related to pixel size and camera resolution. 4 RESULTS AND INTERPRETATION Results obtained with the various techniques described in the previous section are now presented. All results are presented using the system of coordinates outlined in section 3, and with reference time t = 0 corresponding to the moment when water starts to enter into the breach. The test to which measurements pertain is also indicated (test C1 to C5 and D1 to D6). 4.1 Discharge A typical curve for the evolution of the discharge through the breach is plotted in Figure 9. Peak outflow was typically close to 65 litres per second, and time to peak is about 3 minutes. The curve is surprisingly smooth and nearly symmetrical, a feature that seem to be related to the failure mode and material characteristics. The breaching development in the present experiments is mainly diffusive and progresses smoothly

with nearly uniform flow conditions along the down stream slope. This is in accordance with observations by Visser (1998) in largescale breaches of sand dikes, but not with observation of breaches in moraine dams or cohesive dikes (Morris & Hassan, 2002; Temple & Hanson, 1994). In the latter type of breaching, failure is triggered by the upstream migration of a head-cut on the downstream slope, whereby the discharge hydro graph shows a long period of relatively low discharge during the first stage, and then a sudden and drastic increase of discharge as the head-cut reaches the dike

crest and the breach fully develops.

4.2 Surface velocities

Mean surface velocities were derived from the par

ticle tracking measurements. Selected results for test

C3 are presented in Figure 10, showing the time evolu

tion of velocities at selected sections close to the dike

crest. The curved profiles reflect somehow the shape

of the outflow hydrograph, whereas the intercompari

son of the various profiles clearly shows the increase

in velocities as one progresses downstream.

We recall that the plotted values are mean surface

velocities averaged over the entire width of the breach

cross-section. Actual velocities along the centerline

are higher than those presented here. 0 0 1 2 3 4 5 6 5 10 15 20 Time [min] E l e v a t i o n [c m] Figure 11. Water level (black line) and bed level (grey line) evolution obtained from the level profiler located at section x = 59 cm. 0 10 20 30 40 Time [min] W a t e r e l e v a t i o n [c m] x = -22 cm x = -02 cm x = 18 cm x = 38 cm x = 58 cm x = 78 cm (a) (b) 0 10 20 30 40 0 1 2 3 4 5 6 7 0 1 2 3 4 5 6 7 Time [min] B e d e l e v a t i o n [c m] x = -22 cm x = -02 cm x = 18 cm x = 38 cm x = 58 cm x = 78 cm Figure 12. Centreline profiles of (a) water and (b) bed elevations obtained for test C4 with the method of the thin checkerboard panel, at selected cross-sections along the dike. 4.3 Waterand bed-level profiles at the centreline Water and bed levels obtained for test C4 with the level profiler located at x = 59 cm are plotted in Figure 11. Results for the whole series of C-tests ranged within a margin of less than 10% around those values. Note that the lowest attained bed level corresponds to the time of peak outflow. Past this moment it seems that lateral breach erosion continues whereas the flow has no longer enough transport capacity to evacuate all the sediments eroded from the breach side-walls. Profiles obtained manually from the observation along the thin checker-board panel buried

along the centreline are presented in Figures 12a and 12b for test C4.

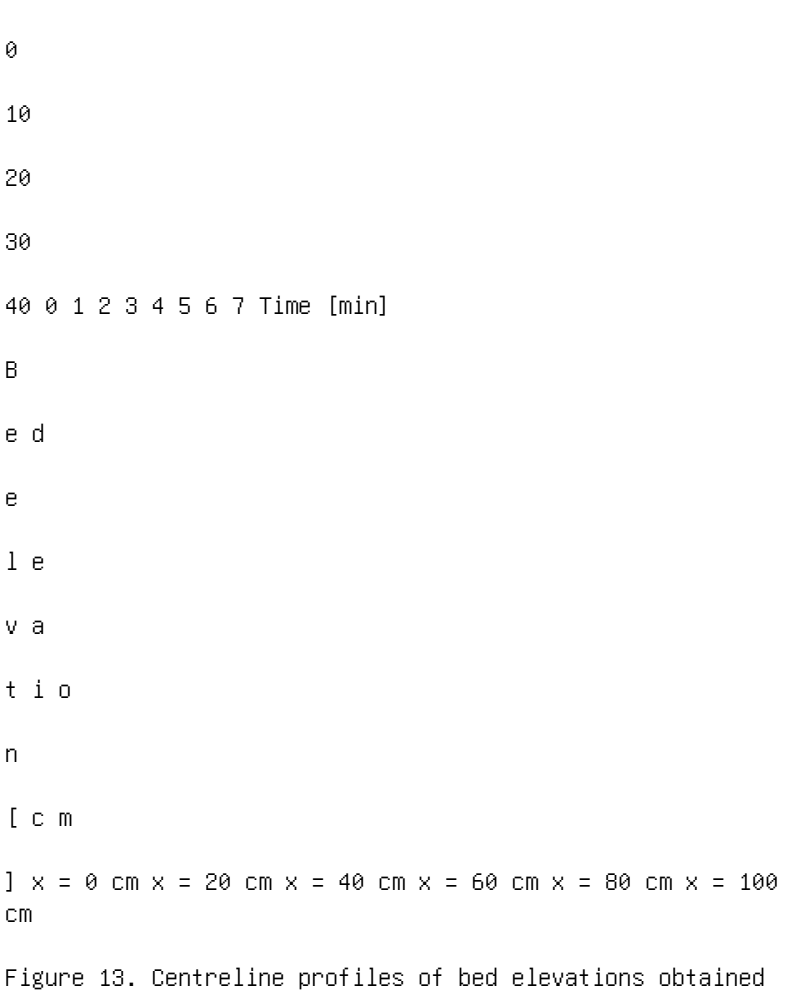

Figure 13. Centreline profiles of bed elevations obtained for test D2 with the same method as for Figure 12.

Figure 13 shows the related bed profiles for test D2, where an additional bottom layer of 10 cm of loose material was provided below and downstream of the dike. Comparison with Figure 12b indicates a slower process towards equilibrium, as the various levels have not converged after 6 minutes. One may also remark a noticeable influence of the presence of the bottom layer

on the vertical erosion, the latter allowing a deeper incision of the breach and a scour hole to develop on the downstream side.

4.4 Breach width

Breach width was obtained from the vertical images at three different sections: upstream side of the dike crest at x = 0 cm, middle at x = 17.5 cm, and down stream side at x = 35 cm. Results are illustrated in Figure 14 for test C1. In a first stage, the breach is wider along the downstream slope.After some time however, the breach widening develops faster on the upstream side, and the overall breach adopts a converging shape. Stabilization occurs after about 4.5 minutes.

4.5 Laser topography

Measurements obtained with the system of sweep ing laser light-sheet are now emphasized. Figure 15 shows an example of the set of reconstructed laser line traces corresponding to one full sweeping cycle of the mirror. The instant chosen, at t = 45 s, corresponds to the first phase of breach development: erosion occurs along the downstream slope, and the transported sedi ments are re-deposited in the wider reach downstream as flow velocities decrease. This creates a fan-like deposit, which is then later reincised as breach ero sion progresses and outflow approaches its maximum

value.

Full digital terrain models of the evolving breach

topography are then obtained by interpolating between

the sets of laser traces. Figure 16 on the follow

ing page, compares the results at selected times. The 0 1 3 4 5 6 72 40 80 120 Time [min] B r e a c h w i d t h [c m] upstream middle downstream Figure 14. Evolution of the breach width as manually measured on the vertical digital images of run C1. The three profiles respectively refer to the upstream side (x = 0 cm), the middle (x = 17.5 cm), and the downstream side (x = 35 cm) of the dike crest. Figure 15. An example of the set of reconstructed laser traces corresponding to one sweeping cycle at time t = 45 s. These profiles are then used to obtain interpolated digital terrain models, as illustrated in Figure 16. initial geometry is plotted in Fig. 16a. Figures 16b and 16c correspond to the first phase, as described above. The fan deposit is re-incised starting from Figure 16d, and the deepening of the breach progresses from downstream to upstream. Figure 16e corresponds approximately to the time of peak outflow, with an important rate of lateral erosion and deepening. The scour hole that develops at the toe of the downstream slope is particularly visible in Figures 16f and 16g. The breach then reaches an equilibrium stage when the drainage of the upstream reservoir is nearly completed. As seen in Figure 16h, the scour hole then gradually fills up again as transport intensity decreases. 5 CONCLUSIONS We presented results from a series of laboratory experiments involving the controlled overtopping and breaching of a coarse sand dike. paid to insure well-controlled soil parameters and test

reproducibility.

A wide range of measuring systems has been tested

on the experiments with success. In particular, the non-intrusive laser imaging technique has proven to provide an unprecedented degree of detail in the evo lution of the breach geometry. Such measurements are crucial for the validation of physicallybased breach models that do not rely on any assumption for outflow, breach topology and lateral erosion rates. We have shown how refractive effects at the air-water interface affects the underwater laser measurements, and have quantified an upper bound of the associated error. Many results were presented, and preliminary experimental findings were briefly discussed and com pared with the observations of previous authors. How ever, much of the interpretation work remains to be done. Further research will be carried out along this line in the future in our research team, including the development and validation of a physically-based mathematical framework and numerical model.

ABSTRACT: Fluvial erosion and mass failure are the two dominant processes causing river bank retreat.

In order to investigate the interaction between these two processes and to establish the relative dominance of

them under different conditions, research is being undertaken at two diverse study sites: Cecina River (Central

Italy) and the River Asker (Southern UK). The study is divided into two main phases: the first phase consists of

monitoring bank erosion processes; the second involves numerical modelling of the observed bank retreat. This

paper presents a description of the river sites, including relevant geotechnical and hydrological characteristics

of the bank materials, a description of the monitoring implementation including the beginning of the monitoring

activity, and the methodological approach for the modelling phase.

1 INTRODUCTION

River bank erosion can contribute significantly to the

sediment yielded from river catchments. Accordingly,

knowledge of the rates and controls on bank erosion

events is fundamental to understanding sediment flux.

Bank erosion occurs through a combination of mass

failures under gravity and fluvial erosion due to the

direct action of the flow. While progress has recently

been made in understanding the processes controlling large-scale mass failure of stream banks (e.g. Osman & Thorne, 1988; Rinaldi & Casagli, 1999; Casagli et al., 1999; Darby et al., 2000; Dapporto et al., 2001; Simon & Collison, 2002), much less attention has been paid to the role that direct fluvial erosion plays in bank retreat. This is unfortunate because fluvial bank erosion can be a significant process in its own right, and also is frequently the trigger for a mass failure event.

To address this limitation, the aim of this research is to quantify the controls on fluvial bank erosion, exam ine the interaction between fluvial erosion and mass failure, and to establish the relative dominance of the two processes under different conditions. One of the key problems that has prevented progress being made on these topics is that it has proved very difficult to obtain reliable empirical data that describe relevant physical controls on the process, particularly during the flood flows that typically generate erosion. Specifically, detailed studies of the erodibility of bank materials, and of near-bank boundary shear stresses, are virtually absent from the literature, primarily due to the problems associated with undertaking accurate fieldwork in the hazardous environment of eroding riverbanks. In this study we have therefore devised a new methodological approach that involves undertaking a combination of monitoring and hydraulic modelling investigations at two diverse study sites. Our rationale is to employ Computational Fluid Dynamics (CFD) techniques to obtain simulated high-resolution nearbank boundary shear stress data as a substitute for empirical data. The first study site is a reach of the Cecina River (central Italy), a gravel-bed river with large lateral bars and actively migrating outer banks. The second is a reach of the River Asker (southern UK), which is a low-gradient meandering river. These sites

were chosen because they represent end-members in a spectrum ranging from very active (Cecina bank erosion rate~7-17 m/yr) to mildly active (Asker bank erosion rate ~0.2 m/yr) eroding river meanders. This

paper outlines the methodological approach that we

are adopting at the Cecina and Asker and includes

a description of the monitoring implementation, the

monitoring activity since autumn 2003, and the

methodological approach for the modelling phase.

2 STUDY AREAS

2.1 Fiume Cecina

The Cecina river (900 km 2) is situated inTuscany (Cen

tral Italy).The study site is located near Casino diTerra

(Pisa) where the tributary Sterza meets the Cecina on

its left bank. The main criteria for selecting this site

were the high annual bank erosion rate and the avail

ability of river stage and flow discharge data from a

gauging station, situated about 2 km upstream, at Ponte

di Monterufoli. The study reach is about 500 m long,

though the actively eroding part of the bank (on the

left side of the Cecina) extends about 170 m upstream

from the Sterza confluence. The average gradient of

the reach is about 0.0021.

The eroding bank has an average height of about

5-5.5 m and it can be defined as a layered type. The

stratigraphy has been characterised by grain size anal

yses of samples collected from the exposed part of

the bank in six vertical sections, combined with the results of two static penetration tests (CPT). Six main units, not all of which are present in every section, were therefore identified (Figure 2) as being composed of the following materials: (1) gravel; (2) gravel-sand; (3) well sorted sand; (4) silt-sand-clay; (5) massive sandy-silt; (6) sandy-silt.

A preliminary geotechnical characterization of these sediments were performed on the fine-grained materials (units 4, 5, 6). Samples were collected using a range of in situ and laboratory tests. Laboratory tests, in addition to grain size analyses, included phase rela tionship analyses and triaxial consolidated-undrained tests (CU) (units 5 and 6). In situ tests included seep age tests (unit 6) to determine the saturated hydraulic conductivity k s (Amoozemeter test: Amoozegar, 1989), Borehole ShearTests (BST: Lutenegger & Hall berg, 1981) (unit 6) and matric suction measurements using a tensiometer. Erodibility parameters (critical shear stress, τ c , and erodibility coefficient, k d) were also determined (units 4 and 6) by in situ jet tests (Hanson & Simon, 2001) using a non-vertical jet test device recently applied specifically to river banks (Dapporto, 2001). A summary of the grain size anal yses, geotechnical and erodibility data is provided in

Table 1 and 2.

2.2 River Asker

The River Asker (49.1 km 2) is situated in Dorset

(Southern UK).The study site is located near Bridport. ITALY T y r r h e n i a n S e a Florence Rome Figure 1. Cecina river basin (Central Italy): location map. Figure 2. Moreover, the Asker site contrasts with the Cecina in that annual bank erosion rates are relatively low, so that the two sites between them cover a wide range of bank erosion rates. The study reach is about 200 m long, with an average gradient of about 0.007.

Figure 3. River Asker: stratigraphy of the bank.

The eroding bank has an averaged height of about 2–2.5 m and it can be defined as a layered type. The stratigraphy has been characterised by grain size analyses of samples collected from two vertical sections of the bank. Three main units were identified (Figure 3) as being composed of the following materials: (1) grey sand with silt (about 0.8–1 m thick); (2) red clayey silt with sand (about 1 m thick); (3) brown sand with silt (about 0.4 m thick).

A series of samples were collected for laboratory phase relationship analyses. Shear strength parameters were estimated by in situ Borehole Shear Tests. Erodibility parameters (critical shear stress, τ_c, and erodibility coefficient, k_d) were determined by in situ jet tests as described previously. A summary of the grain size analyses, geotechnical and erodibility data is provided in Table 3 and 4. Table 3. River Asker: grain size analyses. 1 2 3 Gravel (%) 0 0 0 Sand (%) 59.4 41.8 57.9 Silt (%) 37.5 52 38.2 Clay (%) 3.1 6.2 2.7 D16 (mm) 0.017 0.008 0.013 D50 (mm) 0.073 0.050 0.064 D84 (mm) 0.135 0.100 0.158 3 MONITORING ACTIVITY The principles of the monitoring activity are identical at each study site, though there are differences in the actual implementation of these activities at each study site. Nevertheless, in general the monitoring activity is focused on: (1)

characterising bed topography of the study reaches, for subsequent use in CFD modelling; (2) evaluating the peak flow discharge and water surface profile of that peak flow discharge along the study reaches for a range of flows, again for subsequent use in CFD modelling; (3) monitoring the magnitude of fluvial bank erosion generated by each flow event. The magnitude of bank erosion generated by each flow event is monitored using a combination of lowresolution networks of erosion pins together with high-resolution digital photogrammetry (e.g. Lawler, 1993). At the Cecina study site erosion pins have been installed in 6 sections, spaced at about 6 m intervals along the reach. At each section a set of 3 horizontal erosion pins, spaced at 0.5 m intervals up from the bottom of the bank have been installed.At the RiverAsker, a total of 19 pin sections are used at approximately 3 m intervals, with 4 pins spaced at about 0.3 m intervals up from the base of the bank. In addition, after each flow event a series of ground-based photographs of the eroding banks in each reach are taken for subsequent use in high-resolution digital photogrammetry. This technique, not discussed herein, allows estimates of bank retreat to be obtained across the entire eroding bank face, at approximately 0.2 m 2 spatial resolution. The hydrological characteristics of each flow event are recorded at the Cecina site in a semi-automated way using a network of pressure transducers and crestgauges. In particular two piezometers and a water level sensor have been installed in a section of the reach. These instruments are connected to a data logger that records at 15 minute intervals. In Figure 4 a flow event recorded by the water level sensor and the piezometers is shown. In addition, 11 crest gauges have been installed at different elevations (to cover a large range of flows) along both the Cecina study reach and the tributary Sterza. These sensors and gauges Table 4. River Asker: geotechnical properties and erodibility parameters. between them are able to characterise the water sur

face profile along the reach at peak flows, thereby

defining the ‘lid’ for subsequent use in CFD mod

elling (see below).The peak flow discharge is available at the gauging station located about 2 km upstream at Ponte di Monterufoli. Hydrological monitoring on the Asker is restricted to a network of 10 crest-gauges, spaced at approximately 20 m intervals along the study reach. Similar to the Cecina site, peak flow discharge data is available from the gauging station at Bridport, Dorset, located approximately 150 m downstream of the bank monitoring reach. At both study sites, efforts are made to acquire flow velocity data across the inlet of the study reach using 2D electromagnetic flow velocimeters during the flood events. These data are helpful in specifying the boundary conditions for use in the CFD modelling.

4 MODELLING PHASE

During the modelling phase, a range of specific flow events that occurred during autumn 2003 are selected for further analysis, using hydraulic and geotechni cal data collected during the monitoring phase for the modelling implementation.The first phase of the mod elling involves the evaluation of near-bank boundary shear stress distributions through the use of CFD mod elling. This allows quantification of the bank erosion rate due only to fluvial erosion, using an excess shear stress formula (see §4.1). The second phase comprises

bank stability analysis to determine the bank erosion rate due to geotechnical failure. This involves the use of the finite element seepage and slope stability analyses SEEP and SLOPE for dynamic simulation of bank pore pressures and mass failure conditions (see §4.2). The two modelling phases are, however, linked because the bank erosion rate due to fluvial erosion, determined in the first step, is used to provide dynamically adjusting bank profiles during the seepage and stability analyses. The two modelling phases are now described in more detail. Figure 4. Cecina river: flow event recorded by the water level sensor and the piezometers. 4.1 Computational Fluid Dynamics simulations The shear stress distribution exerted on the bank face by flows of varying magnitude is evaluated by undertaking hydraulic modelling using 3-dimensional Computational Fluid Dynamics (CFD) simulations of monitored flows (e.g. Olsen, 1991; Olsen & Skoglund, 1994; Olsen & Stokseth, 1995; Booker et al., 2001). Models are built using the high resolution topography data sets collected during the monitoring phase, with initial and boundary conditions specified using the flow velocity and water surface profile data obtained during the monitoring. Preliminary analyses of near-bank boundary shear stress distribution have also been evaluated at low resolution by applying a 1-dimensional HEC-RAS model, which allows determination of hydraulic parameters (water surface profile, flow velocity and mean boundary shear stress) under a steady state flow simulation (Hydrologic Engineering Center, 1997). The near-bank shear stress distribution is then estimated from the 1D simulation data using the results of research from laboratory channels (Leutheusser, 1963;

Kartha & Leutheusser, 1972; Knight et al., 1984).

The modelled shear stress distribution allows the deformation of the bank profile caused by fluvial erosion (recall that this is necessary to assess the influence of fluvial erosion on mass bank failure) to be quantified using a simple excess shear stress formula (Partheniades, 1965)

where ε (m/s) is the fluvial bank erosion rate per unit time and unit area, τ 0 (Pa) is the modelled shear stress distribution, k d and τ c (Pa) are the erodibility parameters (defined previously) and a is an empirically-derived exponent. Since the erodibility parameters k d and τ c are determined through the jet testing undertaken as part of the field monitoring described previously, and because a can be assumed equal to unity (Dapporto, 2001), the modelled shear stress is the only unknown parameter required to estimated the fluvial bank erosion rate.

4.2 Geotechnical modelling

Groundwater seepage and slope stability analysis are undertaken using the off-the-shelf software packages SEEP/W and SLOPE/W (GEO-SLOPE International Ltd, 2000). SEEP/W is a finite element code for determining pore water pressure distributions at the scale of a single flow event, and can model both saturated and

unsaturated flow under steady state or transient condi

tions. By assigning initial and boundary conditions,

and defining hydraulic and soil material properties

in relation to the field data collected in the moni

toring phase, the pore water pressure distribution is

computed using the flow equation in conjunction with

the continuity equation expressed in generalized form

for unsaturated soils (Richards, 1931; Fredlund &

Rahardjio, 1993) as follows:

where H is the unknown total head, K x and K y the

hydraulic conductivity respectively in x and y direc

tions, Q is the external flux and is the water

content.

The bank geometry is discretised using rectangular

or triangular finite elements and divided into regions
Boundary condition: flux from rainfall Boundary condition: hydrograph Initial water table 0.0 0.5 1.0 1.5 2.0 2.5 3.0 3.5 4.5 4.0 5.0 5.5 E l e v a t i o n (m a . s . l .)
Figure 5. Finite element seepage analyses: geometry of the problem for the Cecina river. composed of materials with different hydraulic and sedimentary properties. Different volumetric water content and hydraulic conductivity functions, based on the measured grain size distribution, are assigned to each material within the bank. The geometry of the problem in the case of the Cecina River is shown in Figure 5. For the initial point in the simulation, the water table is set to the same level of the river at the start of the selected flow event. Boundary conditions are then defined for transient simulations. These comprise an infiltration intensity versus time function based on rainfall data available from rainfall stations situated close to the sites and assigned to the nodes on the top of the bank, while the flow hydrograph, based on results of hydraulic analyses or on data measured during the monitoring phase for the selected events (Cecina River), is

assigned to nodes along the slope of the bank. The hydrograph is divided into discrete time steps, the model output consisting of the computed pore water pressure in each element within each time step. In the case of the Cecina, these results can be calibrated and compared with observed data from the installed pressure transducers. SLOPE/W is a software package that performs slope stability analyses by applying limit equilibrium methods (including Morgenstern-Price, Bishop, Fellenius, Janbu and more) to compute the factor of safety of the bank. This software is integrated with SEEP/W in such a way that the results (pore pressure distributions) of the seepage analyses are used as input data for the stability analysis. The bank geometry can be irregular so that changes in bank geometry due to fluvial erosion can be modelled.The slip surface geometry can be planar, rotational and composite, with or without tension cracks. Confining pressure is taken into account by specifying the surface water elevation. The Mohr-Coulomb failure criterion in terms of effective stress is used in the case of positive pore water pressure, while the extended Fredlund et al. (1978) failure criterion for unsaturated soils is used in the case

of negative pore water pressure. Geotechnical prop

erties, unit weight and shear strength parameters (c ′ ,

φ ′ and φ b), all determined from the field monitoring

as described previously, are defined for each different

material composing the bank.

In order to address the interaction between mass

failure and fluvial erosion, SEEP and SLOPE are used

to simulate the evolution of bank stability during and

after selected events. Two simulation scenarios are

investigated: on the one hand bank deformation by

fluvial erosion, previously determined using the CFD

modelling and equation (1), is taken into account by

updating deformed bank profiles at each time step of

the selected flow events; on the other hand control sim

ulations in which the bank has not been deformed are performed. Comparison of the results derived from these two scenarios will enable the effect of bank deformation on bank stability to be isolated.

5 CONCLUSIONS

In this paper we have outlined research being under taken at two different study sites in order to inves tigate the interaction and relative dominance between fluvial erosion and mass failure in determining bank retreat.

A description of the study areas and of the main riverbank characteristics sites is provided here. Mon itoring activity includes: (a) an initial topographic survey of the study reaches; (b) measurements of water stages and water surface profiles during flow events; (c) measurements of bank retreat generated by each flow event.

A new methodological approach is undertaken for the modelling phase, based on the combination of empirical data collected during the monitoring activ ity with hydraulic and geotechnical modelling. This approach involves: (a) the evaluation of a near-bank shear stress distribution by applying 3D CFD simula tions to quantify the bank erosion rate due to fluvial erosion; (b) finite element seepage and slope stabil

ity analyses for dynamic simulations of pore water

pressure changes and mass failures.

Two-dimensional fluvial channel model with bank erosion on triangular grid

D. Farshi 1 & H.-E. Minor

Federal Institute of Technology Zurich (ETHZ), The Laboratory of Hydraulics, Hydrology and Glaciology (VAW), Switzerland

ABSTRACT: A 2D numerical model to simulate the bed load transport and bank erosion in alluvial channels is developed based on shallow water equations (SWE) and Exner equation by Finite Volume (FV) spatial discretization. The Roe Riemann Solver has been utilized for the Flux estimation in SWE and the Local Lax-Friedrich solver is used for the bed load transport. A new formulation of bed shear stress has been presented and the bank erosion simulation been achieved through a new approach. Accuracy and stability of the code are tested against an available set of experimental data.

1 INTRODUCTION

In natural rivers and channels the erosion, sedi
mentation and bank line migration cause land loss,
bridge failure, shoaling of waterways and flooding.
In order to obtain maximum benefit and reduce the
adverse effects, research on the prediction of the men
tioned processes and the effective control strategy has
always been a key concern of hydraulic, geological
and river engineers. Therefore the analysis of flow,
bed level variations and bank erosion is a fundamental
prerequisite for many hydraulic engineering problems.
The complicated fluvial phenomenon is dominated
by the flowing water, sediment transport, bed forms
and bank erosion as well. Hence, numerical simula
tion of movable bed channels requires the accurate
prediction of the flow field, sediment transport and
bank erosion. The latter is one of the most difficult
points in numerical simulation, therefore many exist
ing alluvial channel models assume that the channel
banks are rigid, or adjust bank geometry according
to theoretical, but non-mechanical, arguments regard
ing energy or stream power expenditure (Chang 1988),
(Yang & Song 1986). Although changes in channel
depth caused by aggradation or degradation of river
bed can be simulated, changes in width cannot be

computed by most of the mathematical models. When

attempting to model natural systems this is a signif

icant limitation because channel morphology usually

changes with time and adjustment of both width and

depth are the rule rather than exception.

1 Formerly at German Armed Forces University, Hydro

science Institute, Neubiberg, Germany. Developing two-dimensional models for the fluvial process in channel with bank erosion is indeed a new challenge between researchers in recent years. An example is the model of Mosselman (1992), who has extended the model of Olesen (1987) by adding a mechanism for the erosion of cohesive banks, partly using a time averaged description of Osman and Thorne (1988). The model is formulated in a horizontal, channel-fitted coordinate system (s, n) which can be curvilinear and non-orthogonal. Duan et al. (2001) have developed an equation for bank erosion based on the sediment mass balance within a control volume near the bank. They implemented this equation in the enhanced model CCHE2D and simulated meandering process in channels. These models are applied to structured mesh, in which the implementation of the discussed problems is much easier. From the overview on recent literature it is obvious that there is still no general model to simulate the fluvial process, in particular the bank erosion, on an unstructured grid.The important advantage of unstructured grid is the ability to handle complex geometries with ease.The purpose of this work is to develop a twodimensional numerical model which is also capable of simulating these processes. 2 GOVERNING EQUATIONS 2.1 Hydrodynamics equations The two-dimensional unsteady flow of water can be described by Shallow Water Equations (SWE). By assuming hydrostatic pressure distribution and neglecting wind shear, Coriolis acceleration and eddy

viscosity, the following form of shallow water equa

tions (SWE) can be derived:

where U , Q and S are the vectors of primitive vari

ables, fluxes in the x and y directions and source term

respectively, given as:

Here h represents the water depth, ζ the water ele

vation, u and v the velocity components in x and y

directions and g the acceleration due to gravity. S Bx

and S By denote the bed slope in x and y directions. We

developed a new formulation of bed stress components

in order to consider the bed topography and some of

two-dimensional effect of water flow (Farshi 2002):

where τ B =Bed stress vector and z= bed elevation

The first and second component of bed stress vector

correspond to τ B x and τ B y respectively.

2.2 Bed load equation

The bed load continuity or bottom conservation equa

tion can be written in following form: Where p reperesents porosity, ρ s bed material density and u s bed load flow velocity vector. Introducing the bed load flux vector = (1-p)ρ s u s and after integration, (4) becomes: where z denotes bottom level and q b = 1/ρ s ∫ Z B Z F dz bed load transport rate vector. The bed load transport rates (q bx , q by) can be estimated by different equations such as Meyer-Peter and Müller (1948). In order to take the bed slope effects into account, the critical Shields parameter as well as bed load equations have to be modified (van Rijn 1993). 3 NUMERICAL MODEL 3.1 Hydrodynamic model The SWE and sediment flow equation are a nonlinear, coupled partial differential equations system.A unique analytical solution is only possible for idealised and simple conditions. For practical cases, it is required to implement the numerical methods. Keeping this in mind that an unstructured triangular mesh will be used, the Finite Volume (FV) method has been used for the discretization of SWE: in which = the area of the calculation cell Assuming U t is constant over the domain for first order accuracy, it can be written: The equation (13) can be discretized as follows: where m is number of cell or element sides, Q * i, j = (F * i, j , G * i, j) numerical flux through the side of the cell and n j unit vector of the cell side. In FV method,

the key problem is to estimate the normal flux through each side of the domain namely (Q ·n s). There are several algorithms to estimate this flux. The set of SWE is hyperbolic and, therefore, it has an inherent directional property of propagation. Algorithms to estimate the flux should appropriately

handle this property. The Riemann solver, which is

based on characteristic theory, is such an algorithm.

In this work we used an approximate Riemann Solver

due to Roe (1981):

where ❙ ❙˜ J ∗ ❙ ❙ = R˜ ❙ ❙ Λ̃ ❙ ❙ R˜ -1 , R˜ is the eigenvectors matrix

of J˜ ∗ , denoted by e˜ 1 , . . . , e˜ m with corresponding

eigenvalues a˜ 1 , . . . , a˜ m , ❙ ❙ Λ̃ ❙ ❙ = diag (❙ ❙˜ a 1 ❙ ❙ , . . . , |˜ a m |) ,

subscripts R and L are referred to the right and the left

side of the cell interface respectively.

3.2 Morphodynamic model

There are three different formulations for the numer

ical approximation of the bed-updating or Exner

equation:

- The SWE and Exner equation are separately and

numerically approximated using the same time step

- The SWE is converged to a steady solution and

then the bed will be updated. The overall time step

of this formulation is the morphological time step

of the Exner equation and the SWE is converged

to a steady state solution every time the bed is

updated. This approach gives inaccurate results and

also takes considerably longer computational run

times. (Hudson & Sweby, 2000)

• The whole system of the SWE and Exner equations

are numerically approximated. Unfortunately in this

case the Jacobean matrix of the equation system is

singular, which might be expected to create difficul

ties when implementing a numerical scheme for this

formulation. Moreover, it needs an accurate estima

tion of the wave speed of Exner equation, which is

generally not possible, due to the empirical form of

bed-load relations.

In this work, the first approach is used, in which; the

bed-updating calculation is decoupled from the flow

computation. The flow is assumed to be quasi-steady

in hydrodynamic model, which might be reasonable

due to the explicit simulation method. The FV method

has been also utilized to discretize the Exner equation.

The bed-updating equation (4) can be rewritten in the

following integral form:

The above equation can be discretized as follows: where q ∗ Bi, j is numerical bed load flux through the cell side. A simple flux solver like Local Lax-Friedrich (LLF) solver is used to determine the numerical bed load flux through the computational edge: whereα ∗ s = max (|u BL |, |u BR |), u BL and u BR are the sediment migrating velocities in left and right side of the calculation edge. 3.3 Numerical treatment The computation of bank erosion can be decoupled from the computation of bed topography if these phenomena occur slowly. Due to the explicit approach and small time steps of computation, this assumption can be reasonable.

The stability of bank strongly depends on the inclination angle. Referring to topography of bed, the maximum slope has to be computed to be compared with critical slope, namely tan γ cr .The maximum slope of a computational cell can be computed by magnitude of gradient vector (SD) of bed topography at each cell: After comparing γ max and γ cr , it can be decided whether or not the bank will be deformed. In the case of deformation, the cell will be rotated by (γ max – γ cr) about the rotational axis. The main task is to find a method to determine the rotation axes, which is appropriate to unstructured mesh such as in Figure 1. The rotation axis can be represented by rotation vector (RA) as follows: Figure 1. A schematic discretization of a channel bank. A1 A2 SD RA

Figure 2. Slope and rotation vectors of a cell A1=A2.

Figure 3. Physical model of TUM.

The rotation axis is located on the cell in such a form

that the areas of degradation and aggradation in the

cell are equal (Fig. 2).

Each cell is handled individually and rotated to

reach the stable angle. Since the individual handling of

each cell, it is necessary to implement this method in

an iterative approach. Therewith it can be guaranteed

that the calculated elevation of common grid nodes of

cells has the same elevation.

4 APPLICATION

4.1 Straight channel with movable bed

Experiments on a physical model were conducted at

the Technical University Munich (TUM) in Germany

to understand the fundamental flow behaviour to be

used in river restoration activities' planning of two

rivers Iller and Isar in Bavaria, Germany (Schmautz,

2003). The experiments took place in different series

in a specially established, spread over 100 ms long and

8 ms wide, model channel (Fig. 3). Figure 4. Geometry of the experiment (Q= 115.6 l/sec). Figure 5. Evolution of bed and bank erosion. Figure 6. Evolution of width in the half depth. Between different alternatives we choose the following experiment to validate and test the code (Fig. 4): The numerical simulation has been made for the above experiment for 87.6 hours. The bank erosion and bed evolution process is computed and compared with the experimental data. Figure 5 shows the simulated bed elevation changes and bank erosion at a cross section. Figure 6 represents the evolution of channel width with the half depth. As it can be seen

there is a good agreement between the experiment and

computational results.

5 CONCLUSION

This paper reports the research on the development

and verification of a two-dimensional model in simu

lation of alluvial processes in a channel on a triangular

mesh, which enables us to handle and define complex

geometry, easily.

The bed stress term has been handled in a new form

in order to consider the two-dimensional effects of

flow and the bed slope effects in bed stress calcula

tion. The bank erosion evolution has been dealt in a

form, which is suitable for unstructured grids, espe

cially the triangular mesh. However, this method needs

large computational time due to its iterative process.

Influencing factors of flow instabilities in steep and stepped channels

T.F. Ganz

Bayerisches Landesamt für Wasserwirtschaft München, Germany

F. Schöberl

Institute of Geography, Natural Hazards Research, Innsbruck University, Austria

ABSTRACT: Grade control structures are effective measures for restricting flow energy and bed erosion and

therefore frequently applied in steep creeks and torrents. Unfortunately in some cases they seem to be predisposed

for initiating hazardous flow instabilities during flood flows, e.g. instable flow waves at the Ruetz river/Tyrol

overtopping the river banks and causing dynamic stresses on new bank revetments could be observed, triggered

the launch of a systematic model study at the University of Innsbruck. In a first phase limiting discharges

for the occurrence of the instabilities were investigated. In a second step influences on the wave height and

the development along the channel reach were analysed. Significant parameters influencing the emergence

of flow instabilities proved to be the flow discharge and the mean bed slope. In addition to the quantification of

these parameters, the experiments focused on determining further influences like bed roughness, geometry of

the control structures and concentration of clay suspension. It could be proved that bed roughness and clay

concentration do not influence the onset of the instabilities but have a certain effect on the development of the

wave height. Wave frequencies turned out to be independent of slope, discharge, bed roughness and concentration

of suspension, but proved to be strongly related to the step height of the control structures.

1 INTRODUCTION

Drop structures are effective measures for the con

trol of flow energy and bed erosion and therefore

frequently applied in steep creeks and torrents. Unfor

tunately in some cases they seem to be predisposed

for initiating hazardous flow instabilities during flood

flows, e.g. instable flow waves could be observed at the

Ruetz river/Tyrol, triggering the launch of a system

atic investigation at the University of Innsbruck. When

waves develop, channel banks can be overtopped and

inundations are the consequence. Furthermore, the

dynamic stress of wave-crests on the riverbank may

become dangerous for the bank protection. Concern

ing the design of the river banks it is important to

predict the occurrence of waves and the develop

ment of wave height along the river reach. To analyse

the influence of different boundary conditions on the

emergence of flow instabilities, model tests were per

formed in a stepped laboratory flume. In a first phase,

limiting discharges for the occurrence of the instabil

ities were investigated. In a second step influences on

the wave height and the wave development along the

channel reach were analysed.

Most of earlier investigations deal with flow insta

bilities of clear water in smooth channels, e.g. Dressler (1949), Koloseus (1966) and Brock (1969). Whittaker (1982) was one of the first to study the effect of steps and the appearance of unstable tumbling flow conditions when the fully developed submerged hydraulic jump interferes with the physical boundaries of the step-pool system. Recent contributions were for instance provided by De Fessant (2001). Experimental and theoretical evidence for the occurrence of flow instabilities in mudflows goes back to Davies (1988), Savage (1989) and Coussot (1994). Cohesion and increasing viscosity may be seen as factors increasing the possibility of the development of instabilities. 2 EXPERIMENTAL RESEARCH This study is part of a wider research project analysing and assessing the conditions and dependencies of flow instabilities in stepped channels. In a first stage, limiting discharges for the occurrence of the instabilities were investigated, Ganz & Schöberl (2003). In the recently finished second phase, further factors influencing the wave properties and the development along the channel reach were analysed. Particular focus lay on the effect of bed roughness and the influence of varying water-clay mixtures on the developing wave 30 cm 1 : 1 16 cm step 1 : 1 16 cm bottom of platform 4 cm 23 cm roughness dm 3.2 mm 10 cm

Figure 1. Scale model of the stepped channel, cross-section,

amplitudes. As this research was initiated by a real

flood event at the Ruetz river, an alpine river in

Austria, the shape of the model channel resembles

approximately that of the river reach.

In the experiments, a tilting platform of 12 m length

with a slope adjustable up to 10% inclination formed

the basis for the channel model. The simulated chan

nel (bed width 0.3 m and height 0.2 m) was straight

aligned and had a trapezoidal cross section, (Figure 1).

The dimensions of the channel correspond to a model

scale of 1:40. At the bottom of the channel cascade

drops with a constant field length L of 0.505 m and

step height w of 0.04 m, were installed, (Figure 2).

Fluid discharges up to 70 l/s with varying concen

trations of clay were recirculated. The concentration

of the water-clay mixture was stepwise varied from

clear water to 18 Vol.%. Results of the determined

fluid properties according to Ganz (2003) are given in

(Table 1).

The roughness of the side walls was formed by

pasted grains (d m = 3.2 mm). The flume-bed between

the steps was formed by surfaces of varying roughness

by different nearly uniform grain mixtures, (Figure 3).

The equivalent bed sand roughness k was evaluated

by the concept of Monzavi (1972). In the experiments

discharge Q and slope S were systematically varied

for a given clay concentration and step-pool geometry. Figure 3. Used roughness categories. Figure 4. Arrangement of the floating device in the pool field. The progression of water depths was followed by floating gauges installed in each pool field, (Figure 4). Based on this equipment, the development of the waves along the channel and the maximum wave amplitudes at the end of the test reach as well as the wave frequency could be recorded for each test run. 3 WAVE FORMATION The tests demonstrated that beyond a minimum slope instabilities form only between a lower and upper limit of discharge, The step-pool configuration essentially influences the upper flow limit, Ganz & Schöberl (2003), Ganz (2003). Boundary conditions also affect the increment of wave depths along the channel reach. The wave height is strongly related to the flow distance from the inlet section. In Figure 5 the development of the maximum flow depth from gauge to gauge is displayed. As in this example, most of the experiments indicate that the maximum of wave height is reached before the end of the experimental channel. In terms of relative distance from the entrance $x' = x/L$ a maximum is reached for $x' < 22$. When hm is the undisturbed flow depth infront of each step and hmax the peak of the water depth generated by the waves, the local wave amplitude A is given by A= hmax – hm. Figure 5 shows the relative maximum water depth hmax/hm against the distance and the discharge for a given step geometry, mean slope and roughness. The maximum envelop of hmax occurs in the central region between the upper and lower discharge limit.

Figure 5. Development of hmax/hm along the channel for

a given slope, step geometry and roughness dependent on

discharge.

For the generalization of relations and criteria,

dimensionless numbers are used. For constant fluid

properties, dependencies according to Froude are to be expected, thus discharge is expressed by with q the specific discharge per width (m 3 /s, m), g gravity acceleration (m/s 2) and w the step height of the control structure. Relative bed roughness k∗ is given by k/w. Particularly for the analysis of viscosity effects it seems important to cover the whole range between smooth-bed and rough-bed conditions. In this case a combination with the fluid property number is used, thus the combined term is with k sand roughness of the bed (m), g gravity accel eration (m/s 2), ρ s density of suspension (kg/m 3), η s viscosity of suspension (mPas).

A ′ max represents the maximum amplitude A max divided by the step height w. Mean bed slope S and the volume concentration C f of the clay mixture are originally dimensionless numbers.

The main object of the investigation was the eval uation of the role of viscosity and bed roughness. Therefore different scenarios of bed roughness and water-clay mixtures were tested to determine effect on the wave formation.

3.1 Influence of roughness

The development of wave amplitudes for smooth bed conditions as well as 3 different rough surfaces rang

ing from k= 4.0 mm to 13.6 mm were tested against Figure 6. A ′ max dependent on q ′ and slope S for smooth bed conditions; %, k= 0.3 mm; k ′ = 3.1; C f = constant= 18%. Figure 7. A ′ max dependent on q ′ and slope S, rough bed conditions 1; k= 4 mm; k ′ = 43.2; C f = constant= 18%. discharge and slope; k ′ of the smooth bed equalled 3.1, compared to rough beds with k ′ between 43,2 and 139,9. Step-pool geometry and clay mixture were kept constant. Due to the complex dependencies, results were analysed by 2D colour plots (Figures 6–9). Distinct differences in the behaviour between the flow in smooth or rough-bed channels are obvious. According to Figure 6, smooth beds lead to higher amplitudes for rising slopes and a pronounced maximum in the range of 6.5%<S< 9% and 0,25< q ′ < 0, 70. For rough beds a clear attenuation of the amplitudes with rising roughness as well as a shift of the area of maximum wave height to higher slopes can be observed. While for the smaller roughness k ′ = 43, 2 the maximum area is reached for S= 5%, the area broadens for higher k ′ and ends up for k ′ = 139, 9 at S between 6–9%. Figure 10 and 11 allow a detailed inspection of A ′ dependent on varying roughness k ′ and constant slopes of 4% and 8%.

Figure 8. A ′ max dependent on q ′ and slope S, rough bed con

ditions 2; k= 10.1 mm; k ′ = 103.9; C f = constant= 18%.

Figure 9. A ′ max dependent on q ′ and slope S, rough bed

conditions 3; k= 13.6 mm; k ′ = 139.9; C f = constant= 18%.

Figure 10. A ′ max versus varying C f , S= 4%, rough bed

conditions 3; k= 13.6 mm; k ′ = 139.9.

Smooth beds behave contrary to rough beds. With

the higher slope A ′ is amplified, with the smaller slope

attenuated. The grey area marks approximately the

transition between roughand smooth-turbulent flow

conditions. For rough beds the dampening effect is Figure 11. A ′ max versus varying C f , S= 8%, rough bed conditions 3; k= 13.6 mm; k ′ = 139.9. Figure 12. A ′ max dependent on q ′ and slope S, rough bed conditions 3; k= 13.6 mm; k ′ = 279.7; C f = 0%. more pronounced for smaller

slopes than for higher slopes. 3.2 Influence of viscosity The variation of the concentration of water-clay mixture was investigated in the range of C f = 0% - 18%. Overall, the influence of varying concentrations kept astonishing small and can be neglected for first approximations.A detailed demonstration of the influence of concentration on A max is provided by the 2D colour plots in Figures 12-14. For these testruns different inflow conditions were applied so that the limits of discharge differs slightly to those given in Figures 6-9. Figures 15 and 16 allow a detailed inspection of the wave development for constant mean bed slopes. For larger slopes like S= 8%, rising concentrations up to C f = 12% produce an increase of the wave amplitude in the range of 10% . With higher concentrations, A ′ is reduced even below the level ofA ′ of clear water conditions. This marked behaviour for higher slopes almost completely disappears for smaller slopes as S= 4%.

Figure 13. A ′ max dependent on q ′ and slope S, rough bed

conditions 3; k= 13.6 mm; k ′ = 279.7; C f = 12 %.

Figure 14. A ′ max dependent on q ′ and slope S, rough bed

conditions 3; k= 13.6 mm; k ′ = 279.7; C f = 18%.

Figure 15. A ′ max versus variable C f ; constant slope S= 4%,

roughness 3; k= 13.6 mm.

3.3 Wave frequency

Wave frequencies have been checked downstream

from drop to drop in relation to main boundary param

eters. Along the channel no change in frequency could
Figure 16. Range of frequencies for different step - pool ratios. be detected. For the analysis discharge and one further parameter respectively were varied, while all other factors were kept constant. For different discharges, the analysis yielded a certain scatter of data but no definite dependency, (Figure 17). The same was observed for variations of roughness, slope and clay concentration. However, a clear trend could be determined in relation to the step height of the system. As

shown by Figure 18, wave frequency is quasi linearly related to w/L, which further demonstrates the importance of the configuration of the step-pool for the wave formation. 4 CONCLUSIONS AND PERSPECTIVES The study clearly revealed the high complexity of the formation of instabilities in stepped channels. The wave formation is restricted to a certain range of discharge and slope. Maximum wave heights formed between an upper and lower limit of discharge. For a given step-pool geometry, the investigation 0,0 0,2 0,4 0,6 0,8 1,0 1,2 0,0 0,1 0,2 step height w /L f r e q u e n c y f [H z] f max f min

Figure 18. Range of upper and lower envelops of wave

frequencies for different step pool aspect ratios.

demonstrated a significant trend of dampening of the

maximum wave amplitude with increasing roughness.

In addition to this, clear differences in the behaviour

between the flow in smooth or rough-bed channels

could be observed. Smooth beds lead to higher ampli

tudes for rising slopes and a distinct maximum in

the range of 6.5%<S< 9% and 0.25< q ′ < 0.70. For

the analyses colour plots proved to be valuable tools

to illustrate the multidimensional dependencies. The

variation of the clay concentration showed only lim

ited effects on the wave formation. The impact of

increasing concentration was mainly traceable with

steeper slopes. An increase of concentration up to

12% generated a increase of A max while a further

increase reduced the amplitudes again. Overall, the

effect was not as significant as the change in rough

ness.Thus in a first approximation, for conditions with

concentrations below 18% and rough turbulent beds, a Froude-dependency for the wave formation can be presumed. Wave frequencies turned out to be independent of slope, discharge, bed roughness and the concentration of suspension, but proved to be strongly related to the step height of the control structures.

ABSTRACT: Three difficulties exist in numerical simulations of the flowfield at estuary. (a)Water depths are large and it is difficult to apply a 2-dimensional shallow water model to this kind of flowfield; (b) The boundaries are curved and complex, and do not coincide with coordinate lines in the Cartesian system (x_1, x_2, x_3); (c) It is not easy to generate a grid that varies gradually

throughout the whole flowfield. The authors solve these three

difficulties by adopting the 3D governing equations and the use of physical curvilinear coordinates (§ (1) , § (2) , § (3))

which is a physical counterpart of the generalized curvilinear coordinates and was originally proposed by

Truesdell. The proposed model is applied to an experimental channel, and calculated values are compared to

observed values and the agreement between them is generally good. Our next step of study is to apply the model

to real rivers and include sediment transportation to the model.

1 INTRODUCTION

It is very important to predict flowfield and river

bed deformation for channel planning work. However,

there are three difficulties in numerical simulations

of the flowfield at estuary. First, water depths are

large and the flowfield shows a strong 3-dimensional

property, thus it is difficult to apply a 2-dimensional

shallow water model to this kind of flowfield; Sec

ondly, the boundaries are very complex, they include

the external curved boundary of the high-water chan

nel and the internal curved boundary of the low-water

channel, and do not coincide with coordinate lines in

the Cartesian system (x 1 , x 2 , x 3). Moreover, the water

surface, namely the boundary in the vertical direction

keeps varying during a flood; Thirdly, it is not easy

to generate a grid that varies gradually throughout the

whole flowfield. Usually as shown in Figure 1.1, a sig

nificant difference of adjacent mesh size can exist near

the boundary between the low-water and high-water channel, unless a complex process for grid generation is employed. Most existing numerical models in river hydraulics are 2-dimensional, and are unable to deal with the first difficulty. Although some existing models are developed in 3D, they use the Cartesian system (x 1 , x 2 , x 3) and make the imposition of boundary conditions difficult, namely they still retain the disadvantage of the second difficulty. Only a few existing models for rivers can solve both the first and second difficulty by adopting the 3D governing equations and the use of generalized curvilinear coordinates (§ 1 , § 2 , § 3). The generalized coordinate domain is constructed so that a computational boundary in physical space coincides with a coordinate line in generalizedcoordinate space (called computational space also). Figure 1.2 shows a 2-dimensional mapping condition from an irregular physical domain to a square generalized-coordinate domain, where the non-uniform curved segments of s, n which are

Figure 1.1. An image of generated grid.

ized-coordinate domain.

non-orthogonal to each other are mapped to the uni

form straight segments of § 1 , § 2 which are ortho

gonal to each other. The mapping not only deforms

the boundaries but also transforms the directions and

magnitudes of flow variables, i.e., it also transforms

the governing equations. There are many options in

formulating the governing equations transformed from

Cartesian coordinates (x 1 , x 2 , x 3) to generalized curvi

linear coordinates (§ 1 , § 2 , § 3). The main options can be

classified as follows:

(a) The governing equations may be expressed in

a semi-contravariant form in terms of generalized

curvilinear coordinates (§ 1 , § 2 , § 3), in which the Carte

sian velocity of u and the contravariant velocity of

Ucoexist. This is the most extensively used option

and most of the numerical models in computational

hydraulics are developed in this way. However, this

kind of method has two problems. First, the velocity

variables should be arranged at the boundary of a con

trol volume in generalized-coordinate space (§ 1 , § 2 ,

§ 3) when using a staggered mesh, but it is impossible

to arrange the Cartesian velocity in this way. Secondly,

the method suffers from a problem of undesirable mesh

sensitivities. According to some theoretical error anal

yses [1], additional errors associated with the use of generalized curvilinear coordinates (§ 1 , § 2 , § 3) may be significant and consequently, result in a computational stability problem if non-uniformity of the grid in physical space is considerable. Therefore, it is necessary when using this method to have the generated grid in the physical domain grow slowly. (b) The governing equations may be expressed in a complete-contravariant form in terms of generalized curvilinear coordinates (§ 1 , § 2 , § 3), in which the Cartesian velocity is no longer involved. This

method eliminates the first problem stated in (a) which is caused by the coexisting of Cartesian velocity, but still retains the disadvantage of undesirable mesh sensitivities like that in (a). Koshizuka et al. [2] [3] [4] show, theoretically as well as numerically, that stability problems may occur when the mesh size of the adjacent cells differ by more than a factor of 3. From the above descriptions, it can be seen that the existing 3-dimensional model using generalized curvilinear coordinates can deal with the first and second difficulties, but still suffers from a problem of mesh sensitivities caused by the third difficulty stated above. It is the above weaknesses in the existing models that motivate our studies. Namely, our study objective is to develop a new model applicable to the severe calculation conditions with three difficulties at estuary, and provide the useful prediction results of flowfield for channel planning work. As the first step of our study, the developed model is applied to an experimental channel for the easier program debugging and the model verification. Our next step of study is to apply the model to real rivers and include sediment transportation to the present model of flow calculation. 2 THREE-DIMENSIONAL FLOW CALCULATION MODEL As stated in the above, there is a problem of mesh sensitivity when using the generalized curvilinear coordinate. To solve this problem, we must first find out the cause of the problem. When the governing equations are transformed from the Cartesian coordinate system into the generalized curvilinear coordinate system, the Cartesian velocities in physical space of (u 1 , u 2 , u 3) are transformed to the contra-variant velocity of (U 1 , U 2 , U 3) (or co-variant velocity) in generalized-coordinate space. It can be derived out that U i = u (i) /□ξ (i) where u (i) is identical to the velocity along i mesh-line direction in physical space and□ξ (i) is identical to the mesh width in i direction in physical space. Thus, the field of contra-variant velocity in generalized-coordinate space will be very non-uniform once if the generated mesh sizes are rather non-uniform, even if the field of velocity in physical space is uniform. Especially when the field of velocity is also non-uniform, and its

most varying place is the exactly same as that of mesh

size, then this kind of variation will be doubled and

the calculation stability problem will be aggravated.

To solve this problem, Demirdzic et al. [5],

Koshizuka [2-4] and Takizwa et al. [6] introduce the

use of physical components to generalized curvilinear

coordinates that was originally proposed by Truesdell.

The transformed governing equations are expressed in

the coordinate system (§ (1) , § (2) , § (3)) with the veloc

ity of u (i) , where coordinate system (§ (1) , § (2) , § (3)) is

the physical counterpart of the generalized curvilin

ear coordinates (§ 1 , § 2 , § 3), and the velocity u (i) , equal

to U i ×§ (i) , is the physical counterpart of contra

variant velocity U i in the physical curvilinear space.

It can be derived out that u (i) in physical curvilinear

space (§ (1) , § (2) , § (3)) is actually identical to the velocity

along the mesh-line direction of i in physical space.

It should be noted that the superscript parentheses

are used to denote physical components throughout the

paper.

To avoid possible confusion, the coordinate systems

and the velocity denotations mentioned in the paper

are summarized below. (x 1 , x 2 , x 3) represents the well

known Cartesian coordinate system in physical space.

(§ 1 , § 2 , § 3) represents the generalized curvilinear coor

dinate system in generalized-coordinate space (called

computational space also). (§ (1) , § (2) , § (3))

represents

the physical curvilinear coordinate system in physical

curvilinear space which is actually identical to phys

ical space. Figure 2.1 shows these analytical spaces

and coordinate systems. (u 1 , u 2 , u 3) are the Carte

sian velocities in physical space; (U 1 , U 2 , U 3) are

the contra-variant velocities in generalized-curvilinear

space; (u (1) , u (2) , u (3)) in physical curvilinear space are

identical to the velocities along the mesh-line direction

in physical space.

2.1 Governing equations in the physical curvilinear coordinate system

(a) Governing equations in the Cartesian coordinate system

- Continuity equation

- Momentum equation

and, (a) x 1 x 2 j 2 j 1 j (1) j (2) (b) (c) Figure 2.1. Analytical space and coordinate systems (a) physical space, Cartesian coordinate system, (b) generalized-coordinate space, generalized curvilinear coordinate system and (c) physical curvilinear space identical to physical space, physical curvilinear coordinate system. where, i, j, k = 1, 2, 3, u i is velocity in x i direction; P is pressure = ρGH , and ρ, H , G is water density, water level and gravitational acceleration= 9.8 m 2 /s respectively; δ ij is Kronecker's delta defined as δ ij = 1 if i= j and δ ij = 0 if i ≠ j; S i is external forces in x i direction, τ ij is a tensor representing Reynolds stresses; ν T is the turbulent viscosity and can be evaluated as follows: where κ is the Von Karman constant (≈0.4), h s is the water depth; u ∗ is the shear velocity at channel bed; and z ′ is the height from the channel bed. (b) Basic concepts related to transformation of coordinate system Chain rule is often used in the transformation of coordinate system. However, when using this method, the contra-variant velocity of U i and the Cartesian velocity of u i coexist in the

transformed governing equations. In this paper, instead of using chain rule, we transform the governing equations based on the geometric differential calculus. Several fundamental concepts of geometric differential calculus related to the coordinate system transformation are introduced as follows: (b-1) fundamental co-variant tensor g ij If the coordinates of two neighbor grid points in computational space are represented by ξ i and ξ i + dξ i respectively, then their physical distance of ds in physical space has an expression as:

The physical meaning of g ij can be explained as

follows:

When the mesh width of dξ i in computational space

is equal to 1, √ g ii represents the mesh width in i direc

tion in physical space, and √ g ij represents the area of

(i, j) mesh in physical space.

(b-2) Determinant of fundamental co-variant tensor g

where J is the well-known Jacobian which can be also

defined by the determinant of coordinate transforma

tion coefficients. The physical meaning of g is: if the

mesh width in computational space is equal to 1, then √

g represents the cubic volume of (i, j, k) mesh.

(b-3) Physical fundamental coand contra-variant tensor g (ij) and g (ij)

(b-4) Christoffel Symbol and Physical Christoffel Symbol

Christoffel symbol can be expressed by coordinate

transformation coefficients as follows:

and physical christoffel symbol has a relationship with

christoffel symbol as follows:

Christoffel symbol represents how many changes of

the vector component in i direction are caused when

the unit vector in j direction moves one unit length in

k direction.

Figure 2.2 shows the cases of { 2 1 2 } and { 1 2 1 } which

actually represent the curvatures of mesh-line in j

direction and i direction.

(c) Transformation based on geometric differential

calculus

The following transformations from the Cartesian

coordinate system to the physical curvilinear coordi

nate system based on geometric differential calculus

are introduced:

• Scalars 1 2 2 2 1 1 Figure 2.2. Physical meaning of the physical christoffel symbol { 2 1 2 } and { 1 2 1 } . • Vectors • Tensors where, a (i) and A (i) are physical vector and tensor components in the physical curvilinear coordinate system § (i) , and∂/∂§ (j) is the differential operator defined as: (d) Governing equations in the physical curvilinear coordinate system Based on the transformation given in (c), the governing equations can be transformed from the Cartesian coordinate system to the physical curvilinear coordinate system as follows: • Continuity equation:

• Momentum equation:

2.2 Calculation algorithm

SMAC algorithm is employed in the calculation. The

characteristic of SMAC algorithm is that only the

velocity derivative term in the continuity equation

and the pressure derivative term in the momen

tum equation are calculated implicitly, while other

terms are calculated explicitly, and the time derivative term in the momentum equation is discretized with Euler’s method. Besides, a CIP (Cubic-Interpolated Pseudoparticle) originally proposed by Yabe [7-8] is employ to deal with the convective term in the momen tum equation. It is well known that a problem of calculation stability is often caused by the convective term when velocity is high, while the CIP method has the advantage of calculation stability in dealing with the convective term with high velocity.

The transformed governing equations shown in Eq.(2.18-2.19) seem very simple, however they are actually complicated when they are unfolded. The momentum equation in the § (1) direction unfolded from Eq.(2.19) has an expression as:

where n denotes time step and R (1) n+1 is expressed as: Herein, Eq.(2.21) is expressed in a non-conservation form for using CIP method to calculate the convective terms.To explain the essence of CIP method, considering an one-dimensional momentum equation with free water surface as expressed in Eq.(2.22): where g * represents pressure derivative term, friction term, viscous stresses as well as Reynolds stresses and etc.; f represents velocity. Eq.(2.22) can be split into the following two phases which are advection phase and non-advection phase. Advection phase: Non-advection phase: where n denotes time step. It can be seen that Eq (2.23) is actually a wave motion equation. According to the characteristic of wave motion equation, the value of f at future t+□t time at the place of x i is actually equal to the value of f at present t time at the place of x i - u□t as shown in Figure 2.3, i.e., When u> 0 and□t is small enough so that the point of x i - u□t is between the two points of x i-1 and x i , the value of f (x i - u□t, t) can be estimated based on the known values of f (x i-1 , t) and f (x i , t) by various

methods. One of those methods is the CIP method proposed byYabe [7-8]. The CIP method employs a cubic polynomial function F(X) as expressed in Eq.(2.26) to do interpolation between the two points of x i-1 and x i . X = -u i Δt x i-1 t + Δt t x i (u > 0)

Figure 2.3. Characteristic of wave motion.

where X =-u i Δt, and the coefficients of a i , b i can be

evaluated based on the known values of f (x i-1 , t) and

f (x i , t) at present time of t. Therefore, using the central

finite difference method to calculate advection phase

shown in Eq.(2.23), and then using the CIP method to

calculate non-advection phase shown in Eq.(2.24), we

can obtain the answer of original governing equation

of Eq.(2.22).

By extending the above approach to 3-D system, we

have [8]:

The interpolation function within a cubic grid

cell is:

where

and, where, and,

where Δξ (1) ,Δξ (2) ,Δξ (3) are the mesh widths in

ξ (1) , ξ (2) , ξ (3) direction respectively.

The whole calculation procedure can be summa

rized as the following four steps:

(1) To calculate the pseudo-velocity u^ (i) n+1

Eq.(20) can be modified to Eq.(2.32) by substituting

the implicit term of ∂P n+1 /∂ξ (i) for the explicit term of

∂P n /∂ξ (i) in Eq.(2,21), then pseudo-velocity u^ (1) n+1 can

be estimated based on Eq.(2.32) using CIP method.

The same procedure can be applied to estimate the

pseudo-velocity of u^ (2) n+1 , u^ (3) n+1

(2) To estimate the pressure correction P ′

Let,

Then, the following equation can be obtained by

subtracting Eq.(2.32) from Eq.(2.20).

Also, the similar relationships between u (2) n+1 and P ′ ,

u (3) n+1 and P ′ can be obtained in the same way. Putting

these relationships between (u (1) n+1 , u (2) n+1 , u (3) n+1) and P ′

into the continuity equations of Eq.(2.18) , an equation

related to P ′ can be obtained.Thus, the pressure correc

tion of P ′ can be obtained by solving the equation with

TDMA algorithm (Tri-Diagonal Matrix Algorithm).

(3) To calculate the pressure P n+1 and the velocities (u (1) n+1 , u (2) n+1 , u (3) n+1)

The velocity of u (1) n+1 can be obtained based on

Eq.(2.34), and u (2) n+1 , u (3) n+1 can be evaluated simi

larly. The pressure of P n+1 can be obtained based on

Eq.(2.33).

(4) To calculate the water level H

The water level is calculated based on the 2D depth

integrated continuity equation. Concretely, Eq.(2.20)

can be split into the following two equations: where the difference between R˜ (1) n in Eq.(2.35) and R (1) n+1 in Eq.(2.20) is that the former excludes three pressure derivative terms from eq.(2.21). From Eq.(2.36), the following equation can be obtained: where u˜ (1) n+1 can be calculated based on Eq.(2.35). Similarly, the equations for u (2) n+1 and u (3) n+1 can be obtained. Putting these equations into the continuity equation, an equation associated with pressure P is obtained. Here, the pressure of P is approximated by the static pressure of P s which can be expressed by water level of H . Integrating the equation in depth direction then we can obtain an equation related to the water level of H . The equation is then solved implicitly by TDMA algorithm to obtain the water level of H at the future time t +t. In the above, we have introduced the 3-dimensional model in the physical curvilinear coordinate system of ξ (1) ∠ξ (2) ∠ξ (3) where the coordinates in three directions can be non-orthogonal to each other. Although many coefficients related to coordinate transformation become 0 once if the coordinates are orthogonal to each other, it is difficult to generate a mesh being orthogonal to each other in all of three directions. Therefore, considering the balance between the difficulty of mesh generation and the complication of calculation, it is more practical to use coordinate system as (ξ (1) ⊥ξ (2))∠ξ (3) in most simulation calculations in river hydraulics. 3 NUMERICAL EXAMPLES As our first step of study, the developed model is applied to an experimental channel for verifying its correctness. The calculation objective is a meandering channel whose shape is a sine-generated curve expressed as

Table 3.1. Simulation condition of example-1.

Total width of channel(cm) 20

Length of channel (cm) 220

θ max 35 0

Discharge Q (l/s) 2.15

Slope i b 0.009

Manning roughness coefficient 0.015

where θ is the angle between the curved centerline and

the down-valley axis at an arch distance of s; θ max is the

maximum value of θ; and L is the wavelength measured along the curved centerline. Simulation conditions are shown in Table 3.1.

The initial and boundary conditions are adopted as follows:

• Initial condition: The initial values of velocity u (1) , water depth h s and water level H are defined by the uniform flow calculation. The initial values of velocities u (2) , u (3) are defined as 0.

• Boundary condition: At upstream (i= 1) and downstream (i= nend), the cyclical conditions of φ(1, j)=φ(nend, j), φ(nend + 1, j)=φ(2, j) are employed.

• At side wall: free-slip condition is employed.

In the calculation, we choose to use the coordi nate system of (ξ (1) ⊥ξ (2))∠ξ (3) by considering the balance between the difficulty of orthogonal mesh's generation and the complication of calculation. The following sigma function σ is employed to generate the boundary-fitted mesh in vertical direction. The divisions in vertical direction are 5 layers as shown in Figure 3.1 and the divisions on plane are 48*10 meshes as shown in Figure 3.2.

where z b is the elevation of channel bed and H is water level.

Since the water level of H keeps varying dur

ing the calculation process toward convergence, the

boundary-fitted mesh in vertical direction must be re

generated by Eq.(3.2) with time. The ALE (Arbitrary

Lagrangian and Eulerian) [9] method is employed to

handle the mesh’s moving problem. Concretely, for

the momentum equation of u (1) shown in Eq.(2.20),

Eq.(2.32) and Eq.(2.35), the convective term of

u (3) ∂u (1) /∂ξ (3) is replaced by the term of (u (3) –

w 0)∂u (1) /∂ξ (3) where w 0 is the mesh moving speed in

vertical direction. The same treatment is applied to the

momentum equations of u (2) and u (3) .

4 CONCLUSION

In this paper, a 3-dimensional flow calculation model

is developed. The model introduces the physical curvi

linear coordinate system to solve the mesh sensitivity

problem, and employs a calculation algorithm having

the convective term treated by CIP method to improve

the calculation stability for the flowfield with high

velocity. The developed model is applied to an exper

Application of a 2D semi-lagrangian model to unsteady shallow

water flow over dry bed

J. Murillo & P. García-Navarro

Fluid Mechanics, CPS, University of Zaragoza, Spain

ABSTRACT: The work is devoted to the study of the applicability of a Semi-lagrangian method to the two

dimensional shallow water equations. The method is based on the characteristic formulation of the system and

relies on the use of the bicharacteristic curves and a suitable interpolation technique. The interpolation is based

on non-oscillatory bicubic Hermite polynomials. The technique is applied to transient problems involving front

advance over dry beds with special emphasis put on the treatment of the advancing front.

1 INTRODUCTION

The hyperbolic character of the shallow water or

St. Venant equations implies the existence of their

characteristic formulation. The related characteris

tic based numerical methods gained wide acceptance

in one-dimensional applications at the early years of

Computational Hydraulics due to their conceptual sim

plicity and the fact that they are physically based and

can lead to highly accurate results. Numerical models

based on many alternative approaches appeared since

then.

In two-dimensional shallow water models, finite

differences, finite elements and more recently finite

volumes have filled the scientific journals almost from

the beginning. Only a few authors have reported expe

riences using semi-lagrangian methods as applied to

2D flow models. The simplicity of this approach is less

evident in 2D than in 1D applications but the fact that

the method is physically based remains the same and

renders attractive any attempt of validation.

The shallow water equations represent physical laws

defined on a domain filled with water and do not

describe properly the advance over a dry boundary.

This constitutes a moving boundary problem in which

the water column goes to zero. The solution pro

posed in this work is based on the information coming

from the interior wet region along the bicharacteristic

curves.

2 MATHEMATICAL MODEL

The one-dimensional approximation of open chan

nel flow problems using the Saint-Venant equations gives excellent results in general when the underlying hypothesis are justified. The main limitations of this approach are the cross sectional uniform velocity and horizontal free surface. In many cases, a twodimensional approach is required in order to be closer to reality.The mass conservation equation and momentum balance in the x and y directions lead to the following system: where h is the water depth, u is the velocity component in the x direction and v is the component along the y direction, S x o and S y o are the bottom slopes along directions x and y respectively; S x f and S y f represent the hydraulic resistance in the two directions and are formulated as (22) : with n the Manning roughness coefficient and C u the cubic root of the rate of the acceleration of gravity g in

any unit system and its value in the International Unit

System.

The partial differential system defined by (1,2,3)

is hyperbolic and therefore admits a characteristic

formulation. This is next presented and exploited.

2.1 The characteristic form

The characteristic form of the equations in a 1D approach leads to a system of ordinary differential equations and therefore to a simpler mathematical formulation. This formulation is associated to the idea that the information propagates in space and time along characteristic surfaces forming a cone. The practical application of the method based on this formulation relies on curves, called bicharacteristic curves, contained on these surfaces.

The polar formulation of the bicharacteristic curves is:

Eqs. (6) and (7) suggest the linear combination required to eliminate the partial derivatives from the flow equations. If (1) is added to (2) multiplied by c cos θ and to (3) multiplied by c sin θ, we get:

where

A numerical technique can be implemented based on the existence of the bicharacteristic curves. It can be used to supply information at different time levels fol lowing an approach similar to the Hartree method. As suggested by Fig. 1, the solution at point (t_o, x_o, y_o), can be found following backward in time the char acteristic cone up to its intersection with the plane corresponding to time $t = t_o - \delta t$. Three bicharacter

istics are only required to furnish the solution for

u o , v o , h o , at (t o , x o , y o). However, if a second order

solution is required, the cross derivatives ∂u/∂y and

∂v/∂x must also be known at the solution point. One

option is to involve four bicharacteristic instead of
Figure 1. Elements of the bicharacteristic cone. three and an additional equation called the world line. The four bicharacteristics are chosen at increments of π/2 in the polar angle ϕ. The world line is tangent to the vector (1 uv) T and corresponds to a streamline in the plane (x, y). The mass continuity equation along the world line can be expressed as: 2.2 Resolution scheme. To solve the system of equations at a time t o the first step is to know the trajectory of the bicharacteristics, since information propagates along those directions. The coordinates of the intersections of the bicharacteristics with the plane t o − δt can be found using (6, 7) through a first order approximation in δt for the four bicharacteristics. The intersection of the world line with the plane t o − δt is also found in first order. The flow conditions at points 1-5 and their partial derivatives along directions x and y are detrmined by the interpolation among grid points in the plane t o − δt. The final solution is strongly dependent on the interpolation technique used. The knowledge of the flow variables at points 1–5 allows a second order approximation in δt for equation (8). 2.3 Grid movement at the front wave The solution at the advancing wave front is calculated using information from the wet points at the front itself in a previous time step. Katopodes and Strelkoff (1978) and Katopodes and Schamber (1987) defined an integration domain including both interior points and points at the leading front.

Figure 2. Front wave advance.

A different approach consists of approximating the

velocity of the front points using information from the

interior points. Taking into account that the front prop

agation speed must be given by the normal component

of the water velocity at the wave frontier (the flow

does not cross that boundary), the proposed method is based on the projection onto the direction normal to the front wave, of the flow velocities at the front positions (Fig. 2).

The actual values of the variables at the front posi tion at a new time level are unknown and must be obtained from interpolation based on fictitious values at the outer dry area. The alternative is to neglect all information both from the front itself and from the dry zone and therefore to build interpolation polynomials only over the available information at the wet zone. The calculation is hence simplified.

The stability criterion within the calculation grid is: for all points ij in the plane, where δx, δy are the lengths of the interpolation cells.

2.4 Wetting-drying condition

Any numerical model intended to simulate unsteady free surface flows must be able to reproduce moving boundaries separating dry and wet zones. The careless treatment of these boundaries negatively affects the numerical results.

The points chosen for the calculation of the advanc ing front are not, in general, aligned along a direction normal to it. Being this an essential condition for the correct front simulation, it becomes necessary to intro

duce some kind of modification in the information

relying on them. The projection of the velocity on

the direction normal to the front is calculated and the

tangential component is elliminated from th predicted
Figure 3. Velocity projection at the wetting front.
solution (Fig. 3). Otherwise, the numerical results are erroneous. When, on the other hand, the front advances over a positive (adverse) slope, a further point must be taken into account: the local bed slope must be redefined to zero value. If this is not implemented the wave front is not able to advance up the hill as expected leading even to velocity values in the opposite sense to the advancing direction. 3 INTERPOLATION IN TWO DIMENSIONS The interpolation used in the process of calculation of the variables at the intersection of the bicharacteristics and the plane t o – δt is determinant of the problem evolution and numerical accuracy. As in one-dimensional problems, the interpolation must be able to supply accurate and smooth results. The accuracy is related to the method used to estimate the derivatives and the smoothness depends on the restrictions imposed on their values. The interpolative polynomial must not present any undesirable minimum or maximum within the computational cell for stability reasons. In order to achieve the desired properties, the bicubic Hermite interpolation has been used. This procedure requires a refined treatment of the supplied information but produces oscillation free polynomials (Williamson and Rasch 1989). The value of the function as well as an estimation of the derivatives D ij are required at the four cell vertices (Frischt and Carlson, 1980). 4 TEST CASES Two different problems have been used to assess the suitability of the proposed meted: A flooding wave from a corner and a laboratory dam break problem.

Figure 4. Advancing front position at t= 9 min using

CFL= 0.2, 0.4 and 0.6.

Figure 5. Advancing front position at t= 9 min using grids

M1 and M2 with CFL= 0.4.

If discharge is applied at one of the corner points

of a rectangular domain in which there are uniform

slope, and roughness, the problem can be considered

one-dimensional in the radial direction of a set of polar

coordinates. The proposed method will be used on

a rectangular structured mesh in order to verify that

the solution is well behaved. The flow problem is a

challenge for the interpolation scheme in this kind

of grid. Figure 6. Bottom level for the positive slope radial flow test case. In a second stage, the advance of the front in presence of sloping beds will be analyzed. 4.1 Radial front over flat dry bed In order to study the performance of the proposed scheme and the sensitivity to the numerical parameters a first test case is envisaged using two different grids made of squared cells. The first, M1, with cell side lengths of 0.5 m. The second, M2, made of cell side lengths of 1 m. The test case consists of a radial flooding wave advancing over dry bed from a corner. The inlet discharge is Q= 0.00648 m 3 s −1 . The bottom is flat and characterized by a roughness Manning coefficient n= 0.04. The numerical results obtained on grid M1 will be compared using different values of the CFL. Fig. 4 shows the advancing front position at t= 9 min with CFL= 0.2, 0.4 and 0.6. The figure indicates that the differences in advance using CFL= 0.4 y 0.6 are minimum, and that there is some delay when using CFL= 0.2. The comparison of the results using different grid and the same CFL= 0.4 is shown in Fig. 5. This figure contains the plot of the advancing fronts at time t= 9 min. The radial symmetry is conserved in both grids but the results are of worse quality on the larger grid due to the increment in the size of interpolation cell. 4.2 Radial flow over dry slope The second test case is intended to analyze the behaviour of the numerical solution for the radial flood wave in presence of a slope. The test case is analogous to the previous except for the definition of a slope in both directions x and y following the shape of an inverted paraboloid as represented in Fig. 6. The radial wave starts at a corner situated on the uppermost

Figure 7. Water and bottom levels at t= 3, 6 and 9 min.

Figure 8. Bottom level for the adverse slope radial wave.

point and the advancing solution progresses without

any difficulty and not requiring any special numerical

treatment.

Initially, the flow changes very quickly due to the

acceleration induced by the slope. Therefore, the water

level is reduced as the wave advances. When the front

reaches the horizontal part, its advancing speed is

reduced and, at the same time, the water level at the

front increases. The leading grid cells of the wetting

front do not require special treatments. Figure 9. Bottom and water levels at T = 3, 6, 9 and 15 min. 4.3 Radial flow over dry adverse slope In this test case, the evolution of the radial flooding wave over a dry adverse slope as the one shown on Fig. 8 is analyzed.

Figure 10. Wrong results due to the incorrect treatment of

the wetting/drying front at t= 6 min and t= 7 min.

Figure 11. Experimental setup.

The simulation was performed over grid M1 using

CFL= 0.4. The wetting front advances with radial

symmetry until the base of the slope is reached The

flow field is then adapted to the bump progressively

flooding it. The numerical results shown in Fig. 9 indi

cate that the water level rises and the wetting profile

changes due to the presence of the adverse slope.

The previously indicated modifications in bottom

level and velocity direction at the wetting cells was
Figure 12. Dam break surface level at t= 0.08 and 0.24 s.
crucial in this example. Fig. 10 displays two samples of the solution obtained at different times in a simulation carried out without the mentioned modifications. The front was stuck at the foot of the slope generating a non-physical growing discontinuity in water levels when the

bottom level was not adequately modified at the leading edge grid cells. If the velocity corrections had not been implemented, the results would have been totally incoherent. 4.4 Validation: Dam break wave The last test case presented is the validation of the numerical meted against the experimental data obtained in a laboratory scaled dam break setup. The experiment was carried up as described in (Braschi et al. 1994) and the sketch of the experimental facility is presentd in Fig. 11. Two reservoirs are connected by a gate. One is dry and the other is full of water up to a horizontal level 0.14 m. The sudden removal of the gate is used to simulate an instantaneous dam breaking and releases the water leading to a flooding wave that advances over the dry part. The simulation of the flow generated was performed using a uniform square grid of size 0.5 cm, a CFL of 0.45 and a Manning coefficient n= 0.01. Variations of this parameter do not influence the results sensibly

Figure 13. Dam break water levels at t= 0, 32, and 0.48 s.

since the flow is dominated by inertial and pressure

effects.

When the gate is opened, a negative wave propa

gates into the wet reservoir with a celerity depending

only on the unperturbed water level.

Fig. 12 shows the flow water levels 0.08s and 0.24s

after the gate removal.The positive wave advances over

the dry platform, both in a longitudinal and a transver

sal direction. As the front advances, two zones can be

identified, the inner dominated by inertial effects and

the outer more affected by the surface roughness.

At t= 0.24s The depresión wave is near the solid

walls. At time t= 0.32 s after the dam breaking, the

depression wave has already been affected by reflec

tion at the reservoir lateral walls and progresses

towards the interior. This can be seen on Fig. 13.

At t= 0.40 s, the depression wave reaches the

upstream end of the initially full reservoir. When time

reaches t= 0.48 s the reflection waves in the reservoir

cross each other (Fig. 13). On the other hand, at that

time the wetting front has reached the side walls of

the dry reservoir with an abrupt reflection leading to a

considerable rise in water levels.At time t= 0.56 s and

later, the wetting front presents a growing tendency of

the zone dominated by inertial effects with respect to
Figure 14. Dam break water levels at t= 0.56 and 0.64 s.

How a 2-D code can simulate urban flood situations

E. Mignot & A. Paquier

Cemagref, R. U. Hydrology-Hydraulics, Lyon, France

N. Rivière

LMFA, INSA de Lyon, Lyon, France

ABSTRACT: Numerical codes are being used to simulate flood progress in cities but no real knowledge about

the accuracy of these numerical calculations are available. The objective of this study is to check the capabilities

of a 2D code to model a flood in an urban area. A simplified city flood was then modelled experimentally

and its data were compared with the simulation results. Although results can be considered accurate enough

for operational purposes, water depth differences remain, even with a refined mesh. In order to find out which

typical urban situations are difficult to simulate by the code, two experimental test cases representing urban

details were then modelled and calculated. The first one is the flow around a building where the reflections of

the wave on the walls and recirculation behind the building are of major importance. The second one is the

distribution of flow discharge in a four branches crossroad with two incoming and two outgoing streets with the

same width and same bottom slope of 1%.

1 INTRODUCTION

Various computational fluid dynamics methods have

already been used in order to simulate flood scenarios

in urban zones (Neary & Sotiropoulos, 1996; Khan

et al., 2000; Hervouet et al., 2000; Paquier et al., 2003).

The results are encouraging but there is still a lack of

knowledge in the accuracy of the risk assessment. In

order to check the real capabilities of a 2D numerical

code to simulate a urban flood, we use three experimen

tal test cases (two of which are part of the European

Project IMPACT (Soares et al., 2004; Soares et al.,

2003)) representing a simplified city, the flow around

a building and finally the flow within a four branches

crossroad. The comparisons between the experimen

tal and numerical records should permit to check the

difficulties remaining when simulating a urban flood

numerically.

2 PRESENTATION OF THE CODE

The code we used is Rubar20. Here below are pro

vided the equations that are solved and the corre

sponding numerical scheme.The explicit second-order

finite volume scheme solves the 2-D shallow water

equations. The Godunov-type scheme includes 4 steps (Paquier 1998): 1. computing slope of each one of the 3 variables h (or z water level), hu and hv in every cell on x and y axis by the method of the least squares and applying limitations of slopes following in order to obtain TVD (Total Variation Diminishing) scheme. 2. computing values of W = (h, hu, hv) at intermediate time t n+1/2 in the middle of the edge of cell M i to obtain second-order scheme. 3. solving a 1-D Riemann problem in the direction normal to the edge at t n+1/2 in order to estimate the fluxes through edges for the conservative part of the equations. It is possible to use a Roe type linearization that directly provides an estimate of the fluxes. 4. integrating the terms of the second member of the set of equations (1) to (3) on the surface of the cell

in order to add the corresponding contribution and

to obtain the final value of the solution.

3 MODEL CITY EXPERIMENT

3.1 Presentation of the test case

The aim of this Impact Project (Soares et al., 2004)

which took place in Milano (ENEL-CESI) is to simu

late the flow within a simplified urban (or semi-urban)

area. Cubic impervious blocks (simulating buildings or groups of buildings) are placed within a valley laboratory model upstream, which a flood hydro graph is introduced. Several urban configurations are modelled, based on the same valley topography:

- Two buildings configurations (aligned or staggered blocks)
- Two area widths (a whole valley or use of walls to confine the flow around the buildings area)
- Two discharge hydrographs as upstream conditions.

The case presented here below is the confined valley with 16 aligned buildings. Within the urban area, eight gauges (S3-S10) are used in order to describe the water depth evolution during the experiment.

3.2 Description of the flow

During the high upstream discharge period, the flow is rapid in the upstream part of the domain with low water depths. When getting near the building area, the flow slows down and the water depths rise strongly. Then the flow reaccelerates in the streets and the velocity remains low behind the buildings. Downstream from the urban area, the increased passing section leads to high velocities throughout the whole section.

3.3 Comparison Experimental/Numerical results

On the one hand, the numerical hydrographs obtained

have globally the same shape as the experimental water 7 6 3 4 5 8 9 z

Figure 1. Model city benchmark. depth curves and the highest and lowest water levels are located at the same places. On the other hand, important hydrograph differences remain. 3.3.1 Shock against the buildings The first difference that can be outlined between numerical and experimental hydrographs is the front wave reflection on the urban area at S3 and S4. The numerical calculation does not simulate accurately this short increase of water depth because of the size of the cells and due to the equations. In a real case, this could be a problem when comparing natural water marks with calculated higher water depths after a flood. 3.3.2 Hydrographs comparisons In term of typical water depth in the urban area, we present the histogram of the water depth at t= 30 s at all the gauges. We notice that the highest water depths appear upstream from the urban area (S3 and S4); and within the urban area, the high water depths are in the streets in the centre of the city (S7 and S8) and the lowest are downstream from this area (S10). The water depths calculated in the urban area (S5 to S9) are very homogeneous, all between h= 30.7 mm and h= 36.5 mm, whereas in the experimental conditions, the water depth vary much more between h= 28.9 mm and h= 45 mm. This homogeneity could be due to the lack of capability of the equations to model accurately the reflections and recirculations or to a diffusion caused by too large cells within the urban area, which cannot provide a convenient representation of the structures of the secondary flows. Furthermore, V > 1.1 m/s v < 0.05 m/s 7.80 5.40 6.60 Figure 2. Model city velocity at t= 18 s. 0 0.02 0.04 0.06 0.08 0.1 0.12 0 10 20 30 40 50 60 Time (s) W a t e r d e p t h (m) S4 _ Experimental S4 _ Numerical Water depth at S4 Figure 3. Numerical and experimental water depths at S4.

the water depth is usually higher in the experimen

tal records than in the numerical results except at S5

and S10.

All the numerically calculated water depth curves

have a very similar shape and the difference between

them is usually only homothetic while the experimen

tal hydrographs have different shapes: for example, the

falling curves have different slopes.

3.3.3 Influence of the friction coefficient

As the water depths are usually underestimated, we

tested an increase of the Manning coefficient from 0

Figure 6. Experimental water depth hydrographs. n= 0.0162 to n= 0.025. Of course, this tends to increase the water depth: thus, when the water depth is underestimated (S7 and S8), the high friction hydrograph fits the experimental curve better but, if the hydrograph is well estimated with the experimental friction coefficient, the water depth becomes overestimated with a higher friction. Increasing the friction coefficient also reduces the front wave propagation and then the delay between the calculation and experimental hydrographs. However, this timing difference

is not only reduced upstream from the urban area (S3 and S4), it is also reduced when travelling within the urban area and the propagation velocity is then not as well described as in the original friction coefficient case. The friction coefficient cannot be the right parameter to improve accuracy of calculation results. 3.3.4 Influence of refining the mesh A new mesh with a typical cell size of 1 cm is established. Figure 8 shows that the results in term of water depths comparisons are not improved. The meshing size does not seem either to be the parameter responsible for the lack of accuracy of the flow simulation. 3.4 Conclusion Here above, we presented one configuration among the seven experimental test cases. However, all of them Water depths for case 1a at t=30s 0 0.01 0.02 0.03 0.04 0.05 0.06 0.07 0.08 S3 S4 S5 S6 S7 S8 S9 S10 Gauge W a t e r d e p t h (m) Experimental Numerical High friction Figure 7. Fine mesh water depth histogram.

lead to the same conclusions: the 2D code can globally

simulate the flow within a simplified city, but the errors

are locally quite strong:

- The calculated water depths are too homogeneous

within the urban area

- The numerical hydrographs are usually underesti

mated

- The calculated hydrographs do not reproduce

exactly the experimental hydrograph shapes.

Thus, it is useful to check the quality of modelling

in more detailed situations such as the flow around a

building or the flow in a crossroad in order to figure

out from what the main errors come.

4 THE ISOLATED BUILDING TEST CASE

4.1 Presentation of the test case

The aim of this experiment which took place in Univer
sité catholique de Louvian is to investigate the effect
induced by a building placed within a sudden dam
break flow. Note that, depending on the working scale,
this experiment could also represent the flow around
an obstacle such as a parked car within a street during
an urban flood. The experimental benchmark (Soares
et al., 2003) was carried out within a horizontal open
channel with a reservoir where steady water is stored
until the beginning of the experiment. At the reser
voir downstream boundary, the width of the channel
is narrowed to 1 m in order to concentrate the flow
and represent a natural dam-break when opening the
gate. Further downstream, at around 3.5 m from the
reservoir, in front of the gate, a 0.8× 0.4 m imper
vious building is introduced with a specific angle to
the flow direction. The following measurements are
taken in order to compare the experimental data with
the results of the simulations: water depths at the
five gauge points and velocity fields at t= 1 s, t= 2 s,
t= 10 s.

4.2 Description of the flow

The flow is rapid when getting off the reservoir creat
ing two recirculation zones on the sides of the dam gate

due to depression; then, it slows down suddenly (and water depth rises) when arriving close to the building. The flow passes around the building and a clockwise re-circulation zone appears downstream. At around one channel width downstream from the building, the flow tends to become one-dimensional (the velocity magnitude tends to be homogeneous on the channel section). Reflections against the channel sides bottom slopes and against the building are strong, and create complex local secondary flows. G1 G2 G3 G4 G5 Gauges for water depth measurements Impervious Building Reservoir. H 0 =0.40 m Horizontal channel H0=0.01 m Gate opened at t=0s Section 3.6 m Figure 9. Isolated building benchmark scheme. Zones of-recirculation 1-dimensional flow High velocity zone Figure 10. Velocity field at time t= 15 s. 4.3 Numerical calculation of single building This experimental test case was simulated using a grid based on the regularity of the mesh upstream and downstream from the building, the cells around the building are then somewhat distorted. The typical size of the cells is 10 cm for a total number of cells around 10 000. 4.3.1 Influence of the building In order to investigate the influence of the introduction of the building (or obstacle to the flow) in the channel, we present gauges G1 and G5 hydrographs with and without the building (plain channel). Upstream from the building (G1), the water depths are similar in both cases at the beginning of the experiment until the flood wave reflects on the building wall and that backwater effect appears. Then, the original hydrograph rises suddenly, the lager water level being induced by the flow section reduction with the obstacle. Afterwards the hydrographs keep the same shape but the plain channel has lower water depths. Downstream from the building (G5), Fig. 12 shows a slight wave delay of 0.4 seconds when introducing the building. Furthermore, the wave peak remarkable without the building does not appear with the building, case in which the highest water depth is lower. During the second part of the event (t > 15 s), the limnigrams are very similar. Numerical hydrographs at point 1 0

4.4 Experimental/Numerical comparison

4.4.1 Global comparison

The experimental velocity field could not be mea

sured in the whole wetted area because of technical

difficulties in the most oscillating water level zones

(for instance around the hydraulic jumps). Moreover,

at t= 1 s, the velocity was measured both in the area

reached by the wave and in the zones where some wind

disturbance or channel oscillations created a slight

water motion.

T= 1 s: flood wave propagation

At t= 1 s, the front wave has an ellipsoid aspect and

the front wave has reached the distance x= 2.1 m. This

first wave seems to be well simulated, even if one
dv<0.4m/s 0.4<dv<0.5 m/s dv>0.5 m/s Figure 14. Velocity differences between numerical results and experimental records at t= 1 s. Expanding area (Supercritical flow zone) Trail building flow (low velocity) Subcritical flow zone (building blockage) Reaccelerating zones Figure 15a. Numerical velocity (m/s) at t= 5 s. main error seems to be related to the shape of the front. In the experimental record, the maximum water level (white colour) is very close to the front of the wave whereas this distance is larger in the numerical cases. This is confirmed by the image below where the main differences (dash line) are situated in the highest velocity zone (wave front). There seem to be a slight error in the dimension of the expanding front wave; however, this dimension difference is of the

order of magnitude of one cell of calculation. T= 5 s: developed structures After 5 s of experiment, the front wave has already passed the building area and the flow structure is established. Figure 15 shows that the flow structures appear on the experimental records and numerical results at the same place and with almost the same size. Figure 16 shows that the main differences between numerically calculated water depths and the experimental records are located in four specific areas: Zone B: calculation overestimates the velocity values.

Figure 15b. Experimental velocity records (m/s) at t= 5 s.

Figure 16. Differences between numerical and experimen

tal velocity results at t= 5 s.

Zone C+C': the low velocity zone is shorter in the

numerical calculations compared to the experimental

case.This result shows the larger impact of the building

on the overall flow in the experimental case compared

to the numerical one.

Zone D: The low velocity zone protected by the

building, is wider in the calculation compared to the

experimental case.

Zone E: We see in both the numerical results and

experimental records that there is a frontier near point

E between a high velocity zone and a lower one. This

frontier is not exactly at the same place in both cases.

4.4.2 Hydrograph comparison at the gauges

The 5 gauges were placed in very specific loca

tions within the flow: either next to hydraulic regime

change zones (supercritical to subcritical and vice

versa: G1, G2, G4), in high wall reflection zones (G3)

or finally at the border of the trailing zone behind the

building (G5).

In a hydraulic jump location zone (example next to

G2), the hydrographs are influenced by the motion of

the hydraulic jump. In the experimental conditions, the

hydraulic jump passes slowly through the gauge loca

tion and afterwards, G2 remains on its subcritical side.

In the numerical calculation, at t~ 19 s, the gauge 2

enters the subcritical zone after the displacement of the

cross=G2 location. hydraulic jump so its water depth
increases suddenly. However, shortly after, the hydraulic
jump travels back, passes G2 and the water depth decreases
again. But, a slight change of a numerical parameter
(example Manning increasing from 0.1 to 0.11) can modify
the hydraulic jump location slightly but with a large
influence on the hydrograph shape at G2. Note that the
water depth in both regimes is estimated accurately. Figure
18 shows that the displacement of the regime frontier
implies a displacement of G2 from the supercritical to
subcritical zone. However, G2 remains close to the
hydraulic jump. Thus, only errors in the location of the
hydraulic jump spoiled the simulation of water depth at G2.
Another difficulty to model locally the water depths is in
the areas of high reflections like near G3. Indeed, the
shallow water equations cannot integrate the large slope
(the slopes of the channel side are 45%) and have
difficulties to represent these reflections. Then, the
results are smoother than the experimental data but the
shape of the hydrograph is similar. 4.5 Conclusions When
comparing calculation results with experimental data, we
noticed that the numerical code could provide a convenient
overall representation of the flow: high and low velocity
areas, hydraulic jumps and trailing zones. However,
concerning the water depths and velocities at the five
gauge points situated around the building, we found
differences corresponding to the difficulties of the code

to simulate local flow characteristics accurately. The major differences seem Water depth at Gauge 3 0 0.02 0.04 0.06 0.08 0.1 0.12 0.14 0 5 10 15 20 25 30 Time (s)

to come from:

• Slight errors in the locations of the hydraulic jumps (spatial errors).

• The difficulty to represent the reflections on the walls (building or banks).

• The size of the trailing zone downstream from the building.

5 FOUR BRANCHES CROSSROAD TEST CASE

In dense urban areas, the flows take place mainly in the streets and the crossroads. The influence of the cross roads is mostly the distribution of the flow between the different streets joining there. This experiment aims at improving the knowledge of the discharge distri bution in a four channels crossroad that is the most

popular street junction configuration in a city. In a future study, the capabilities of the numerical code to predict the flow distribution in a crossroad should be tested. Previous studies about open channel junctions mainly focused on three channels junctions either in dividing or combining flows and almost exclusively in subcritical conditions. To the authors' knowledge, the only work with 4 channel junctions was performed by (Nania, 1999); it includes an experimental study of 2 incoming and 2 outgoing flows with equal width concrete channels and for three slope configurations; from the experiments, an empirical relation was built to provide the discharge distribution as a function of the inflow Discharge Weighted Head (W = ρgH s , with H s the Specific Head of the flow). Thus, experiments are performed at LMFA to increase the knowledge in such configurations.

5.1 Experimental set-up

The set-up is composed of 4 rectangular channels, made of glass, of length L= 2 m and of width b= 0.3 m) oriented perpendicularly to each other, with the (xy) frame defined Fig. 18. The channels slope Qe y Qs x Qs y 2 m 0.3 m Junction entry sections Upstream gate Hydraulic jump Oblique jump Qe x Figure 20. Four channel crossroad. is 1.27% and the junction is a horizontal square. The water enters the two incoming channels through honeycombs and a gate used to adjust the normal depth, as the flow is supercritical. Both incoming and outgoing discharges are measures thanks to electromagnetic

flowmeters. Upstream water depths are acquired thanks to a moveable point gauge, with a reading accuracy of 0.1 mm and junction entry section water depths are measured by resistive probes to obtain an average water depth over about ten seconds. 5.2 Description of the flows The upstream flows are usually supercritical and meet within the junction creating locally a very complex secondary flow. The crossroad causes an abrupt flow deviation, resulting in hydraulic jumps. As reported by (Nania 1999) and depending on the upstream discharges, the general flow can be of two types. When the two upstream discharges (Qe x and Qe y) are not too different one from another, a hydraulic jump occurs in each inflow channel at specific distances from the junction depending on both discharges: this is called “type 1” flow. A “type 2” flow is obtained when one incoming discharge is much larger than the other.Then an oblique jump appears in the large discharge inflow channel and a hydraulic jump occurs in the low discharge channel. For a specific discharge rate (one inflow discharge much larger than the other), the flow can become entirely subcritical in the low discharge incoming channel but a virtual hydraulic jump can be located upstream from the gate. Downstream from the junction, two recirculation zones appear along with two contraction zones. Further downstream, the flow regime becomes supercritical again because of the slope. 5.3 Choice of parameters First aim of the study is to find one single equation providing the part of discharge in each direction as a Flow rate repartition as a function of the Specific Momentum at the inflow section y = 0.4023x + 0.3 R 2 = 0.9894 y = 1.2525x - 0.3696 R 2 = 0.994 y = 1.168x + 0.1227 R 2 = 0.9864

Specific Momentum.

function of the inflow conditions. The slope of each

channel is constant (1.27%) and should not appear

as a parameter. A parameter representing the inflow

conditions can be the Specific Momentum:

where h is the local water depth and Q is the

inflow discharge. The Specific Momentum is con

served through the hydraulic jumps, contrarily to the

Discharge Weighted Head used by Nania (1999).

In fact, the parameter considered is M x /M T (Spe

cific Momentum in the x direction divided by the total

Specific Momentum (M T =M x +M y)) calculated

using the inflow discharge and the normal water depth

set upstream from the hydraulic jump, to express the

discharge distribution: Qs x /Q T (Qs x =Outflow dis

charge along x channel and Q T =QS x +QS y). So, the

final equation may be written as:

5.4 Experimental results

The results obtained for 45 different inflow discharge

configurations set for the 1.27% slopes are sketched

Fig. 21.

It seems that two linear regimes exist, a first one concerning the type 2 flow (on the right side, the oblique hydraulic jump is from the x channel, and on the left side, it is from the y channel) and another one, in the centre of the graph, corresponds to type 1 flows. It should be noticed that the configurations where the flow is completely subcritical in one upstream channel fit perfectly with the curve when considering their vir tual normal depths upstream from a virtual hydraulic jump. When using the inflow Discharge Weighted Head (W = ρgH s instead of the Specific Momentum, the results are quite similar. Hence, further experimental measurements, with different geometric configurations as for example with different slopes, must be performed to underline all the parameters describing the flow distribution. 5.5 Conclusions This test case is the first step of a global experimental benchmark, which should improve the knowledge about the flow distribution at a crossroad. The results presented here permitted to test several parameters to use in order to establish the flow distribution law but more experiments are necessary to validate the various options (Specific Moment, Discharge Weighted Head. . .). In addition to this experimental benchmark, simulations using the 2D code presented in paragraph 2 will be performed to check if the flow distribution can be estimated accurately. 6 CONCLUSIONS We simulated a flood in a simplified urban area with 20 cubic buildings. We noted that the numerical results qualitatively corresponded to the experimental data but that some differences existed and could not be reduced with a finer mesh. Then, we modelled two typical urban flood configurations: the flow around a building and the flow distribution in a four channels crossroad. The numerical simulation of the flow around the building agrees with the experimental data; however, a perfect representation of the flow requires a fine mesh and then the use of many cells. The experimental study of the flow distribution in a crossroad permitted to present a distribution curve for a

1% slope crossroad in which two regimes seem to appear; more experiments are still necessary to validate both this last curve and 2D model in this context. More generally, the numerical simulations of these test cases permit to improve our knowledge about the capability of a 2D code to model a flood in a dense urban area and the way to define the calculation grid. However, a complementary validation on various field test cases remains necessary.

Detailed validation of CFD for flows in straight channels

N.G. Wright, A.J. Crossley & H.P. Morvan

School of Civil Engineering, The University of Nottingham, UK

T. Stoesser

Institute for Hydromechanics, University of Karlsruhe, Germany

ABSTRACT: An investigation has been made into the flow in open channels using a commercial Computational

Fluid Dynamics (CFD) package. The study has focused on the ability of the software to correctly predict the

complex flow phenomena that occur in channel flows. Previous work (Morvan et al. 2002) has shown the

capability of CFD in predicting the flow in natural rivers. In this project, the predictions are contrasted against

high quality flume measurements obtained for a trapezoidal channel, and a comparison is made between the

different turbulence models available.The results show that

whilst all the models generally give similar predictions for the bulk features of the flow, there is a marked difference between the secondary flow characteristics, and that the accuracy of the predictions increases with the level of complexity of the turbulence model used. Results from a LES model confirm the importance of turbulence modelling.

1 INTRODUCTION

The features inherent in open channel flow result from the complex interaction between the fluid and a num ber of mechanisms including the channel bed and walls, friction, gravity and turbulence. In the past such flows have been modelled using simplified models (for example the Saint Venant equations), which predict mean characteristics of the flow and often contain a high level of empiricism. With advances in computer power, interest has risen in applying more sophisti cated techniques providing more accurate results and more in-depth information. In other fluid flow fields such as aeronautics, the implementation of more com plex models has mirrored the advances in computer technology and 3D models are now commonly used. However this transition has not occurred as rapidly in open channel flow modelling, and most hydraulics models are either 1D or 2D with very few applica tions of 3D models. This is, in part, due to the inherent difficulties found in applying CFD in a natural river

channel (Wright 2001): inter alia, irregular geometry,

vegetation and roughness representation.

In this work the application of a generic commer

cial Computational Fluid Dynamics (CFD) package

to open channel flows is considered. The software

includes various models to solve general fluid flow

problems and is widely accepted as a modelling tool

in other fields. In this study, the Reynolds Averaged

Navier-Stokes equations (RANS) are used to represent the fully developed flow in a prismatic trapezoidal channel. The RANS equations are obtained by applying time averaging to the full Navier-Stokes equations, which results in six new terms known as the Reynolds stresses. A turbulence model is then needed to account for the Reynolds stresses in order to close the system of equations. In industry the accepted standard is the two equation k-ε model which assumes that the turbulence is isotropic. More complex models exist which account for the anisotropic nature of turbulence, but at an increased computational cost to the user often making the choice prohibitively expensive. The technique of Large Eddy Simulation does not rely on Reynolds averaging and directly predicts larger eddies whilst using a model for smaller ones (Smagorinsky 1963). In collaboration with researchers at the University of Karlsruhe, LES has been implemented for the channel under consideration here and preliminary results are reported. In the present study, the very nature of the flow is driven by the anisotropy of the turbulence and several different turbulence models are evaluated including the k-ε model, various standard Reynolds stress models and the new ω Reynolds stress model. The research programme is being conducted by the Universities of Birmingham and Nottingham and involves detailed CFD experiments for comparison with experimental data collected at Birmingham (Yuen 1989, Knight et al. 1994). The latter encompasses discharge, velocities and shear stresses. So far the

investigation has focused on a trapezoidal channel

which whilst being a simple geometry involves some

complex fluid flow patterns. These patterns are similar to those found in a rectangular open channel (Broglia et al. 2003).

The CFD investigations have examined the influence of grid size and structure, discretisation, turbulence model and wall treatment. The research programme has focused on generating the correct qualitative and quantitative flow features from the CFD software. Bulk quantities such discharge (bulk velocity), maximum velocity and mean shear stress have been used to ascertain the quality of the predictions, in respect to the experimental data. In addition, consideration has also been given to the velocity and bed shear stress distributions, with particular emphasis on generating the secondary flow (recirculation) patterns that should be present in a prismatic channel.

Results to date have demonstrated that the CFD is able to correctly predict the mean shear stress and subsequent shear force on the channel bed and banks. However, with standard turbulence models it is not possible to obtain the correct shear stress profiles. The study has also highlighted the complexities involved in obtaining the correct secondary flow pattern. The currents which are known to be induced by turbulence and the wall effects in open channel flow, should lead to the

maximum velocity occurring below the free surface.

However in all of the results obtained so far in the study,

the maximum velocity has occurred at the free surface.

Initial results obtained using a Large Eddy Simula

tions (LES) model have demonstrated that LES can

predict open channel flow phenomena more success

fully than RANS based models, and this application is

being further investigated.

2 MATHEMATICAL MODEL

The CFD software is designed to solve generic fluid

flow problems and the model components are deriva

tives of the full unsteady Navier-Stokes equations

which for an incompressible fluid can be written as

where u is the velocity vector with components u, v

and w, p is the pressure, ρ is the density, υ is the kinematic viscosity and the S M components represent additional momentum source terms such as the effects of gravity. For a complete derivation of the equations seeVersteeg & Malalasekera (1995).To fully resolve the Navier-Stokes equations at all length scales would require excessively fine grids and small time steps due to the effects of turbulence. This renders the direct solution of Equations 1 to 4 impractical for all but low Reynolds number flows. However it is possible to model the effects of turbulence on the flow without considering every single eddy, by considering time averaged effects. This is encompassed by defining mean values which when substituted into the full Navier-Stokes equations, give rise to the Reynolds Averaged Navier-Stokes equations which were used in the CFX simulations. Instead of using these mean values it is possible to use LES to predict the time variation of the larger eddies. The LES code LESOCC developed at the Institute for Hydromechanics (Breuer & Rodi 1996) was used to perform the LES simulations. The code solves the filtered Navier-Stokes equations on a curvilinear, block-structured grid discretised with the finite volume

method. A non-staggered grid with Cartesian velocity components was used and both, convective and diffusive fluxes are approximated with central differences of second order accuracy. The SIMPLE algorithm is employed in order to ensure mass conservation and to couple the pressure to the velocity field.Time advancement is achieved by a second order, explicit Runge-Kutta method. LESOCC is highly vectorised and parallelisation is accomplished by domain decomposition and explicit message passing via MPI. The subgrid stress of the filtered Navier-Stokes equations is computed using the dynamic approach of Germano et al. (1991). The linear no-slip (u + = y +) boundary condition is used for the bottom and the side walls since the first grid point is placed in the viscous sub-layer (y + ≈ 7). 3 GEOMETRY AND DATA 3.1 Experimental data To evaluate the performance of the CFD software, a comparison has been made against high calibre experimental measurements obtained from the SERC funded FCF programme (Knight et al. 1994) and by Kenneth Yuen as part of his PhD study at the University of Birmingham (Yuen 1989). The project has not only been concerned with demonstrating that the CFD is providing solutions that are quantitatively correct with respect to the experimental data, but also that the flow properties are qualitatively in line with expectations, for example the presence of re-circulations. The knowledge gained from this study will also be used to provide guidance 1 1 2b=0.15m

to the hydraulic community on how to apply CFD to

open channel flows.

The results presented in this report focus on one

particular geometry from Kenneth Yuen’s PhD thesis

which serves to illustrate the difference in perfor
mance between the different turbulence models. In the
original experiments various channel geometries were
considered including simple and compound channels.
Parameters such as the slope and cross-section were
altered and the measurements recorded at a given
cross-section once a uniform flow had developed. Dif
ferent flow depths were considered which led to a
series of data being collected for different discharges
and Froude numbers. In this report Experiment 16
is considered, where the cross-sectional geometry is
shown in Figure 1. The channel slope was 0.001 and
the discharge was recorded at 0.02630 m 3 s −1 with the
water temperature measured at 14 ∘ C. The characteris
tics of the flow are summarised in Table 1.

3.2 Model data for the RANS simulations

A model based on the geometry of Experiment 16 was
created with the same cross-section as shown in Fig
ure 1. Periodic boundaries were used at the channel
inlet and outlet such that the predicted profile would be
the same throughout the channel length. This enabled
a much shorter length to be utilised than if a mass flow
condition was implemented, whereby the flow profile
would need a significant length to develop. Choos
ing to implement periodic boundary conditions thus

reduced the number of cells required in the streamwise

direction, enabling more cells to be concentrated on the

cross-section. A channel length of 0.1 m was chosen

and a symmetry plane was imposed along the central

plane of the channel (such that only half of the geome

try was modelled), as shown in Figure 2 together with 1 1 H=0.15m b=0.075m B=0.225m z x L=0.1m y Figure 2. Computational geometry in CFX. the co-ordinate frame of reference. The channel itself was constructed as half of a flat trapezoidal box with the centreline coinciding with the x axis. The channel bottom was aligned with the y co-ordinate line and z co-ordinate represents changes in the vertical direction. The flow was driven by introducing a momentum source into the equations which accounted for the effects of gravity. This force was resolved into components acting parallel and perpendicular to the channel length to allow for the co-ordinate transformation whereby given that tan θ= S 0 . As the water temperature in the original experiment was measured to be 14 ∘ C, a value of 999.25 kg m 3 was used for the water density and together with g= 9.8066502 (the internal value of g in CFX) this gave Additionally the dynamic viscosity of the water was set to μ= 1.1666× 10 −3 N s m −2 . Note that in the results presented the z-component of the momentum source was set to zero as it was causing a number of numerical difficulties, whilst having no influence on the flow field. If required, a hydrostatic pressure field can be added as a post-process. The flow was initialised by setting the initial velocity equal to the mean recorded value in all of the cells i.e. The free surface was represented as a symmetry plane, and smooth no slip walls were applied at the remaining boundaries. 3.2.1 Mesh for the RANS simulations Two different meshes were constructed based on the requirements of the turbulence models used. Both meshes consisted of structured hexahedral cells. Emphasis was placed upon creating a sufficient use

Figure 3. A cross-section of Mesh 1.

of periodic boundary conditions reducing the need for

many elements in the streamwise direction. The first

mesh consisted of 10× 100× 200 (200000) cells. A

cross-section of the mesh is shown in Figure 3. Note that a biased seeding was used along the spanwise component of the free surface in order to reduce the y + variation at the channel wall. Thus the cell at the centre of the channel was three times the width of the cell at the bank.The second mesh followed the same structure as the first but consisted of 10× 200× 200 (800000) cells.

3.2.2 Mesh for the LES simulations

The LES simulation used a mesh of 161× 100× 100 in the x, y and z directions respectively. It should be noted that in the LES the streamwise length is much greater than for the RANS models. This length is required to allow the eddy structure to develop. This is unnecessary with a RANS simulation as these fluc tuations are averaged out. To account for wall effects, van Driest damping functions and the Werner-Wengle wall model were used.

4 RESULTS

Comparative results were obtained using five differ ent turbulence models. The first model considered was the industrial standard k-ε model (Versteeg & Malalasekera 1995) which assumes that the turbu lence is isotropic and does not solve the Reynolds stresses explicitly. As the name implies, the model

is based upon solving the turbulent kinetic energy, k , and the turbulence eddy dissipation, ε. In contrast to this, the Reynolds stress models solve the six Reynolds stresses directly hence accounting for the anisotropic nature of turbulence and are thus more computationally demanding. Note that ε is still present in the standard formulation. Three different variants of the standard Reynolds Stress approach were tested in which the differences were accounted for by different values for the model constants. These models were the Launder, Reece and Rodi Isotropisation of

Production (LRR-IP) (Launder et al. 1975), Launder, Reece and Rodi Quasi-Isotropic (LRR-QI) (Launder et al. 1975) and the model due to Speziale, Sarkar and Gatski (SSG) (Speziale et al. 1991). Both the k-ε and standard Reynolds Stress models use wall functions in the near wall region which relate the tangential velocity to the wall shear stress in the log-law region of the flow. This prevents the need to introduce a fine mesh near the wall, which would be required if the viscous sub-layer was to be resolved. The final RANS model tested was the Reynolds stress-ω or SMC-ω model (CFX Ltd. 2003), in which the flow equations are solved right through to the wall without the use of wall functions. The formulation is based on an equation for ω, the turbulent frequency as opposed to ε in the standard Reynolds stress models. One of the benefits of the approach is that the viscous sub-layer can be resolved with fewer cells than would be required for an ε based model such as k-ε or the standard Reynolds stress approaches. The bulk property results from the model comparison are summarised in Table 2 and compared with the theoretical and experimental values. Note that the k-ε, LRR-IP, LRR-QI and SSG results were obtained on Mesh 1, and that the SMC-ω results were

produced on Mesh 2. From Table 2 it can be seen that all the turbulence models predict the correct value for the mean shear stress compared with the theoretical value, which is in close agreement with the value recorded in the experiment. However in all of the simulation cases, the mass flow rate is over-predicted by between 12 and 15%. This may be due to the use of a smooth wall in the CFD as it has been assumed that the low Manning's n value from the experiment represented an almost smooth wall. Contour plots and vector plots of the secondary flow are shown in Figures 4–13 for the CFX results. Note that to improve clarity not all of the vectors are shown and the display magnitudes have been adjusted for each turbulence model. As expected the results from the k-ε model show no indication of the contours bulging towards the bottom corner of the channel, and there

Figure 14. Wall shear stress distribution results from the RANS model comparison. the wall. The results from the LRR-IP model are fairly similar to the k-ε profiles. It is

noted by CFX that this formulation does not contain any wall reflection terms which may partially account for the results obtained. The LRR-QI and SSG results both show bulging of the contours and evidence of re-circulation although the magnitudes of the phenomena are less that expected. Typically the scale of the secondary velocity should be of the order of 2-3% of the bulk streamwise velocity (Broglia et al. 2003). The results most in line with expectations are those from the SMC-ω turbulence model which show significant bulging of the contours and strong evidence of secondary flow. A feature of all of the predictions is that the maximum velocity occurs at the free surface, which in reality is not the case. Consideration has also been given to the shear stress distribution occurring on the channel bed and walls. Figure 14 shows a comparison between the results from the various turbulence models and those measured in the original experiment.All of the results show a characteristic local minimum at the corner of the channel and a decrease towards the free surface in line with expectations and the experimental measurements. The predictions all show the shear stress increasing towards the centre of the channel, whereas the experimental value decreases. In addition the LRR-QI, SSG and SMC-ω models all indicate a decrease at a point approximately two thirds below the free surface, with a marked decline present in the SMC-ω results comparable to that at the channel corner. Note that this point coincides with where the maximum distortion of the contours is present and the strongest secondary flows occur.

The LES results in Figure 15 show the bulging of

the contours towards the bottom corners in a similar

manner to the SMC-ω results. This figure also shows

the streamlines which demonstrate a three cell pattern

in a similar way to the more complex RANS models.

Figure 16 shows the u ′ w ′ Reynolds stress. To emphasis

the fact that LES can predict time-varying velocities

Figure 17 shows an instantaneous velocity field.

5 CONCLUSIONS

The results show that the CFD predictions accu rately predict the average shear stress value for all of the turbulence models tested. In all of the cases, the mass flow rate was over predicted, with none of the models appearing significantly better than the others. It was observed that the k-ε model failed to predict any evidence of secondary flow, and that the standard Reynolds stress approaches indicated some re-circulation with varying degrees, but all were below the expected magnitudes. The most realistic results were obtained using a non-standard Reynolds stress model in which the equations were integrated through to the wall without the use of wall functions. A com parison of the bed shear stress distributions showed that whilst all of the models gave the correct aver age value, none of the models captured the expected profile, which was observed in the experimental mea surements. Whilst the LES results need more analysis the results so far indicate that this approach has con siderable benefit compare with the standard RANS models and even the more complex SMC-ω model.

However, it must be borne in mind that this technique

requires considerably longer run times.

A number of choices had to be made within the

modelling strategy that can have a significant effect

on the results. These have to be carefully considered,

just as in experimental work, and novice users may not

always be aware of these.

6 FURTHER WORK

This study has focused on the application of a generic

Synthetic hydrographs as a design tool for flood routing evaluation

U. Maione

Dipartimento di Ingegneria Idraulica, Ambientale e del Rilevamento, Milano, Italy

ABSTRACT: In this paper the procedure for the determination of Synthetic Design Hydrographs (SDHs),

proposed by some of the Authors in previous works, is validated comparing the statistical distribution of peak

discharges obtained at the end of a river reach by routing a long series of historical floods and by routing the

synthetic floods only. The selected reach is the end branch of the Parma river, a tributary of the Po river (Northern

Italy). The mathematical model was calibrated on the basis of three recent historical floods. Then all the historical

floods and the SDHs have been routed in the river reach. Historical and synthetic peak discharges at a downstream

section were then compared in probability plots. The results show that the distribution obtained by routing the

historical floods seems to be correctly described by the results obtained by routing the SDHs.

1 INTRODUCTION

Peak discharges are significantly reduced in mild slopes river reaches by routing effects due to water volumes temporarily stored in the main channel and in the flood plains. Often these effects are masked by the contribution of tributaries or hill slopes encountered downstream. If concentrated or distributed inputs are negligible, as in the lower reaches of many tributaries of the Po river (Northern Italy), peak discharges really decrease. The amount of reduction depends on a combination of hydrological input and geometry of the reach and flood plains. Flood waves with the same peak discharge but different volumes are of course reduced in different ways.

There is then an interest to define Synthetic Design Hydrographs (SDHs) which are capable to model in a statistically correct way the dumping effect due to routing on the historical floods. In this way it would be possible to derive the peak discharge distribution at a downstream section of a river reach by routing only few SDHs instead of a long series of historical floods.

In previous works (Maione et al. 2000a, b) the Authors proposed a procedure to estimate SDH in gauged river sections where a long series of hydro

graphs is available. The method is based on the

statistical analysis of recorded flood waves through the

construction of the Flow Duration Frequency (FDF)

reduction curves of given return period and the deter

mination of the temporal location of the peak value for

each duration. In this paper the procedure for the determination of SDHs is validated comparing the statistical distribution of peak discharges obtained at the end of a river reach by routing a long series of historical floods and by routing the synthetic floods only. 2 SYNTHETIC DESIGN HYDROGRAPHS (SDHS) DERIVATION PROCEDURE SDHs can be derived (Maione et al. 2000a, b) from Flow Duration Frequency reduction curves (FDF) that furnish the maximum average discharge Q D (T) in a given duration D for each value of the return period T , where The FDF reduction curves are analogous to the IDF curves that relate the maximum average intensity, duration and frequency of rainfall. Their construction is obtained through the statistical processing of historical hydrographs. The analysis can be performed on the annual maximum average discharges for each duration ranging from 0 (corresponding to an instantaneous discharge) to a sufficiently large value, say, D f representing the characteristic duration of flood events for a given river section.Alternatively, the maximum values of the average discharges that exceed a given threshold

value for each duration can be sampled according to

the Peaks Over Threshold method (POT).

The estimation of the FDF reduction curve can be

conveniently obtained relating the quantiles Q D (T) to

Q 0 (T) by means of the reduction ratio ε D (T):

In the more general case, the reduction ratio is a

function of duration D and return period T . The conve

nience of the position (2) comes from the circumstance

that if the CV (Q D) and the functional form of the

probability distribution of Q D are independent of the duration D, ε D is independent of return period T and reduces to the ratio of the averages of Q D and Q 0 :

Under these assumptions the estimation of the FDF curves reduces to the estimation of peak flood dis charge quantiles Q 0 (T) and of the reduction ratio ε D .

Some different approaches have been proposed in literature for the identification of the functional form of the reduction ratio ε D that best fits the experimental data (NERC 1975, Fiorentino 1985, Bacchi et al. 1992)

Bacchi et al. (1992) used a deductive approach for the derivation of the reduction ratio based on a formulation that considers the crossing properties of continuous gaussian stationary stochastic processes.

From this formulation the following equation for the reduction ratio has been deduced:

in which Γ(D) is the variance function, i.e. the ratio of the variances of the instantaneous process and inte grated one. The parameter θ is the scale of fluctuation, i.e. the integral of the autocorrelation function of the instantaneous process.

Once the FDF reduction curves have been obtained, the construction of the SDH is performed imposing that the maximum average discharge for each dura tion coincides with the value deduced from the FDF;

the shape of the hydrograph is defined by the Peak

Duration values r D (0≤ r D ≤ 1), that are the ratios

between the time prior to the peak (in the time inter

val in which the maximum average discharge of given

duration falls) and the duration D. For each duration

the value of r D is calculated from all the historical

hydrographs; then the average value is computed and

adopted for the construction of the SDH.The data sam

pling modality is illustrated in Figure 1. The procedure 0 12 24 36 48 60 72 t (hours) 0 100 200 300 400 500 600 Q (m 3 / s) D = 16 hours r D •D = r 16 •16 Q16 Figure 1. Data sampling of Q D and r D from historical hydrographs (in this example D= 16 hours). is similar to that employed for the Chicago Design Storm (Keifer & Chu 1957). However, in the present case the coefficient r D is a function of D, whereas in the Chicago Design Hyetograph r is defined as the ratio between the time prior to peak intensity and the total rainfall duration and is made a constant for all durations. Therefore the following conditions determine the SDH: The rising and the falling limbs of the SDH are obtained by differentiating Equation 5 with respect to duration D as follows: If both FDF and peak duration ratios r D can be fitted by derivable curves, Equations 6 and 7 can be solved 0 12 24 36 48 60 72 D (hours) 0.4 0.5 0.6 0.7

analytically; otherwise numerical methods must be

applied.

3 SYNTHETIC DESIGN HYDROGRAPHS FOR PONTE BOTTEGO GAUGING STATION

The mentioned procedure was applied to the 45 years

long historical series of floods recorded at the Ponte

Bottego gauging station on the Parma river, a tributary of the main italian river Po.

From the 67 recorded flood waves, the 45 annual maximum average discharges for each duration ranging from 0 to 72 hours have been extracted. In some years (10 out of 45) the annual maximum for the selected durations belongs to different flood events.

Figure 2, in which the coefficient of variation CV(Q D) versus D is reported, shows that the assumption of CV(Q D) constant with the duration can be reasonably accepted for the considered sample.

Log-normal, Gumbel (EV1) and General Extreme Value (GEV) probability distributions have been considered in order to describe Q 0 (T). Parameters estimation was based on the Method of Moments for the first two distributions, whereas for the third the method based on L-moments has been adopted. Figure 3 shows, on Gumbel probability chart, the data sample (Gringorten plotting position) together with the fitted probability distributions.

The Hosking test (Hosking et al. 1985) on the k = 0 hypothesis with a significance level α= 5%, k being the exponent of the GEV distribution, demonstrates that the choice of the GEV distribution is justified, so that the peak discharge Q 0 (T) have been expressed in

the form:

The estimation of ε D has been performed by means

of Equation 4, which was demonstrated by Ballarin

et al. (2001) particularly suitable to fit the empirical

reduction ratios of medium-large catchments. 0 200 400 600 800 1000 1200 1400 Q 0 (m 3 /s) 2 5 10 20 50 100 200 T (y e a r s) upstream historical Gumbel distribution Lognormal distrib. Q 0 data sample together with the fitted probability distributions. 0 12 24 36 48 60 72 D (hours) 0.3 0.4 0.5 0.6 0.7 0.8 0.9 1 ε D ( ) observed Equation 4 Figure 4. Reduction ratio. The value of θ= 7.2 hours was obtained by a least squares estimation. The corresponding reduction ratio is plotted in Figure 4 together with the empirical ones. Considering that Equation 4 is a one-parameter curve the agreement is quite good for all the durations. Figure 5 shows the FDF curves for return periods ranging from 2 to 200 years. The equation of the Peak-Duration curve has been obtained by interpolation of the empirical patterns available for the gauging station. The interpolating function r D (D) was chosen of the form indicated below together with the least squares estimates of the four parameters: with a= 0.260, b= 3.432, c= 18.636, d = 1.49, D being the duration in hours. 0 12 24 36 48 60 72 D (hours) 0 200 400 600 800 1000 1200 1400

Figure 6. Peak position and interpolating function.

In Figure 6 the interpolating Equation 9 is plotted together with the average values obtained from the historical series.The average absolute difference between the empirical values of r D and those obtained from Equation 9 is 5%.

Once the estimates of FDF and Peak-Duration curves have been obtained, the SDHs follow immediately by analytical derivation of Equations 6 and 7. Figure 7 shows the SDHs obtained for return periods ranging from 2 to 200 years.

4 TOPOLOGICAL AND MATHEMATICAL DESCRIPTION OF THE RIVER REACH

The selected reach (Fig. 8) is the end branch of the Parma river, starting at Ponte Bottego gauging station and ending at the confluence with the Po river (northern Italy). The total length measured along the thalweg is about 38 km with a very mild average slope of 0.06%.

The river is formed by a deep main channel which meanders within two levels that maintain high levels over the surrounding plains. Once flood waters leave -12 0

12 24 36 48 60 t (hours) 0 200 400 600 800 1000 1200 1400 Q (m 3 / s) T =100 T = 200 T = 50 T = 20 T = 10 T = 5 T = 2
Figure 7. SDHs for Ponte Bottego gauging station. Figure 8. Location of the considered river reach. the main channel, flood plains of significant width are inundated; in some places flood plains are directly connected with the main channel; elsewhere one or more dikes must be overtopped before the inundation of the flood plain commences; this allows flooding only for high return periods and in the meantime increases the routing efficiency.

The mathematical model adopted for the flood

routing is the hydrodynamic module of the software

Mike11, produced by the Danish Hydraulic Insti

tute (DHI, 2002). The model solves the vertically

integrated equations of conservation of mass and

momentum, under the usual St. Venant hypotheses:

where Q= discharge, A=wetted area, q= lateral

inflow, h= stage above datum, R= hydraulic or

resistance radius, C =Chezy resistance coefficient,

α=momentum distribution coefficient, x= distance

along the channel (positive downstream), t= time,

g= gravitational acceleration.

The solution of the complete Saint Venant Equa

tions is based on a six-nodes implicit finite difference

scheme (Abbott & Ionescu 1967).

Using the cross sections derived from a recent topo

graphical survey a quasi-2D mathematical model of

the river reach was implemented.

The topographical description of the area to be

modeled is achieved through the introduction of cross

sections of the channels and flood plains which lie approximately perpendicular to the direction of flow. The transverse extent l of each cross section depends on whether the flood plain is to be simulated and by what method. In order to describe in a more complete way the characteristics of natural rivers, the pres ence of flood plains can be represented with several schematizations.

Open flood plains have been directly connected with the main channel and considered to contribute to the total conveyance of the section, even if the rough ness is usually higher. Closed flood plains have been described as “pockets” linked to the main channel (and sometimes together) through broad-crested weirs rep resenting length and elevation of the separation dykes. Pocket areas were assumed to contribute only to the storage of the reach.

The existing bridges have been introduced by means of the culvert structure available in the model.This was necessary in order to take into account the occurrence that, for high return period flood events, the bridges can result partly full.

5 CALIBRATION OF THE ROUTING MODEL

The November 2000 historical flood was simulated in order to calibrate the roughness coefficients of

the main channel and of the open flood plains. The

discharge time-series, obtained by converting the 1 3 / 1 1 / 0 0 0 . 0 0 1 3 / 1 1 / 0 0 1 2 . 0 0 1 4 / 1 1 / 0 0 0 . 0 0 1 4 / 1 1 / 0 0 1 2 . 0 0 1 5 / 1 1 / 0 0 0 . 0 0 1 5 / 1 1 / 0 0 1 2 . 0 0 1 6 / 1 1 / 0 0 0 . 0 0 1 6 / 1 1 / 0 0 1 2 . 0 0 1 7 / 1 1 / 0 0 0 . 0 0 1 7 / 1 1 / 0 0 1 2 . 0 0 0 100 200 300 400 500 600 700 800 Q (m 3 / s) 23.5 24.0 24.5 25.0 25.5 26.0 26.5 27.0 27.5 h (m a . s . l .) h

(m

a .

s . l

.) measured computed

Figure 11. Comparison between recorded and calculated water levels at Colorno gauging station.

Comparison between recorded and calculated water levels at Colorno gauging station is shown in Figure 11. The measured peak water level was probably slightly underestimated since the gage is located on the down stream face of an arc bridge which was partly full. Apart from the first hours, in which the behavior of the computed level differs significantly from the recorded one, the overall characteristics of the recorded water levels at Colorno station are satisfactorily reproduced. As a validation of the chosen roughness coefficients two further recent historical floods were simulated. Also in these cases the overall characteristics of the recorded hydrographs were satisfactorily reproduced with differences of less then 0.20 m in the evaluation of the peak levels.

6 ROUTING OF THE HISTORICAL FLOODS AND OF THE SDHS

The historical series of floods and the SDHs previously

derived have then been routed in the river reach.

For each historical flood the discharge time-series

obtained by converting the recorded level hydrograph

at Ponte Bottego was imposed as upstream boundary

condition. The more suitable downstream boundary

condition would be represented by the historical water

level time-series at the confluence with the Po river.

Since these data were not available for all the historical

floods, the same constant water level (hˆ= 25 m a.s.l.)

for all was assumed in the computations. The negligi

ble influence of this assumption on the discharges at 1 7 / 1 2 / 6 0 0 . 0 0 1 8 / 1 2 / 6 0 0 . 0 0 1 9 / 1 2 / 6 0 0 . 0 0 2 0 / 1 2 / 6 0 0 . 0 0 2 1 / 1 2 / 6 0 0 . 0 0 2 2 / 1 2 / 6 0 0 . 0 0 2 3 / 1 2 / 6 0 0 . 0 0 2 4 / 1 2 / 6 0 0 . 0 0 0 50 100 150 200 250 300 350 400 Q (m 3 / s) Upstream discharge Downstream discharge Figure 12. Comparison between upstream (Bottego) and downstream (Colorno) discharges for December 1960 flood event. the reference section of Colorno was verified by routing the few historical floods for which recorded water levels were available at the confluence twice: once adopting the recorded water level hydrographs, then imposing the constant water level hˆ as downstream boundary conditions. Consistently the same boundary condition hˆ was adopted for routing the SDHs. In order to obtain the initial conditions (Q and h at t= 0 along the river reach) a steady-state profile was computed corresponding to the first value of the discharge time-series and to the hˆ water level at the downstream section (subcritical flow). As an example, in Figure 12 the comparison between upstream (Bottego) and downstream (Colorno) discharge time-series for December 1960 flood event is shown. Figure 13 shows the SDHs in the same sections while in Table 1 are reported the numerical values of the peak discharges Q 0 for the SDHs, together with the routing coefficient η=Q 0 Upstr. /Q 0 Dwnst. for all the return periods considered. The routing coefficient is high (i.e. the dumping effect is small) for T = 2 since for this return period neither open nor closed flood plains are involved by the flow. The routing coefficient then

decreases for intermediate return periods (between T = 10 and T = 100 years) when the inundation of the flood plains by the water leaving the main channel is significant. For the higher value of the return period (T = 200 years) the routing coefficient again increases due to the high flood volumes involved. -24 -12 0 12 24 36 48 60 0 200 400 600 800 1000 1200 1400

* Colorno section.

All the 67 historical floods were considered in

order to obtain the annual maximum peak discharge

series at the Colorno section (Table 2). For compara

ble events belonging to the same year it could in fact take place the swap between maximum upstream and downstream peak discharge, the latter depending also on the behaviour of the complete inflow hydrograph (see for example years 1987 and 1998 in Table 2). Considering only one flood event per year could then lead to an incorrect evaluation of the sample of annual maximum peak discharges at the downstream section of Colorno.

From the 67 routed historical hydrographs the sam ple of the 45 annual maximum peak discharges was extracted and placed on a Gumbel chart according to the Gringorten plotting position. On the same graph the peak discharges of the routed SDHs were placed, attaching to each value, at first in a somehow arbi trary way, the return period of the corresponding start ing SDH. Table 2. Figure 14 shows the comparison between historical and synthetic peak discharges at the Colorno section. For a more immediate comprehension of the appreciable routing effect of the river reach, the upstream peak discharges (historical and synthetic) are also plotted in the same figure. The overall behaviour of the routed SDHs peak discharges fits satisfactorily those of the routed historical floods: this confirms that the return periods, at first somehow arbitrarily attached to the routed SDHs, are statistically meaningful. Synthetic results are in better agreement with historical ones especially for return periods ranging from 2 to 10 years. In this range the fit can be evaluated at first sight and is besides more reliable due to the less uncertainty in positioning the historical data on the probability chart. For higher return periods (20-200 years) the comparison is much 0 200 400 600 800 1000 1200 1400 Q 0 (m 3 /s) 2 5

(Colorno) sections.

more difficult as it would require a deeper statisti
cal interpretation of the historical results. However,
the trend of the historical peak discharge distribution
seems to be correctly described by the results obtained
by means of the SDHs.

7 CONCLUSIONS

A procedure of estimation of Synthetic Design Hydro
graphs has been proposed in previous works by some
of the Authors (Maione et al. 2000a, b). The method
is based on the construction of the Flow Duration Fre
quency reduction curves (FDF), obtained from the
statistical analysis of the average flood discharges
of given duration and on the determination of the
Peak-Duration r D .

In this paper the SDHs are evaluated and then
applied to model the flood routing effect in a mild slope
river reach where a long series of historical floods is
available.

The statistical significance of the derived SDHs is
then evaluated comparing the distribution of peak dis
charges obtained at a downstream section of a river
reach by routing a long series of historical floods and
by routing the synthetic floods only.

The satisfactory results obtained suggest that SDHs
construction procedure is reliable and the return peri

ods attached, at first in a somehow arbitrary way, to

the routed synthetic floods have statistical meaning.

This approach has a twofold advantage. Firstly,

whereas a historical series of floods is available, it

allows to evaluate the distribution of peak discharges

at a downstream section simply routing few syn

Surface water modeling of the Biebrza River network

R. Verhoeven & R. Banasiak

Hydraulics Laboratory, Ghent University, Belgium

D. Swi tek, J. Chorman´ski & T. Okruszko

SGGW, Warsaw, Poland

ABSTRACT: The Biebrza River, situated in the north-eastern part of Poland, flows through the last extensive,

fairly undisturbed river-marginal peatland in Europe. Its valley intensively drains the surrounding plateau and

the outwash plain into the river and creates a very complex ground and surface water system. The carried study

focuses on the upper and middle basin of the river with a length of about 80 km. It aims at the elaboration of

a surface water model as a tool for the water resources management in the catchment. During intensive field

measurement campaigns a large amount of information on the topography and on the hydraulic characteristics

has been gathered. The data is used to provide an accurate and reliable input for a flood-routing model and to

guarantee high quality modeling after ample calibration. Special attention is paid to the simulation problems

related to storage and flow in the complex network of inundation fields as an important part of the drainage

system and to the impact of dense vegetation on the

discharge characteristics. Coping with these difficulties, the

simulation results show fairly good agreement with measurement data.

1 INTRODUCTION

The Biebrza River and surrounding wetlands are sit

uated in the northeastern part of Poland, in an ice

marginal valley, some 195 000 hectares in area (Fig. 1).

This region forms the last extensive, fairly undisturbed

river-marginal peatland in Europe, containing endan

gered plant and animal species in a large variety of

fully developed ecosystems. It is internationally recog

nised as a reference area for restoration of deteriorated

peatlands.

Biebrza Valley, according to the geomorphologic

description, is an extensive depression formed dur

ing the last glaciation. It is filled with several thick

deposits of fluvioglacial sands. The Biebrza Valley

was divided [Zurek, 1984] into basins using a relation

of higher order morphologic features such as ancient

and young morainic plates, glacier outwash plains or

river flood terraces. There are 3 major basins, respec

tively identified as the Upper Basin reaching from the

springs of Biebrza to the mouth of the Netta River;

the Middle Basin covering the area from Netta to the

mouth of Rudzki Channel and the Lower Basin situ

ated in the southern part of the valley up to the alluvial

cone of the recipient Narew River.

The Upper Basin has a length of some 40 km (62 km

along the river) and a width of 2–3 km, with two Figure 1. Biebrza Valley – site map. basin-lake widenings: in its middle part and in the transition zone to the Middle Basin. The Middle Basin is the biggest, 40 km long and up to 20 km wide. It forms a vast, very plat depression paludified by the surface waters of Biebrza and its

tributaries flowing from the Lake District, as well as

by the ground waters of two aquifers.

The river in Lower Basin has a length of 30 km and

a width ranging from 12 to 15 km. The flood plain

composes of flat peatlands and a mud zone of 2 km

along the river border.

The Biebrza river, as a whole, is a typical lowland

river. It has mild slopes (in average about 10 cm per

1 km) and a strongly meandering character. It features

varying cross-sections and an irregular longitudinal

profile. The variability of the hydrological character

istics along the river is also typical. This is due to the

fact that the valley intensively drains the surround

ing plateau and the outwash plain into the river. The

surface water system is quite complicated consisting

of a complex drainage system, network of inundation

fields and storage areas. The flow is highly influenced

by the dense vegetation.

A comprehensive study has been launched to tackle

several water management problems, especially in the Upper and Middle Basin of the river. This happens within a bilateral project joining efforts of Flemish and Polish research teams. The project is aimed at the development of methods to increase the use and the efficiency of wetland area's, the creation of new artificial area's where the same functions could be implemented and at the study of water management measures to be taken to protect the wetlands ecosys tem. Special effort is put on the development of a numerical model, allowing the simulation of the impact of different measures on the water balance of the catchment. For this, starting from the existing data, additional measurement campaigns need to be per formed in order to define the input parameters and the boundary conditions of the model.

So far, starting from 1999 several intensive field measurement campaigns have been realised over the vast area of the Upper and Middle Basins, delivering a large amount of data, which can be used to provide an accurate and reliable input for flood routing model.

2 DATA COLLECTION

2.1 Topographical data

A Digital Elevation Model (DEM) of the research area is being developed. For this the ArcInfo 7.2

TOPOGRID command is used.This method, originally developed to interpolate DEM for hydrologic mod elling purposes, was also several times successfully applied to construct a model of floodplain topogra phy (Cera et al., 1996; Townsend & Walsh, 1998; Chormanski, 2003). For the elaboration of DEM, first, the necessary data were collected by field measure ments and map analysis. Consequently, the Digital Elevation Model has been created as a raster model by spatial interpolation. The main data source for the model generation was a set of contour lines elaborated in digital form on the basis of topographic maps with a scale of 1:25 000.The DEM of the research area was created as a raster network with a cell resolution of 25 meters. Because the topographic maps do not accurately show the flat areas at the valley bottom, the construction of a proper elevation model needs additional measurements. Therefore, the database was extended with topographical data from field measurements. The efforts were focussed on the area close to the river channel. Information was collected along the Biebrza River banks every few hundred meters making use of a precise GPS set working in Differential RTK mode (Hoffmann-Wallenhof et al., 1997). Also, a number of valley cross-sections were measured by traditional levelling.As a result, Figure 2 shows the DEM of Biebrza valley for the section between Jastrzêbna and Sztabin. 2.2 Hydraulic data The hydraulic data collection focuses on the determination of the friction coefficients of the different river reaches and on the steady state calibration of the numerical model to be developed. Until now, several intensive field-measuring campaigns have been developed in different seasons over the period 1999–2003. Figure 3 gives a schematic overview of the measurement locations along the river over a length of about 80 km. The track length of the strongly meandering river between the consecutive cross-sections has been calculated using the digital topographical maps. In all these locations discharges were recorded from a bridge or from a boat using propeller meters or electromagnetic velocity meters. Usually, the measurements were conducted twice in order to increase the

measurement accuracy. The local water surface has been recorded in multiple, discrete cross-sections along the river leading to a fairly accurate recognition of the longitudinal water surface profile (Fig. 4). From these recordings the friction slope of every reach of the river was calculated. Input of these data into the simulation model lead to the determination of the friction characteristics. 3 NUMERICAL SIMULATION 3.1 Numerical tool The HEC-RAS software package is adopted to model the surface water flow. This tool, developed by Hydrologic Engineering Center (HEC) of the US Army Corps of Engineers (USACE), is a software package intended for calculating water surface profiles in a full network of channels, a dendritic system, or single river reach (HEC, 2000). The HEC-RAS software

Figure 2. Digital Elevation Model for Biebrza valley – Upper Basin section.

Figure 3. Schematic representation of discharge measure

ments.

uses the St. Venant equations to compute water surface

profiles given cross-section data, roughness coeffi

cients, and flow rates. In addition, the program has

a number of special capabilities related to the analysis

of culverts and bridges at roadway crossings and to

model weir overflow structures, dam-burst and water

storage interactions. It can be considered as quasi

two-dimensional software, as it is capable to include

off-channel storage and inundation fields. Depending

on the flow conditions, inundation fields are simulated

as separate channels or as storage cells. The total flow

is distributed according to conveyance between the

main river channel and the floodplain. The upstream

boundary conditions can be a discharge or a stage 115,2

Recorded water surface profile along the section between Sztabin and Ostrowie (14.05.2003). hydrograph. The available downstream boundary conditions are: a stage hydrograph, a flow hydrograph, a single-valued rating curve or a looped rating curve (Manning's equation). Furthermore, the software is supported by the inundation fields mapping system, as described above, by the delivery of supplementary topography information in order to construct full flood plain cross sections that reflect accurate channel and overbank data. Inversely, results exported from HEC-RAS may be processed in the ArcView3D analysis extension for floodplain mapping and analysis. This includes the locations of the cross-section cut lines (Fig. 2) along with water surface profile data and a set of polygons that describe the extend of the modelled floodplain. 0

Figure 6. Determination of friction coefficient.

3.2 Friction coefficients in the steady state model

Once all discharge data have been processed, the fric tion coefficient of each part of the river network can be calculated in two different ways: As the field cam paigns were performed in periods with stable water conditions, one can suppose the flow regime do be in a steady state with uniform flow and apply the Manning formula in each gauging point to calculate the friction coefficient. The values of the coefficients obtained by this approach are shown in Figure 5.

The strong variation of the friction coefficient as a function of vegetation development is striking. In this region vegetation starts to grow in late April and reaches full growth in early summer. By this it isn’t sur prising that although the water stages recorded during the campaigns of June 2002 and April 2003 were very similar, the discharges inApril were 2 to 3 times higher in April than in June. The alternation of the friction characteristics is particularly strong in the upper sec tion of the river, where the channel is relatively small and where almost the whole cross-section is taken by plants. The growth of the plants not only increases the resistance to flow but also reduces flow velocities and

disturbs the velocity distribution.This important effect

has also to be accounted for in the unsteady state flow

simulation presented in the next section.

The second method uses the theory of hydraulic

water surface profiles: Starting from the data on 100.0 101.0 102.0 103.0 104.0 105.0 106.0 107.0 0.0 1.0 2.0 3.0 4.0 5.0 6.0 7.0 8.0 Distance Osowiec-Goniadz [km] L e v e l z [m a s l .] water table bottom profile Figure 7. Longitudinal profile. geometry, water levels and discharge, the Bresse equation allows calculation of the friction coefficient in a river reach between two gauging locations. When looking at Figure 6, it is clear that the second method delivers much better results. The irregularity of profiles, with significant changes in cross-sectional area and longitudinal slope (Fig. 7), that could not be completely recognized, must be compensated by the calibrated friction factor. 3.3 Extension to floodplains The knowledge of the value of the friction coefficients as well as accurate information on the geometry is of primordial importance for the quality of the results of the hydrodynamic models. Up till now only information on the low water level friction characteristics is available. As during flood flow the value of these coefficients might be substantially different, it is also important to focus the field campaigns on high water level situations that normally occur between early and late spring. This is the reason why most field campaigns were planned in this period. Unfortunately, in the last four years springs have been (very) dry in the Biebrza region, leading to a lack of important data concerning the flood routing.Therefore, for a good and reliable reconstruction of the hydraulic flow conditions fluctuations related to different water level and flow regimes in the river catchment, additional field measurement campaigns under high water level conditions need to be elaborated in the (nearby) future. The actual situation necessitated the use of other data.A flood event recorded in Spring of 1996 has been employed as an auxiliary data set for model development on flood conveyance in the Biebrza valley. 3.4 Unsteady state simulation In the first stage, the modeling of surface water flow is performed for a part of the Upper Basin of the Biebrza River, restricted to the cross-sections between Sztabin (downstream) and Ostrowie (Jastrzebna). The distance between both these section is 15 km. For both cross-sections discharge hydrograms 0 20 40 60 80

] Q(t) Sztabin Q(t) Ostrowie

Figure 8. Discharge observed at upstream and downstream

gauges.

Q(t) for the period 10.04.1996–30.06.1996, (shown in

Fig. 8) are used to define the upstream and down

stream boundary conditions. There is a significant

difference in discharge rates between these two cross

sections. This is mainly due to the lateral inflow of

melting snow during the flood event. The lateral dis

charge inflow, Q leb (t), from the Lebiedzianka brook is

added 12.23 km upstream of Sztabin. Next, the uni

form lateral inflow is imposed along the river section

as Q in (t)=Q Sztabin (t)–Q Q Ostrowie (t)–Q leb (t). This

solution is obviously a rough approximation of the

actual situation, as it does not account for the tempo

ral and spatial variation of the lateral inflow. A more

realistic approach on this issue needs to be elaborated

in further study.

During flood periods, the river valley consists of parts which mainly act as a storage for flood water and of effective transport areas. The particular areas have been identified according to topography reading and land use. Consequently, the storage areas and friction coefficients for the flow active zones were adapted by calibration for steady and unsteady flow so that the observed and calculated values became congruent.

To obtain a better agreement between observed and calculated water levels in the unsteady flow simula tion, the friction coefficient had to be varied in such a way that it takes into account the temporal change of flow resistance due to the growth of vegetation. This appeared of crucial importance for the period under concern. Not only modification of the roughness was incorporated in this step but also the changes in the transport effective area over the cross-section had to be anticipated. The increase of the n-coefficients only to reflect the growth of the plants results in a reduction of the flow velocity and subsequently in a delay of the flood propagation in respects to the recorded event.

Based on all these considerations and on a care ful calibration procedure it is possible to develop a reliable numerical model, able to reproduce the natu

ral situation. Figures 9–11 present the calculated and 0 20 40 60 80 100 120 140 160 180 96-04-10 96-04-24 96-05-08 96-05-22 96-06-05 96-06-19 96-07-03 Date Q [m 3 / s] Q(t) observed Q(t) calculated Figure 9. Figure 13. Water stages calculated for 2 different friction situations.

The level of the water surface profile for maximum discharge as generated by the model is used to delin eate the flooding boundaries across the valley. The results from this floodplain mapping, as obtained from ArcView are presented in Figure 12.

It is clear that possible flow condition alternations will influence the conveyance of the flow in channel and valley. Therefore, different scenarios need to be tested in terms of impact of individual or groups of parameters, or changes in the water supply configu rations. An example will demonstrate the impact of changing the friction on the flood water stages for the same event as considered above but supposed to happen e.g. in late spring.Therefore the friction coeffi cients for the floodplain and the channel are increased by a factor 2. Figure 13 shows the water levels along the river for both scenarios. The water levels in the second case rise around 30 cm. This results also in an increase of the flooding area from 13.483 km 2 to 15.896 km 2 . Certainly, this example does not fully reflect the potential changes in the flood plain area of the valley due

to the growth of vegetation. In analogy to variation of the friction factor in the main channel, as shown in Figure 5, the variation in flood plain area can be even much more considerable. 4 CONCLUSIONS The surface water management in the Biebrza valley is under extended and well-designed study. The numerical model for surface water flow is being developed using handsome and effective tools. The numerical modelling approach, although based on some primary assumptions, reveals promising results. The first flooding simulations on a restricted part of the network revealed a good reproduction of recorded field data. The model performance will further be improved given a more extended base of hydrometrical data, especially in terms of overbank flow conditions. It is obvious that due to the large area to be covered by accurate and reliable data sets and the complexity of the river network, the development of a complete simulation model is a long-term business. However, large progress has been made so far, identifying weak spots of the data acquisition, schematic representation and numerical solution. The feasibility of the numerical model has been well recognized. A right approach combining both field recognition and numerical experience should guarantee the successful

realization of the ambitious task to facilitate and

encourage the water management and the conserva

tion of the natural beauty of the region, in particular

of the Biebrza National Park.

ABSTRACT: In this paper, an implicit unstructured gird algorithm for solving two dimensional Shallow Water

Equations (SWE) has been developed. It is based on cell-centred Finite Volume Method (FVM) and can handle

cells of triangular and Quadrilateral types. The algorithm includes piecewise linear least-square interpolation and

uses Roe's approximate Riemann solver to compute fluxes. In addition, a new technique is introduced to prevent

instabilities and oscillations caused from the bed slope terms in the case of problems with arbitrary topography

and hydraulic structures. The method results set of nonlinear algebraic equations for the flow variables in each

cell. The system of equations can be iteratively solved. Second order accuracy in time and second or higher order

accuracy in space can be achieved in this method. The proposed method is validated and verified via solving

some examples and comparison of the results obtained from the new method with the other methods.

1 INTRODUCTION

Flows in open channels are often modelled by a set

of hyperbolic partial differential equations, i.e. the

well known shallow water equations (SWE). Algo

rithms for solving SWE on structured grids have

become widespread in recent years (Delis et al. 2000;

Fennema and Chaudhry 1989; Panagiotopoulos and

Soulis 2000; Valiani et al. 1999). However, these

algorithms have shown difficulties in predicting sat

isfactory results in complex geometries due to mesh

irregularities. As a result, attention has turned to the

development of the algorithms on arbitrary unstruc

tured grids. Many current unstructured algorithms utilize explicit time integration (Anastasiou and Chan 1997; Beffa and Connell 2001; Nujic 1995; Zhao et al. 1996) that can be computationally expensive if a long period of time has to be simulated. On the other hand, the explicit approach is computationally efficient when applied to meshes that are coarse. For cases where finer meshes are used, the time of computations significantly increases. For the sediment transport problem, which is not a high gradient phenomenon and often needs a time range of several years or decades, the simulation takes a lot of time therefore, an implicit scheme could be more useful which allows large time steps to obtain solutions in a computationally efficient manner. The application of the implicit schemes in SWE is often an extension of the schemes used in computational fluid dynamics (CFD). As pioneers, Fennema and Chaudhry (1989) have used implicit finite difference schemes, developed by Beam and Warming (Beam and Warming 1976; 1978) for hyperbolic systems in conservation law form, for the solution of two-dimensional SWE without source terms. In general, good results are reported, even though quite dissipative. However, these schemes are only first order accurate in space and employ the flux splitting in a nonconservative way. Later, Jha et al. (1996) proposed a modification for achieving full conservation, employing the use of the Roe-average approximate Jacobian (Roe 1981). MacCormack (1982) presented an implicit analog of his earlier widely used explicit method (MacCormack and Paullay 1972) for solving the equations of compressible viscous flow. Panagiotopoulos and Soulis (2000) have extended the implicit MacCormack scheme to integrate the flow equations. They developed a numerical method to solve SWE in generalized coordinates describing the depth-averaged, steady, subcritical and supercritical free-surface flows with the presence of

hydraulic jumps. In the other paper, Klonidis and Soulis (2001) have developed another finite volume scheme to calculate steady, two-dimensional SWE. The formulation is based on transformation of the flow equations into

a non-orthogonal, boundary-fitted coordinate system.

Therefore, the method is suitable for structured grids.

The shortcoming of an implicit finite volume model

for two-dimensional SWE on unstructured grids can

be seen. This method should have the shock capturing

capability and a suitable treatment of bed source terms.

In this paper, an implicit robust model for numerical

solving of SWE on unstructured grids is introduced.

The proposed method has a special treatment of the

bed source terms therefore it is able to model flow

over an initially dry and irregular bed.

2 SYSTEM OF GOVERNING EQUATIONS, SWE

The system of SWE in the conservative form is

given by:

with

where F(q)= [f(q),g(q)] T is the flux vector, h is the

water depth, u, v depth averaged velocity in xand

y-direction, respectively, S 0x , S fx are bed and friction

slope in x-direction and S 0y , S fy are bed and friction

slope in y-direction. The bed slope is defined in x

direction as:

and the friction slope is estimated using the Manning's

formula. For example, in x-direction, it is:

S 0y , S fy are defined in a similar way.

3 NUMERICAL ALGORITHM

3.1 Discretization of the governing equations

The system of governing equations is discretized using

the finite volume method (FVM). Integrating Eq. (1) n x y Ω Γ Figure 1. Notation for finite volume method. over an arbitrary triangular cell and using the divergence theorem, the basic equation of the FVM is obtained as: in which n is unit outward vector normal to the boundary (see Figure 1); dA, dl are area and arc element, respectively. After some manipulation, the semi-discrete form of the equation is: where the subscripts i and m denote quantities for the i-th cell and m-th face of the cell, respectively and N is the total number of the faces for that cell. In an implicit scheme, the flux vector F is computed at the new time level k + 1. Using implicit scheme, Eq. (6) can be rewritten in the following form: where R i =A i S(q i) is the right hand side terms evaluated in cell i at the known time level k . Expanding F about a known time level, we get: where J= ∂F/∂q is the flux Jacobian matrix. Substituting Eq. (8) into (7) leads to:

Following Jameson and Turkel (1981) and Yoon and

Kwak (1992), the flux Jacobian matrices are splitted

as follows:

with

whereV and c= √ gh are the velocity vector and speed

of the wave, respectively and α is a relaxation factor

of order unity. Eq. (9) now becomes:

or written in matrix form:

in which:

is the unknown vector. The formulation of the matrix

M and the vector RHS are given by Komaie (2003). To

numerically solve the discretized Eq. (12), the major

steps of the solution procedure are reconstruction, flux computation and evolution. These steps are illustrated below.

3.2 Reconstruction

For the first step, reconstruction, a cell-centered scheme is used. The piecewise linear, least-square reconstruction procedure used here is similar to those used by Barth (1993) and Coirier (1994). Each of the three primitive variables h; u and v is assumed to linearly vary within a finite volume as:

where U can be any of the above variables. The bars in Eq. (15) denote cell-averaged values as defined in the last equations. In high gradient regions, a gra dient limiter is normally used in Eq. (15) to ensure that the reconstruction polynomial does not produce new extrema near a flow discontinuity such as a shock wave. Limiters can also control the numerical oscil lation that are common with second and higher order

numerical schemes. In this paper, the limiter is applied to the gradient terms (Anastasiou and Chan 1997) so that: where r is the vector from cell centroid to the midpoint of the edge and 0< < 1 is a chosen limiter. When is set to zero, the computation domain is characterized by piecewise constant regions resulting in a first-order scheme. The non-linear limiter is given by: where: with: This procedure is carried out sequentially for the two cells separated by the common edge. These values are then used in the Riemann solver to estimate the flux across the edge in the flux computation phase. When β= 1, is the Minmod limiter and when β= 2, the limiter is Roe’s Superbee limiter. The Minmod limiter is used in this paper. 3.3 Flux computation

In the next step, the normal component of the flux vector, i.e. F m .n m in Eq. (12), should be estimated. With the piecewise linear reconstruction, the unknown variables are continuous and assumed to linearly vary within a finite volume. However, no guarantee exists that the variables will be continuous across adjacent finite volumes because a different polynomial is used in each finite volume. As a result, a flux formula is needed to compute a single flux at a finite volume boundary using fluxes from the adjacent volumes. In this paper the Roe's approximate Riemann solver is used (Roe 1981). Roe's method may be the most famous Riemann solver in CFD and SWE (Brufau et al. 2002; Erduran et al. 2002; Roe 1981; Sanders 2001; Toro 2001; Tseng and Chu 2000). Define the normal component of the flux vector as:

Then F n can be computed using the Roe FDS

method as:

where the subscripts L and R denote the flow condi

tions to the left and right sides of the cell face and

A i+1/2 is Roe flux difference splitting matrix.

3.4 Evolution

Now it is possible to solve the Eq. (12) for each cell.

There is a part of RHS in Eq. (12) that relates to

the unknowns of the neighbour cells. Therefore, the

system of the algebraic equations should be solved

iteratively. The nature of the method enables us to

implement it on parallel computer systems. In addi

tion, it is efficient because no block or scalar tridiag

onal inversions need to be calculated. After achieving

convergence, the solution is updated to find the flow

variables at the end of a time step. The main ques

tion is whether there is any condition to restrict the

time step of the computation for the proposed implicit scheme. It is clear that the CFL condition is not appli cable here. But from the mathematics it is well known that to achieve a numerically stable method, the Matrix M= [m ij] should be diagonally dominant. It means:

3.5 Treatment of the bed source terms

Here, the new developed method for numerical imple mentation of the bed source terms is presented. The proposed method is simple and robust and it is inde pendent of the Riemann solver. It also holds the conservation property that is defined by Bermudez et al. (1998). For the description of the method, two options should be considered:

- How the method deals with the terms 0.5 gh 2 in the flux terms.
- Which scheme is used to numerically compute S b (q).

3.5.1 Flux modification

The flux vector on the edge can be computed with a desired Riemann solver but after that, the term 0.5 gh 2 should be recomputed for the sloped edge (Komaie 2003):

which h i and h j are the water depth at the two ends of the edge based on the constant water level assumption over the edge. 1 2 3 Figure 2. Sloped wet cell and the water surface level, 3D imagination. 3.5.2 Source terms Now

it is required to compute the integral of the bed source term vector over a cell ▯: If we assume that the bed slope in xand y-direction in every cell is constant, then we have It means that the bed term integral is converted to the multiplication of two parameters: cell bed slope and the volume of water in the cell between water surface level and bed level. For the case of wet cell, i.e. all three nodes are under the water surface (Figure 2), the volume of water is: which A is the cell area and h i (i= 1, 2, 3) is the water depth at ith-node of the cell. For the partially wet cell the above Eq. should be modified so that the real volume of water is obtained. In the case that only one node is under water surface (Figure 3), the location of points “a” and “b” should be 3 1 2 a b

Figure 3. Sloped partially wet cell and the water surface

level, 3D imagination.

found at which the water surface plane, i.e. .η= const.,

intersect the edge lines.At these points, the water depth

is zero. With the help of similarity of triangles in , one

can easily find for the point “a”,

in above Eqs., x k and y k are the coordinates of the point

k . For the location of the point “b”, similar formula

tions can be found. Now it is possible to compute the

wet horizontal area of the element, i.e. A ab1 :

and finally the volume of the water in the cell can be

computed as follows

In the case that two nodes are under water surface, the

same method can be used.

4 NUMERICAL EXAMPLE

Under a research work mainly supported by the cen

tral public funding organization for academic research

in Germany (DFG), a physical model has been stud

ied at the Aachen University of Technology (RWTH)

to understand the fundamental flow behaviour in

meandering channels and rivers with overflow into

floodplains (Stein 1990). In order to perform the experiment, a 15.0 m long, 3.0 m wide and 0.35 m deep channel was built from PVC with a variable longitudinal slope in the range of 0 to 0.2% (Figure 4). The channel was equipped by the Laser Doppler Anemometer (LDA) tools to record the velocities. Stein (1990) has tested two basic variants whose essential difference was the existence or nonexistence of the vegetation on floodplains. The flow behaviour for the dominant flow in floodplain or in main channel could be systematically analyzed through the variation of the vegetation on floodplains. The analysis of the measured data of both variants showed that the mechanisms of flow in the case of dominated flow in main channel exhibits partly strong threedimensional character (Stein 1990). This experiment has been already used by different researchers to verify their models (Farshi 2002; MinhDuc 1998; Schröder 1996; Stein 1990; Wenka 1992). In this work, we also simulated this experiment with smooth conditions on the floodplains. In accordance with the statements of Stein (1990) and Wenka (1992) and based on the objective of the current work, it was not expected that our twodimensional model can simulate the threedimensional flow processes. However, the quality of measured data makes it possible to determine, how far the numerical results are and whether the numerical model is able to approximate the considered phenomena basically and to describe their influence on the averaged flow parameters. Here the test case A5 with the constant longitudinal slope of 0.05% is considered. For this variant, the average water depth in the main channel at the inlet section is h m = 0.15 m , where the subscript “m” means the average in main channel. It is tried to keep the above water depth constant along the channel, as long as this is admitted by the flow conditions. Wenka (1992) used different input velocities for the main channel and the floodplains in variant A5, i.e. V m = 0.23 m/sec for the main channel and V f = 0.30 m/sec for the flood plains. The subscript “f” represents the average in the flood plains. To test the ability of the model, a computational mesh has been generated (depicted in Figure 4). It is an unstructured grid that contains triangular and quadrilateral cells. It includes 4802 nodes and 5219 cells in which 4093 cells are quadrilateral and 1126 cells are triangular. The element size ranges between

0.02 m and 0.20 m. In order to reduce the effect of boundary condition on the results, the simulated channel is longer than physical model (15 m instead of 11.34 m) but the other geometrical parameters are the same. The above discharge with the described velocity distribution was applied to the proposed model as inlet boundary condition in the form of the inlet hydrograph.

Figure 4. Meandering channel: geometrical dimensions and computational grid.

The outlet boundary condition was selected in the form

of critical depth in the wet edges.

After calibration, the constant Manning's coeffi

cient n= 0.015 was selected. The time step of 0.015

sec was chosen. After shock capturing the time step

and Courant number has been increased. At the end of computation at runtime 850 sec, the time step has reached 1.334 sec that corresponds to average Courant number 32.3. Figure 5 shows the comparison between the computed and the measured values of the resultant velocity at cross-section 7. the computed and measured results can be seen. Stein

(1990) and Wenka (1992) are not successful to sim

ulate the velocity distribution in this region by their

turbulence models. Minh Duc (1998) has also sim

ulated this variant and could reproduce the velocity

distribution at the right hand side of the main channel

well but his model could not achieve good agreement

at the left side.

In practical applications, it is most interested to

compute the water surface elevation (WSE). In such a

complex flow system, correctly computing the WSE is also a difficult task. In Figure 6, the computed values and measured data are compared in cross-section 5 for test case A5. 5 CONCLUSIONS A new implicit numerical scheme has been introduced and applied for SWE. The method can be applied on unstructured grids with triangular cells. In addition, a new simple treatment of source terms is proposed. The results show a good agreement of the proposed

method with the comparable sources. The new method

gives a well-computed velocity distribution that could

result quite reasonable bed shear stresses. For the high

gradient applications, the new method needs more run

time than explicit methods. The main advantage of this

method is for the quasi steady state conditions in which

the much higher time steps could be used.

Supercritical flow in channel intersections

N. Rivière & R.J. Perkins

LMFA, Lyon, France

ABSTRACT: Experiments have been conducted in a configuration formed by the intersection of four identical

channels. Each channel is made from glass and measures 2 m long and 0.3 m wide; the slope of each channel can

be fixed independently, as can the flow rate in the channel. In this configuration the flow enters the intersection

through one of the channels, and is evacuated by the other three. The results show that, immediately after entering

the intersection, the incoming flow behaves as a free, rectangular supercritical jet. The surface profiles of the jet

as it collapses correspond well to the theoretical solution obtained for the classical dam break problem. Close to

the exit from the intersection the walls of the side channels have an important influence on the flow in the main

channel, and the dam break solution has to be corrected in a way that is still to be precise.

1 INTRODUCTION

During severe flooding of urban areas, the water in

the streets can reach a depth of a metre or more, caus

ing severe economic losses, and possible loss of life.

We therefore need to be able to predict flood prop

agation in urban areas, in order to design suitable

protection (possibly by directing the flood waters to

previously identified sacrificial zones) and to develop

reasonable and realistic emergency planning. Because

of the complexity of the problem, and the number

of different situations that have to be considered,

the most suitable approach is by numerical simula

tion, usually by solution of the St Venant equations.

This approach has the additional advantage that as

more and more detailed information on street geom

etry becomes available through GIS databases, this

information can be readily – indeed automatically –

included in the numerical model. In the simplest possi

ble configuration, the city street can be considered as a

rectangular channel with a free surface flow, and there

have now been many simulations of flood propagation

in urban areas based on this approach. In general, we

can conclude from these studies that the St. Venant

equations provide a reasonable model for the flow in

individual streets, but that they are not well-suited to

flow in street intersections, where the flow is nec

essarily strongly three-dimensional, and the slope of

the free surface can be significant. Unfortunately for

these numerical simulations, street intersections often

play a crucial role in determining how the incoming

flow is distributed between the various outlets, and

in determining the corresponding depths. The failure to model these intersections correctly can therefore have serious consequences for the overall quality of the modelling. There have been very few experimental studies of flow in channel junctions, and even fewer for conditions that correspond to those encountered in city streets. Most studies have been related to flow distribution in networks of irrigation channels, where the intersection is usually formed by the junction of three channels (in the form of a T or a Y), and where the flow regime is sub-critical. They can be divided in two groups: the junctions with two upstream reaches and only one downstream, and the bifurcations, with only one upstream reach. In urban applications the basic configuration is more likely to be a cross, with one or possibly two of the streets feeding the junction. The slope of a city street can easily be of the

order of a few percent, so it is quite common for the flow regime to be supercritical in certain areas. Most of the available literature describes experimental or numerical studies of subcritical flow in simple channel junctions. For example Weber et al. (2001) provide a complete set of experimental data for a 90 ◦ junction, including water depth, surface and bulk velocity fields and turbulence characteristics.The available analytical models are mainly based on mass, momentum and energy balances (see, for example, Gurram and Karki (1997) or Shabayek and Hicks (2002)). Usually, this approach requires additional assumptions such as a uniform depth of the flow in the whole intersection, a critical Froude number in the contraction zone or a hydrostatic pressure distribution.

Such assumptions will not usually be valid for flooding

in urban areas. Empirical models have also been

proposed, in which several physical phenomena are

modeled by a single coefficient, such as a contraction

coefficient (Hsu et al., 1998). Again, these methods

depend strongly on the experimental conditions and

are, as far as we are aware, restricted to the subcritical

regime. In the supercritical regime, Greated (1966),

and Schwalt and Hager (1994), focus on the devel

opment of the surface wave, whereas Hager (1989)

also measures velocities but in quasi-constant depth

flows.

Even fewer studies have been devoted to channel

bifurcations, and the introduction of a third outlet

channel complicates the problem considerably, espe

cially for analytical studies. Ramamurthy and Satish

(1988) derive an expression for the flow division in

short open-channel branches, based on momentum

and mass conservation.This gives the upstream/branch discharge ratio as a function of the channel widths ratio and the downstream main channel Froude number.

The model assumes a hydrostatic pressure distribution, negligible head losses in the vicinity of the intersec tion and is restricted to branch Froude numbers higher than 0.35 and upstream Froude numbers smaller than 0.7. For rectangular equal width channels, the model was improved to become independent of the branch channel Froude number (Ramamurthy et al., 1990). To avoid the need for such assumptions, other researchers have proposed empirical models. Krishnappa and Seetharamiah (1963) provide an experimental corre lation for the discharge ratio as a function of the upstream Froude number and the channel depths ratio, which is restricted to 90 ∘ angle separations and to subcritical upstream flows and supercritical branch flows. Nougaro and Boyer (1974) provide a diagram giving the discharge ratio valid on a wide range of Froude numbers (suband supercritical) and of junc tion angles, but they show a strong dependency of the results on the downstream conditions (Nougaro et al., 1975). More recently, there have been several 1D and 2D numerical simulations of flow in channel junctions. Shettar and Murty (1996) used a 2D code with a k-ε

closure to study a 90 ◦ bifurcation. The widths of the main channel and the branch are identical and the depth to width ratio is approximately 0.15.Their results com pare well with experimental measurements available in the literature. Khan et al. (2000) adopt a mixing length model, which is more applicable for large-scale problems. All these studies are restricted to subcritical flows, avoiding the problems arising in the applica tion of suitable boundary conditions for supercritical flows. Finally, Nania et al. (1998) simulate flow in the intersection of 4 channels (2 inlets – 2 outlets), using 1D and 2D codes, for subcritical and supercritical flows. x y q t q f q lat q lat L=2m b=0.3m Figure 1. Experimental set-up. 2 EXPERIMENTAL SET-UP The set-up consists of an intersection of four identical channels (fig. 1). Each channel is made from glass, with a length L= 2 m and width b= 0.3 m. The slopes of the four channels can be fixed independently, and each channel can function either as an inlet or an outlet for the intersection. In this study, only one channel functions as an inlet, with a discharge q t that varies from 2 to 20 l/s; the x-axis is therefore aligned with this channel. The flow leaves the intersection via the other three channels – two lateral channels (aligned with the y axis) and one longitudinal channel (x-axis). The flow enters the inlet channel through a honeycomb and then passes under a sluice gate, which serves to impose the upstream water depth and hence the Froude number. The outlet conditions are free. Discharges are measured by electromagnetic flowmeters; the discharge from the longitudinal channel was also calculated by measuring the filling time of the outlet reservoir. Water depths were measured using a moveable point gauge with an accuracy of±0.15 mm. This last technique becomes unusable in the strongly perturbed zones close to the intersection. 3 ANALOGY BETWEEN A SUPERCRITICAL JET DEVELOPMENT AND A DAM BREAK The flow in the inlet channel is supercritical as it enters the intersection, and it traverses the intersection

as a free, supercritical, jet. Hager and Yasuda (1997) studied the development of a supercritical jet in a semi-infinite expansion, and showed that the jet profile was similar to the evolution of the water surface during the breaking of a dam on a dry bed. In their study, the upstream Froude number was greater than 3, and the initial section of the jet was square; as a result the depression wave reaches the centerline of the jet rather rapidly, and the theory becomes rather complicated. In this study the ratio of the upstream depth to y' 4/9h 0 h 0 z t=0 c 0 .t 2c 0 .t t

Figure 2-a. The unsteady problem: the dam-break.

the channel width (h 0 /b) is much smaller than 1, and

so the dam break model is more applicable.

Consider a dam holding back a semi-infinite reser

voir of initial depth h 0 (fig. 2-a); at t= 0 the dam fails

and the water surface then evolves as (Stoker, 1957):

where t is the time and c 0 is the velocity of propagation

of the depression wave in the reservoir:

The water propagates over the dry bed with a velocity

2c 0 , whilst the depth of the water at the site of the dam

(y ′ = 0) remains constant, equal to z= 4h 0 /9 (fig. 2-a).

We can apply this model to compute the evolution of

the jet in the intersection (fig. 2-b). Upstream of the

intersection (x ′ < 0) the flow is confined by the walls

of the rectangular channel; within the intersection the

water surface is modified by the propagation of dam

break waves into the two lateral channels, which we

can model using the solution for unsteady case, by

making the transformation t= x ′ /U 0 .

To justify the assumption of a semi-infinite body of

fluid upstream of the breaking wave we have to ensure

that there is no interaction between the two negative

waves produced by the flow into each of the lateral

channels.This means that c 0 .t < b/2, or, in other words

x/Fr 0 < b/2; since the length of the intersection (x max)

is equal to b we can write: Fr 0 > 2.

Two configurations have been studied, with the

characteristics given in table 1.

The surface profile in the side channel is plotted

in figure 3, in dimensionless form (z/h 0 v y/(x ′ /Fr 0)) x'=U 0 .t y' x' depression wave swells q t q f q lat q lat brass plate Figure 2-b. The spatial problem: the jet development. Table 1. Main characteristics of the two jets (Fr 0 > 2). Configuration 5%-0% 1%-1% q t (m 3 /s) 0.01 0.01 bed slope S 0x 0.05 0.012 bed slope S 0y 0 0.012 h 0 (cm) 2.06 2.8 Fr 0 3.6 2.16 h 0 /b 0.14 0.2 for different values of the dimensionless distance travelled by the jet (x ′ /Fr 0). The error bars plotted on the first figure are indicative of the errors for the other profiles. The strong axial velocities in the jet create intense eddying motions on the walls of the side channels (fig. 2-b) which increase the water level and limit the applicability of the model to x ′ /b< 0.7-0.8. The dimensionless results for the two conditions are in close agreement with each other, and with the theoretical curve based on the dam break model. The increase in z ′ observed for y ′ < 0 in the 5%-0% configuration can be explained by the difficulty of generating a flow in a horizontal canal; this effect disappears when the canal is inclined (the 1%-1% configuration). In the following section we will develop a model for the flow distribution in the different channels, based on the surface profiles given by the dam break model. 4 A MODEL FOR THE FLOW DISTRIBUTION The cross section of the axial flow in the intersection decreases as the jet advances. By continuity, the lateral flow q lat must be given by the flow that has left the jet; x/Fr0=0.06 0 0,2 0,4 0,6 0,8 1 1,2 -1,50 0,50 2,50 4,50 y/(x/Fr0) z ' / h 0 dam break 1%-1% 5%-0% 0 0,2 0,4 0,6 0,8 1 1,2 -2,00 0,00 2,00 4,00 6,00 8,00 y/(x/Fr0) z ' / h 0 dam break 1%-1%

5%-0% x/Fr0=0.1 0 0,2 0,4 0,6 0,8 1 1,2 -0,50 0,00 0,50 1,00 1,50 2,00 y/(x/Fr0) z ' / h 0 dam break 1%-1% x/rF0=0.003 x/rF0=0.03 -0,2 0 0,2 0,4 0,6 0,8 1 1,2 -20 0 20 40 60 80 y/(x/Fr0) z ' / h 0 dam break 5%-0%

Figure 3. Theoretical and experimental surface profiles at different locations within the intersection (S 0 = 1, 2% et 5%).

at any distance x ′ from the entrance to the intersection

we can therefore write:

from which we obtain:

The total flow in the lateral canal is given by evaluating

this expression for x ′ = b:

The strong eddying motions around x ′ = b modify the

structure of the jet significantly, and hence tend to

invalidate the theoretical model for the lateral flow.

To test the influence of these motions thin brass plates

were installed at the downstream end of the intersec

tion, so as to extend the walls of the outlet channel and

isolate the flow from the influence of the stagnation

regions (fig. 2-b).The lateral flow rates were measured

for different plate lengths, and the results are shown

in figure 4. These curves confirm that the theoretical 0 0,05 0,1 0,15 0,2 0,25 0,3 0 0,2 0,4 0,6 0,8 x/b F r 0 . q l a t / q t theory 1%-1% 5%-0% 1 Figure 4. Influence of the stagnation regions on the applicability of the theoretical model. model provides a good estimate for the lateral flows provided that the stagnation regions do not influence the flow (x ′ /b< 0.7). On the other hand, the greater the zone of influence (x ′ /b> 0.7→ 1), the more the side flow is diminished, relative to its theoretical value. The principle explanation for this reduction in flow rate is that the increased surface levels in the stagnation regions serve to drive flow back out of the side channels into the main channel; as a result, equation (5) overestimates the

total lateral flow by about 25% in both configurations. In order to assess the accuracy of equation (5) over a much wider range of flow rates we have compared the y = x

lateral flow rates for flow conditions in the range 2-20 l/s.

measured q lat-exp and theoretical q lat-theo values for a

range of different conditions. The results are shown in

figure 5, with the measured flow rates plotted as a func

tion of the theoretical value (eq. 5). This figure shows

that the different data sets can be grouped together

according to the slope of the inlet channel; since the

upstream Froude number depends essentially on this

slope, this is equivalent to grouping them according to

Froude number.

The first two data sets are for a longitudinal slope of

5% with an average Froude number F r0 ≈ 3.5, and side

slopes of either S 0y = 0% or S 0y = 1.2%. The experi

mental points are very close to the theoretical values,

and the difference does not seem to depend on S 0y .This

probably remains true provided that the water level in the exit canal does not impede the development of the jet within the intersection; this was always observed to be the case for S 0y ≥ 0. For any given upstream Froude number the difference between theoretical and mea sured values varies as α/h 0 , where α is a constant. This dependence should be related to the capacity of water in the side channels to flow back into the main channel, above the level z ′ = 4/9h 0 .

The other data sets correspond to lower values of the longitudinal slope, with Froude numbers less than 2. For S 0x = 1%, we have F r0 ≈ 1.6 and S 0y = 0%, and for S 0x = 1.2%, F r0 ≈ 1.8 and S 0y = 5%. The measured flow rates are rather less than those predicted by the dam break model, principally because of the influence of the stagnation regions on the downstream walls of the lateral channels; this effect depends strongly on the upstream Froude number, and increases as the Froude number decreases. For example, for the con figuration S 0x = 1.2%, S 0y = 5% the Froude number was increased to F r0 ≈ 2.2 (by lowering the upstream sluice gate) and the measured flow rate becomes closer

Factors on flood problems in Ubon Ratchathani province, Thailand

C. Chinnarasri, U. Israngkura & S. Jarukamol

Water Resources Engineering Research Lab. (WAREE), Department of Civil Engineering,

King Mongkut's University of Technology Thonburi, Bangkok, Thailand

ABSTRACT: Lowland areas alongside of Mun River in Ubon Ratchathani Province, Thailand are flooded

frequently. The investigation on the significance of the flood causing factors was done by calculating the river

water levels at different magnitudes of these factors. The combination of these magnitudes resulted in 108 study

cases. Flood hydrographs from river tributaries were constructed by NAM Model using 30 day rainfall over

each basin. Mekong River water levels were analyzed from measured data at Kong-Chiam gauging station.

The discharges and water levels at different locations along the river reach were computed by MIKE 11 Model

covering 30 days period. The results showed that the flood flow at station M7 was the most significant factor as

it could produce flooding on the target area when its magnitude was at only 2 year return period or 2,500 m 3 /s.

and when its magnitude was increased the river water level then increased considerably.

1 INTRODUCTION

Ubon Ratchathani is a province in the northeastern

region of Thailand. Mun River which is the largest

river in this region flows across this province from west

to east approximately and discharges into Mekong

River at Khong Jeam district. Lowland areas along

side the river reach from the confluence of Chi River to Mekong River as shown in Figure 1 are flooded very frequently.

The latest flood inAugust 2002 resulted in a damage of about US$ 47 million.The major causes of flooding, apart from the lowland topography, are the large floods from the upstream watershed and from the river trib utaries along the river reach and the backwater effect from Mekong River. In planning a flood mitigation scheme for this area, it is necessary that the boundary of the flooded area and the flood levels under differ ent hydrologic conditions as well as the significance of each hydrologic factor must be identified so that the proper mitigation measure could be established.

The objectives of this study are to determine the area which is subjected to severe flooding, the combination of hydrologic events at the commencement of flood ing, and the most significant hydrologic factors which causes flooding.

2 METHODOLOGY

2.1 General

The flood hydrographs from the upstream watershed,

the lateral inflow hydrographs from river tributaries

and the stage hydrograph in Mekong River at various return periods were determined then the stage hydrographs along the river reach as caused by several combinations of those three hydrologic factors were derived. The peak stage profiles were then plotted and the areas subjected to frequent floodings were

identified. The hydrologic conditions which lead to the commencement of flooding over this area were observed. The hydrologic factor which caused flooding at the lowest return period and which caused the flood stage rising sharply when its magnitude was increased would be considered as the most significant factor.

2.2 Flood hydrographs from upstream watershed and Mekong River water level

Flood Hydrographs from the upstream watershed were derived from the recorded flow data at gauging station M7 which is just downstream of Chi River confluence and has a drainage area of about 106,673 sq.km. The derived hydrograph of a return period covered a length of 30 days and had the peak discharge equal to the value at that return period. The position of peak discharge and the shape of the hydrograph were made nearly similar to the 30 days hydrograph of large flood in 2001.The peak discharges at various return periods are as shown in Table 1. Figure 2 shows the derived flood hydrographs from the upstream watershed which were used in the study. 12 24 36 48 60 72 84 96 108 120 Time (hr) 0 40 80 120 160 200 R a i n f a l l i n t e n s i t y (m m / h r) Figure 3. Examples of synthesized rainfall over Lam-Se sub-basin. The Mekong River water levels at various return periods were derived from the recorded data at Khong Jeam gauging station at the mouth of Mun River. The peak water levels at various return periods are as shown in Table 1. As observed from historical data, during

severe flood occurrences the water level varied just slightly so in this study it was assumed to be constant at the value of the specified return period. 2.3 Flood hydrographs from tributary river basins The drainage area of 12,751 sq.km. from M7 to Mekong River consists of 6 sub-basins. Their boundaries together with the rainfall and streamflow gauging stations are as shown in Figure 1. Since there were no streamflow gauging stations at the outlets of these subbasins, their outflow flood hydrographs which drain into Mun River had to be determined from a rainfall-runoff model. NAM model developed by the Danish Hydraulics Institute (DHI) was used in this study. This model was calibrated and verified by the data of three watersheds above stations M69, M80, and M110 (see Figure 1). The model parameters of each basin obtained from these processes were correlated with some physical characteristics of the watershed and the best relationships were used to determine the Nam parameters for each subbasins. The rainfall of a return period which was used to generate runoff from a sub-basin was the areal average maximum 5-day rainfall which contained maximum 1 day and 3 days rainfall of that return period and had a time distribution pattern similar to the average pattern of heavy storms over this region. Figure 3 is the example of the synthesized rainfall. 2.4 Computation of flood stages along the river The flood stages along the river reach as caused by several combinations of those three hydrologic factors were computed by the one-dimensional hydrodynamic flood routing model which is a module of MIKE 11 computer program package developed by the Danish Hydraulics Institute (DHI 1982). The model Upstream boundary M7 M u n R i v e r Lum-Se Lum-Nummun yoi 1 Lum-Dom Yai M11A Model calibration point Lum-Nummun yoi 2 Lum-Dom Noi Houy-Tung Lung Pak Mun Dam Mekong River Downstream boundar y Seree Pracha-thipatai BridgeKm. 1131.00 Km. 1161.15 Km. 1166.10 Km. 1173.40 Km. 1182.57 Km. 1188.27 Km. 1201.07 Km. 1207.12 Km. 1201.57 Km. 1215.57

is as shown in Figure 4. River cross sections spacing

at about 3 km. interval were used in the computa

tion. River section at Sta. 1131+ 00 km. where M7

is located is the upstream boundary.

The model was calibrated and verified by the observed hydrologic data during August 1 to October 31, 1996 and during July 1 to September 31, 1997 respectively. Figure 5 shows the computed water levels at gauging station M 11 A from model calibration and verification against the observed water levels.

The model was then used to compute the flood stage hydrographs under several combinations of the three hydrologic factors.

3 RESULTS

3.1 Flood prone area

The peak flood level profiles under each combination of hydrologic factors were plotted as shown in Figure 6 as an example. From these plots, it could be observed

Maximum water level Computed Measured 13-10-19963-9-1996 23-9-199614-8-1996 a) Model calibration Maximum water level Computed Measured [meter]

that the area subjected to severe floodings lies between River Sta. 1133+ 050 km. to Sta. 1161+ 150 km.This flood prone area lies in the urban and semi-urban area in Muang District and Warin Chamrab District.

3.2 Peak flood stage and flood commencement conditions

The peak flood stage at River Sta. 1133+ 050 km. which is at the upstream end of the flood prone area was used as the index to indicate the flood harshness over this area. Its values under several study cases are as shown in Table 2. As can be observed from Figure 6, large area on both banks of the river would be flooded when the water level at this station is at +114 m.MSL or higher. When the upstream flood hydrograph at M7 is at 2 year return period this condition will commence when the flood hydrographs from tributary watersheds are at 10-year return period and the Mekong water level is at 100-year return period. But

when the upstream flood hydrograph increases to 5-year return period, whatever the Mekong water level may be, the flooding would always occur even when the river tributary flood hydrographs were at the return period lover than 2 year. Combinations of hydrologic events on the right and below the bold line in Table 2 are those which will produce severe floodings. 3.3 Significant level of each hydrologic factor As can be seen from Table 2, when the flood at M7 is at a magnitude lower than or equal to the flood magnitude

Figure 6. Peak flood level profile: 5-yr flood at M7, 10-yr lateral inflow and 100-yr Mekong River level.

at 2-year return period the chances of the area being

flooded is very rare, i.e., it will occur only when the lat

eral inflow is at the magnitude of up to 10-year return

periods and the water level in Mekong reaches the 100

year return periods level but when the upstream flood magnitude increases to 5-year return period flooding could occur even there in very low lateral inflow. This indicated that the upstream flood is more significant than the lateral inflow flood and the Mekong water level.

Figure 7. Increase in flood level with increase in return period of a factor.

Figure 7 shows the effects on flood water level as caused by increasing the return period of one factor while holding the other two factors constant at a return period. For the same increase in return period, the increase in upstream flood magnitude resulted in the largest increase in flood level while the increase in Mekong water level yielded the least increment.

From these investigations, it is justified to rank the flood from upstream watershed as the must significant flood causing factors and the Mekong water level as the least significant one.

4 CONCLUSIONS

It could be concluded from this study that:

1) The river flood plain where severe flooding occurred lies between River Sta. 1133+ 050 km.

and Sta. 1161+ 150 km. just downstream of gaug

ing station M7. Larger part of this area is the urban or semi-urban area in Muang district and Warin Chamrab district of Ubon Ratchathani Province. 2) Severe floods would rarely occur if the flood magnitude at M7 is lower than or equal to 2-year return period flood but would occur when flood magnitude at M7 is at 5-year return period upward even though there is very small amount of lateral inflow and very low water level in Mekong River. 3) As the flood from watershed area above M7 is the most significant flood causing factors, any flood mitigation plan which can reduce this flood to the magnitude at 2-year return period at the optimum cost would be the most desirable one.

Urban fluvial flood modeling using a two-dimensional diffusion

wave treatment

D. Yu & S.N. Lane

School of Geography, University of Leeds, Leeds, UK

ABSTRACT: This paper applies a 2-D raster-based diffusion wave model to determine patterns of fluvial

flood inundation in urban areas using high resolution topographic data. As this is a new application area,

the aim of this paper is to explore the effects of model spatial resolution upon estimated inundation extent.

Model response shows that even relatively small changes in model resolution have considerable effects upon the

predicted inundation extent as well as the flood wave travel time. This is associated with two connected effects:

(1) poorer representation of both cell blockage and the associated surface routing process resultant from the

smoother floodplain as the mesh is coarsened, where the flow routing is especially complex; and (2) the effects

of (1) upon both the water velocities and water levels which in turn determine which parts of the floodplain the flow can actually travel to. Thus, coupling of high resolution data, which can capture small scale variation in topography, to more sophisticated representation of the inundation process will be required in order to obtain effective predictions of flood inundation extent in urban areas.

1 INTRODUCTION

Fluvial flood modeling usually requires the prediction of flows over complex topography. Flow routing over floodplains is known to be highly two dimensional and notably where strong shear layer develops between the main channel and the floodplain, even three-dimensional (Knight & Shiono, 1996). Two-dimensional, depth averaged models have been extensively described in the engineering literature for some time and are increasingly being applied to natural river-floodplain systems (see the review in Lane, 1998). Indeed, developments have seen two dimensional models of floodplain flows come into widespread use (Beven, 2000), including TELEMAC 2D (e.g. Galland et al., 1991, Bates et al., 1995) and RMA2 (e.g. Bates et al., 1992, 1995). Traditionally, two-dimensional models have been constrained by the scarcity of detailed topographic data (Marks & Bates, 2000, Horritt & Bates, 2001). This constraint is being

gradually relieved by the emergence of new data cap

ture techniques, particularly in the field of airborne

remote sensing, including interferometric synthetic

aperture radar (SAR) (e.g. Brackett et al., 1995, Horritt

& Bates, 2001), aerial digital photogrammetry (e.g.

Biggin & Blyth, 1996, Lane, 2000, Westaway et al.,

2001, 2003) and LiDAR (laser induced direction and

ranging) (Krabill et al., 1984, Flood & Gutelius, 1997,

Marks & Bates, 2000). These new topographic data sources, which can yield synoptic information at a resolution that in some cases is better than 2.0 m and a precision that is better than 0.15 m, are providing new opportunities for modeling floodplain inundation from both fluvial and pluvial sources. More recently, raster-based models have gained credence in the modeling of floodplain flow inundation extent (Bates & De Roo, 2000, Horritt & Bates, 2001a, b). This typically uses a one-dimensional representation of channel flow linked to a two-dimensional treatment of flow over the floodplain, commonly involving a diffusion wave treatment. An application of the diffusion wave approach was first reported by Cunge et al. (1976) and similar methods have been used by Estrela & Quanias (1994) and Bechteler et al. (1994). These approaches use an explicit twodimensional treatment of mass conservation but a highly simplified representation of momentum conservation, commonly based upon determining the magnitude of flow between any two adjacent cells according to the water surface elevation difference and the Manning equation. Bates and De Roo (2000) developed a raster-based model (LISFLOOD-FP) based on this concept and compared it with a relatively coarse resolution (50–250 m) two-dimensional finite element scheme. Unlike other models, this model was specifically designed to predict flood inundation and ignored or minimized the representation of processes that were not considered central to the aim (Bates & De Roo,

2000). Tentatively, these results indicated that topog

raphy and a basic process representation was more

important than a complete process representation for

effective prediction of inundation extent. However, issues such as model calibration, friction parameter representation and the differing resolutions of the two models needed to be addressed before these conclu sions are confirmed (Horritt & Bates, 2001b). Horritt and Bates (2001b) compared LISFLOOD-FP with a two-dimensional finite-element model (TELEMAC 2D). Though the raster-based and the two-dimensional finite-element models showed similar performance, insufficiently accurate validation data and the lack of friction parameterization data made it difficult to dis tinguish between the two kinds of model formulations. More recently, the ability of the LISFLOOD-FP model to predict flood extent and flood wave travel times has been compared with a 1D model (HEC-RAS) and a 2D model (TELEMAC-2D) using independent calibration data from hydrometric and satellite sources (Horritt & Bates, 2002). Results revealed that the LISFLOOD FP model required independent inundated area data for calibration in order to achieve good predictions of inundation extent. It is also debatable as to whether or not raster-based models can provide an adequate representation of inundation velocities and hence the development of inundation through time. In summary, these results suggest that, compared to fully explicit

numerical solutions including finite element (e.g. Bates et al., 1992), finite difference (e.g. Gee et al., 1990) and finite volume (e.g. Lane & Richards, 1998) formulations, raster-based models have major advantages in terms of their ease of formulation, computational efficiency and simplified calibration. However, questions remain over their relatively simple representation of the flow processes, due partially to the poor representation of momentum transfer on the floodplain.

Much existing research into two-dimensional modeling of flood inundation has focused upon relatively rural areas. Wheater (2002) identified the improved representation of urban flooding at both local and catchments scale as one of the key priorities in current fluvial flood modeling practice. Thus, the aim of this paper is to evaluate the extent to which diffusion wave based models can be applied to situations where there is inundation of relatively urbanized areas. This is an interesting application area because potential flood damage is proportionately greater than rural areas and urban flood inundation receives a relatively high political profile. In modeling terms, these areas may also benefit significantly from the availability of high resolution topographic data as urbanization leads

to the presence of structural elements on the floodplain

which may have significant impacts upon patterns of

flood inundation. These may not be well-represented

through traditional treatments of roughness involving up-scaling of sinks in the momentum equations. Thus, the focus of this paper is application of a basic 2D raster-based model to understand inundation in an urbanized area. 2 FLUVIAL FLOOD PROCESSES IN URBAN AREAS The presence of significant structural features (houses, walls etc.) on a river floodplain is important in relation to both the volume of the floodplain that can be occupied by the flow and the direction that the flow takes across the floodplain. Harnessing high resolution topographic data has appeal as it may reduce the uncertainty into how to parameterize the effects of structural 'topography' upon inundation. In both oneand two-dimensional (both diffusion wave and depth-averaged) models, topographic structure is commonly represented through up-scaling of a roughness parameter with calibration where necessary. This is well-established for representing the effects of individual grains and grain organizations in models of flow in gravel-bed rivers where the roughness length is multiplied upwards (e.g. Lane & Richards, 1998, Lane et al., 1999) and for representing the effects of vegetative roughness in floodplain flow models, where Manning's n is scaled upwards (e.g. Mason et al., 2003). In onedimensional modeling, using the St. Venant equations, the roughness parameter commonly appears through a friction slope relationship that not only represents bed roughness, but also turbulence effects and dispersion processes, the latter resulting from depthand width-integrating the full three-dimensional form of the Navier-Stokes equations. One-dimensional models tend to have high sensitivity to roughness and this makes roughness a key focus of parameterization in one-dimensional models. Raster-based flood inundation models have commonly used a uniform roughness coefficient for the floodplain but have treated it as the key calibration parameter (Bates & De Roo, 2000, Horritt & Bates, 2001a, b, Horritt & Bates, 2002). In relation to sensitivity, it has been found that LISFLOOD-FP is insensitive to roughness coefficient on the floodplain (Horritt & Bates, 2002) when inundation area was considered. In relation to flood inundation, roughness parameterization could become more complex if the required roughness value were allowed to vary spatially as a function of local structural complexity. Horritt (2000)

used a simple distributed roughness calibration scheme in fluvial flood modeling and got a minor improvement over the uniform parameterization. LiDAR data has been successfully used to upscale n in a distributed way for floodplain vegetation (Mason et al., 2003) although this assumes that: (1) vegetative roughness relationships developed from flume experiments can be applied to two-dimensional map ping of n from vegetation height; and (2) the prime control on n is vegetative roughness and there is no need to calibrate roughness to take into account the effects of other processes (e.g. turbulence). However, the extent to which this approach can be extended to urban areas is questionable. First, parameterization of n is based upon manipulation of a sink in the momen tum equations, either through the bottom stress term that appears in a full solution of the depth-averaged equations, or through n in the simpler momentum rep resentation in a 2D diffusion model. Structural features such as houses, walls etc. also have a blockage effect which reduces the volume of storage that is possi ble on the floodplain and which can have a major effect upon routing. Research by Lane et al. (in press) shows that traditional parameterization of high reso lution topographic variability in 3D hydraulic models using up-scaling of roughness heights does not nec essarily represent mass blockage effects properly. The same conclusion may hold for floodplain structural elements in 2D models. Second, many structural ele

ments have topological properties that create complete barriers to flow (e.g. walls) and which can have a very major effect upon the flow routing process. Upscaling of n may reduce flux across linear sets of grid cells, but will not necessarily recognize the full topological features of a structure.

High resolution topographic data has the capability to deliver sufficient information on floodplain structural elements for modeling purposes. However, as yet, there has been no application of this information to urban flood inundation modeling. In this paper, we focus upon diffusion wave treatments of urban flood modeling as these make it possible to use higher spatial resolution topographic data as compared with more computationally intensive methods such as those based on finite elements. As raster-based fluvial flood modeling gives poor representation of the momentum transfer over the floodplain, there is a related need to describe local wetting and drying processes more adequately to compensate the effect. Various algorithms describing the wetting and drying processes in flood modeling have been developed in finite element methods (e.g. Defina et al., 1994, Bates, 2000). LISFLOOD-FP has no explicit treatment of the wetting process and water is allowed to flow out of the cell

as long as the outflow energy slope is positive. This is not realistic in reality in that, in most cases, the water front during wetting will lie within the cell and only part of the cell will be wet at a particular time step. It is also more likely to affect inundation extent in urban areas. As the routing process is strongly controlled by elevation differences between cells, if diffusion across the floodplain is too rapid, water will not necessar ily reach higher elevation areas as the spread of flow reduces water surface elevations locally, confining spread to lower elevation areas. In urban areas, the complexity of elevation variation makes this particularly important. The importance of this process will be model resolution dependent: with coarser grid cells, representing this process adequately will become more important. Given the above, in addition to explicit representation of structural elements in a diffusion wave model, we also explore the interaction between model resolution and inundation extent and the role of wetting and drying parameters. 3 MODEL APPLICATION: DATA SOURCES The model used in this paper takes the same structure as that of the JFLOW model developed by Bradbrook et al. (in review), but modified for the purposes of urban flood inundation modeling.The model is applied to a reach of the River Ouse in Yorkshire, U.K (Fig. 1) near Tadcaster. This reach was chosen because of the availability of a one-dimensional hydraulic model for the main river flow, high quality LiDAR data for the floodplain surface, and remotely sensed data on inundation extent and water levels for a large flood inundation event in November 2000, as well as the dense presence of structural features on the floodplain. The latter data have been used to determine inundation patterns and water levels using digital photogrammetry and image analysis (Lane et al., 2003). The LiDAR had a resolution of 2 meters. The original LiDAR data had been post-processed to standard data quality requirements using methods set by the U.K. Environment Agency's National Centre for Environmental Data Surveillance in Twerton, Bath. This 0 500 1,000250 Meters elevation (meters) High : 35.01 Low : 18.32 N Figure 1. The reach of the River Ouse in Yorkshire, UK, on which the

flood event in 2000 was simulated. (a) LiDAR data of 2-meter resolution. (b) Flooding imagery which provides the validation data for the model.

includes standard assessment of data quality to guar antee a precision of±0.25 m throughout, improving to ±0.15 m in relatively flat areas with solid reflectance surfaces. The data includes returns from building and trees. For the purpose of urban inundation modeling, some additional image processing was undertaken. Whilst buildings needed to be retained, it was nec essary to remove elevations within the LiDAR dataset associated with tree canopies under the assumption that only tree trunks would have a significant effect upon inundation. The removal of trees was achieved using the same data source used for model validation. Similarly, different surfaces (e.g. grass, road, garden etc.) might need to be allocated different roughness parameters. Spatial distribution of roughness parame ters is not addressed in this study. Instead, a uniform roughness value of 0.06 was used based on the typi cal values suggested by Chow et al. (1988). Although most previous studies use roughness parameters as key calibration parameters, this has not been attempted in this study.

In order to remove tree canopies and also to provide model validation data, 1:4500 scale aerial imagery was

obtained. This had been acquired during the falling limb of a major flood event on the 11th November 2000 (Fig. 1). This flood was estimated to be the highest recorded in York since 1625. The imagery was scanned at 21.2μm resolution using a standard desk top scanner. Ordnance Survey benchmark data were used to rectify the imagery to a root mean square error of better than±2.0 m (i.e. commensurate with the resolution of the LiDAR data). Supervised classification was then used to assign the floodplain into functional units: (1) inundated areas, to provide data on flood extent during the falling limb of the hydrograph for model validation; (2) trees, in order to allow correction of the LiDAR data for canopy height effects; and (3) other elevations. Only canopy locations were removed from the LiDAR data.

A one-dimensional hydraulic model of the Ouse from Skelton (upstream of the city) through to Naburn Weir (downstream of the city) is used to provide estimates of flux from the river to the floodplain for a major flood inundation event (estimated to have a return period of greater than 100 years) in November 2000 in the form of a stage hydrograph in 530 hours (Fig. 2). The connectivity between the one dimensional model and the floodplain is established

through a weir equation. This assumes that the flood

plain is protected by an embankment that essentially

acts as a continuous, broad-crested weir. This may be

identified from topographic data (e.g. LiDAR). The

flux to the floodplain is then determined from predic

tions of water stage in the river channel using a weir

equation: 6 7 8 9 10 11 0 100 200 300 400 500 600 Time (hours) w a t e r s t a g e (m e t e r) Figure 2. Stage hydrograph in the main river channel. Arrow points to the time when the validation imagery was acquired. where H is the water surface elevation of the river channel and z is the height of the river embankment on the floodplain. Water level hydrographs are interpolated to each river adjacent floodplain cell at each time step and inflow from the river channel occurs once the water surface of the river channel is higher than that of the adjacent floodplain cells. The flow in the river channel at each time step is assumed to be uniform throughout the simulation. 4 MODEL APPLICATION: SIMULATIONS, ACCURACY ANALYSIS AND VALIDATION The flood event was simulated using three different spatial resolutions: 8-meter, 16-meter and 32-meter and time series of inundation extents for these simulations are shown in Figures 3-5. These show the wetting process for 38 hours. The comparison of the predicted inundation extents obtained using different model resolutions at the time when the validation data was acquired are shown in Figure 6. Comparison of the time series inundation extents obtained using different model resolutions for the first 38 hours shows that model is quite sensitive to spatial resolution with respect to both the inundation extent and the flood wave travel time. Flood inundation is more rapid with a coarser resolution. For example, the model with a 32-meter resolution has roughly the same inundation pattern at around 30.5 hours, as that obtained from the 8-meter resolution model at 38 hours. For the 16-meter case, it took about 32 hours to get the same pattern. This is expected considering the poorly represented inertial processes in a diffusion wave model. In order to compare the accuracy of the predicted inundation extents statistically, accuracy assessment was undertaken using a method adopted from remote sensing (Congalton & Green, 1999). In this method, an error matrix is set up to express the number of sample units assigned to a particular classification category in one classification relative to

the number of sample

The comparison of the predicted inundation extents obtained using different model resolutions at the time when the validation data was acquired. imagery on the falling limb of the flood event was classified into three classes:

dry areas, wet areas and the wetting front. At each time step, the model divides the whole modeling site into three categories to represent the wetness of the grid cells, namely wet cells, wetting front cells and dry cells. The wetness of a particular cell is decided by the wetting parameter. A wet cell is one with a wetting parameter equal or greater than one, a dry cell is one with a wetting parameter equal to zero and a wetting front cell is one with a wetting parameter greater than zero and smaller than one. If temporal validation data in the form of inundation extent at a regular time interval is available, the accuracy of the model prediction can be assessed at each particular time points where the validation data is available.Thus, more insight into how the model behaves in relation to both the flood wave travel time and inundation extent

can be gained. However, in this application, as only the validation data at one point on the falling limb of the hydrograph is available, the accuracy of the model pre diction was only assessed against the validation data for this point. Once the error matrix has been con structed, the overall accuracy can be computed as the sum of the corrected classified cells divided by the total number of cells. Besides the overall accuracy, a discrete multivariate technique called Kappa analy sis can be used to statistically determine if one error matrix is significantly different from another (Bishop et al., 1975).The result of performing a Kappa analysis is a KHAT statistic, which is the measure of accuracy or agreement (Cohen, 1960).The KHAT statistic is based on the difference between the actual agreement in the error matrix (i.e., the agreement between the predicted cell status and the reference data as indicated by the

major diagonal) and the chance agreement as indicated by the row and column totals (i.e. marginal). A KHAT value can be calculated for each error matrix and is a measure of how well the predicted data agrees with the reference data. Confidence intervals can then be com puted using the approximate large sample variance and the fact that the KHAT statistic is asymptotically nor mally distributed. The significance of the KHAT value for a single error matrix can be tested to determine if the agreement between the predicted data and the ref erence data is significantly different to no agreement by calculating the Z statistic. In addition to comput ing the Kappa coefficient for an entire error matrix, it may be useful to look at the agreement for an indi vidual category within the matrix. This can be tested using the conditional Kappa coefficient, resulting in a KHAT statistic which is an estimate of the conditional Kappa coefficient. Similar to the overall KHAT statis tic, the variance of the conditional KHAT value and the Z statistic can then be calculated to determine if the classification is significantly better than a random result. The overall accuracy, KHAT value and condi tional KHAT value for wet cells at the point when the validation data is acquired for model simulations using 8-meter, 16-meter and 32-meter resolution are

compared in Table 1.

Comparison of the inundation extents and the accu

racy assessment of the model predictions obtained

shows that the model performance is sensitive to

spatial resolution when the inundation extent is

for wet cells considered. The overall accuracy of the model prediction decreases as the mesh is coarsened. KHAT statistics give a similar pattern. Landis & Koch (1977) divided the possible ranges for KHAT into three groups: a value greater than 0.80 (i.e., 80%) represents strong agreement; a value between 0.40 and 0.80 (i.e., 40–80%) represents moderate agreement; and a value below 0.40 (i.e., 40%) represents poor agreement. In this application, the simulation with the 8-meter resolution gives a KHAT of 0.76 which represent strong agreement of the model prediction with the validation data. According to KHAT statistics, prediction from simulation with 16-meter resolution also shows strong agreement with the validation data. While the agreement is rather poor for the 32-meter case. The high sensitivity of model prediction to model resolution is thought to be the causes of two connected effects. First, the effect of resampling a dense mesh onto a coarse one will result in a smoother floodplain. It is found that, for the finite-element method, the twostage filtration effect of raw data into a digital elevation model and then into a numerical mesh coarsens the data used in the model (Bates et al., 1996) and will reduce the detail and accuracy of the resultant land surface (Marks & Bates, 2000). This also holds for the resampling process in raster-based modeling. Three commonly used resample methods: nearest-neighbor interpolation, bilinear interpolation and cubic convolution interpolation have some degree of smoothing effect on the input data. Bilinear interpolation determines the value of a cell based upon the weighed distance average of the four nearest input cell

centers. It generally causes some smoothing to the data. Convolution interpolation tends to smooth the data more than the bilinear interpolation due to the smooth curve used and the large number of cells involved. The smoothing effect of the nearest-neighbor interpolation is the least among these three methods and was the resample method used in this model. Second, the representation of small-scale wetting processes will be simplified when the mesh is coarsened.The effect of the wetting treatment in the model is to slow down the flow transfer. The velocity controls the timing of the wetting process for a grid cell and the evaluation of the velocity will be resolution dependent.As the mesh is coarsened, the variance in velocity decreases and the timing of the wetting front migration tends to have a greater possibility of error due to the simplified description of the timing of the flow routing which will otherwise become much more complex in a denser mesh. This explains the high model sensitivity to model resolution in relation to flood wave travel time. Likewise, the difference between water surface elevations of two grid cells determines the direction of the flow routing and the variance in water surface elevations tends to decrease as the mesh is coarsened. The heterogeneity of water surface elevations in the

cells will decrease and this may result in a significant

chance of errors in terms of the direction of flow. This

is especially true for the flow routing in urban areas

where structural features on the floodplain can have

considerable effect on flow direction and timing. The

cell blockage effect associated with structural features

will have a less control on the timing and direction

of the flow with a smoother floodplain resultant from

a coarser resolution. It is expected that the higher

resolution the data, the more adequately represented

small-scale routing processes and thus the more accu

rate prediction with respect to both flood wave travel

time and the inundation extent.

The effect of mesh resolution will also depend on floodplain configuration in relation to the magnitude of flow associated with a given return period. For a floodplain that is fully occupied with a low return period, mesh resolution will have less effect on high flows. For an unconstrained floodplain, where the lateral extent of a flood continues to increase even at low flows, resolution effects are likely to cause significant error.

5 DISCUSSION

This paper demonstrated the effect of model spatial resolution upon the estimated inundation extent in a two-dimensional raster-based diffusion wave model, with application to a reach of the River Ouse in Yorkshire, U.K to simulate a flood event in the year 2000. Model response shows that the model is quite sensitive to spatial resolution in terms of both the flood wave travel time and the inundation extent. This is thought to be caused by two interrelated effects: (1) the smoothing effect of mesh coarsening on the topological data; and (2) the poorer representation of small-scale flow routing processes associated with the reduced topological complexity resultant from (1). The local topological complexity due to the presence of small-scale structural features on the floodplain in

urban areas makes this even more complex for urban flood modeling, as many of these features have topo logical properties that may have a major effect upon both the timing and direction of the flow routing. First, the details of the structural features may be reduced as the mesh is coarsened, resulting in a poorer rep resentation of these features in the model. Second, current methods of representing small-scale flow rout ing processes associated with structural features in flood models have their limitations. Traditional meth ods of representing structural features usually involves up-scaling of the roughness parameter which, in pre vious research, has been used as a key calibration parameter to compensate for the poorly represented momentum transfer process in raster-based modeling.

ABSTRACT: This study uses digital image processing to
survey the confluence behavior of a tributary with

hyperconcentrated flow entering the main river. The
experiment has two parts: in the first, digital terrain
data

were computed via coordinate transformation from profiles
extracted by laserlines; in the second, velocity fields

were obtained by using Voronoï imaging method to analyze
the images through low-pass and high-pass filters

when trace-particles were added. The measurement approach
is described and preliminary results are presented.

Through the discussion of alluvial fan morphology, we can
better understand the interaction of this mechanism.

1 INTRODUCTION

With both heavy rainfall and mountainous terrain of

weak geological structure, the island of Taiwan is

subject to frequent debris flows. In upland basins, tor

rential river valleys and steep gullies are subject to both

flooding and landslides. This study examines various

ways in which flow slides and river currents interact,

including blocking of rivers due to either accumulated

debris or to the formation of landslide dams across

the channel width. In other situations, local narrow

ing of a channel can occur due to partial invasion

by a debris fan. At the outlets of debris flow gullies,

thick deposits may be left for water currents to slowly

transport downstream.

The confluence behavior of a tributary with hyper concentrated flow into the main river is a common phenomenon in mountainous regions.When the hyper concentrated flow tributary enters a main river, a natural dam would be formed by the enormous sedi ment carried by the tributary. Chen (1999) collects and analyzes numerous kinds of natural dams from the lit erature and field survey after the Chichi earthquake of September 21, 1999 in Taiwan. In addition, a prelimi nary classification is established according to the basic concepts of sediment transport (Chen & Peng 2003a). Parker et al. (1998a, b) propose a theory and applica tion for alluvial fans and fan-deltas formed by chan nelized fluvial and sheet flow. Tsai & Shieh (1997) find the morphological similarity of debris-flow fans by laboratory experiments and numerical simulations. However, previous studies which research the con fluence behavior are very limited because it involves numerous factors concerning the confluence mechanism. To study the morphology of an alluvial fan formed by a tributary entering the main river, we did experiments to measure the alluvial fan terrain and confluence velocity field by applying digital image processing. The methods of measurement used in this paper can increase the precision and convenience over previous methods. 2 EXPERIMENTS 2.1 Experimental device The experimental device includes a main channel which is 3.5 m long, 0.2 m wide and 0.15 m high, and a minor branch which is 0.8 m long, 0.1 m wide and 0.25 m high. There is also a gate which can be opened suddenly at the middle of the branch channel to release the mixture of water and sediment as a dam-break type. Besides, in the main channel there are two tanks, one above the upstream end and the other below the downstream end, to construct

the circulatory system. To keep the circulatory system working, we used a pump to draw out the water in the downstream tank into the upstream tank which can overflow by controlling two valves to determine discharge of inflow into the main channel and outflow into the downstream tank. When the hyperconcentrated flow in the branch enters the main channel, it forms an alluvial fan under the water surface of main channel. We measured the morphology of this alluvial fan and the velocity field of confluence to study this mechanism.

The overall experimental process was separated into

pre-test and formal-test. The purpose of the pre-test

was to determine the physical parameters of experi

mental materials. Then formal testing was carried out,

including several procedures as follows: (1) determine

the discharge of main channel in uniform flow; (2)

determine the concentration and volume of the hyper

concentrated tributary; (3) calibrate the branch slope

and the confluence angle between main channel and

branch, when the main channel slope set to zero; (4)

release the mixture into the branch and measure the

velocity field of confluence; (5) stop the inflow of main

channel and survey the topography of the alluvial fan;

(6) repeat these steps for different conditions.

2.2 Methods of measurement

The experiment included two parts: the first is that

the digital terrain data of the alluvial fan was com

puted using coordinate transformation from profiles

extracted by laserlines; the second is that the velocity

fields were obtained using Voronoï imaging method to

analyze the images via low-pass and high-pass filters when adding the trace-particles. These two methods are illustrated as follows.

2.2.1 Survey of topography

The measurement is illustrated in Figure 1. By using a laserline projection above the measured region of the alluvial fan, the profile image was captured via a digital camera set beside the region with an angle of depression. Then the 2D images of various profiles can be transformed into 3D space coordinates, using the method of transformation proposed by Spinewine et al. (2003) and illustrated in Figure 2. A transfor mation is then required to relate the set of 2D image coordinates of any point P to its world coordinates. Define r P = [x P y P z P] T as the world coordinates of point P (see Fig. 2), and R (A) P = [X (A) P Y (A) P] T as the 2D image coordinates of point P associated with the cam era viewpoint A. The transition from camera to world coordinates generally requires a translation and a rota tion (Jähne 2002). Thus for each viewpoint A, one can specify a matrix [A (A)] and a vector b (A) such that where α is a scalar parameter; matrix [A (A)] and vec tor b (A) must be calibrated from a set of points for which both the world coordinates and the image coor

dinates are known (see Spinewine et al. 2003, Ni 2004

for details). The overall procedures are shown in Fig

ure 3, and the digital terrain data were obtained from

executing them. Figure 1. Illustration of the system used to survey topography. Figure 2. Illustration of coordinate transformation. Figure 3. Flow chart of digital image processing. 2.2.2 Measurement of velocity field Consider a 2D velocity field of confluence between the main river and a tributary, which is governed by shallow water equations. If the variation of velocity in vertical direction can be negligible, then the velocity field of water surface will be regarded as the mean velocity field over the flow depth. Therefore the surface velocity field can be measured by

Figure 4. Overview of the Voronoï match algorithm: (left)

image of a granular flow abstracted into point-like parti

cles (+); (center) Voronoï diagrams constructed on these

points (thin lines) and on the points of the next image of

the sequence (thick lines); (right) displacement vectors (true

scale) obtained by matching the Voronoï 1-stars (Capart et al.

2002).

Figure 5a. Photo of alluvial fan at the sample site.

using the Voronoï imaging method after adding the

trace particles. The Voronoï imaging method was basi

cally developed for the measurement of granular flows

(Capart et al. 2002). Its principle is to first extract the

point-like particle positions of discrete digital images,

secondly to construct the Voronoï diagrams for these

points at two successive time instants, and finally to

compute the velocity vectors by matching the local

Voronoï patterns (Fig. 4). Generally, the surface veloc

ity fields can be effectively captured by a digital video

camera if they do not have especially large velocities

(Chen & Peng 2003b).

2.3 Experimental materials and conditions

The experimental materials were sampled from the

alluvial fan located on the Cho-Shui River close to

24k+ 500 of Highway 16 in Taiwan (Fig. 5a) and

the particle size distribution diagram of materials is

sketched as Figure 5b. Based on these materials, we

designed a series of experiments to study the con

fluence mechanism between a main channel and its

tributary. The factors of influencing confluence are

generally considered to be the angle of confluence,

the ratio of discharge between main channel and trib

utary, the slopes of main channel and tributary, and Figure 5b. Distribution of particle size. Table 1. Experimental conditions. The experimental conditions are shown in Table 1. 3 RESULTS We carried out numerous tests based on these experimental methods and obtained the following results. The results include 54 sets of digital terrain data for the alluvial fan and 30 sets of velocity field of confluence. 3.1 Morphology of alluvial fan An example of the results is shown as Figure 6. From these results of digital terrain

data, we calculated the

Figure 6. Measurement results in the terrain (where con

fluence angle is 90 degrees, discharge of main channel is

0.66× 10 −4 cms, density of mixture is 1.9 g/cm 3 , and slope of

branch is 10%): (top) digital terrain data of survey; (bottom)

comparison between measurement and actual terrain.

residual volume of alluvial fan in the main channel

and found the relation between volume and slope of

tributary (Fig. 7). Figure 7 indicates that the volume of

alluvial fan could not be affected apparently by conflu

ence angle and density of mixture; it is predominated

by the slope of tributary. Meanwhile, a high density of

the mixture in the tributary also increases the residual

volume in main channel when the slope of tributary is

30%. We suggest that the amount of alluvial fan car

conditions are the same as Figure 9). Figure 10b. Relation between u/U 0 and y/B at x= 23.5 cm (confluence) when t= 2.0, 2.2, 2.4, 2.6 and 2.8 sec (other conditions are the same as Figure 9). the width of the main channel (B), respectively, for a dimensionless value (Figs. 10a, b). In Figure 10a, the velocity profiles are unstable with different time instants due to the vortices during t= 1.0~ 1.8 sec intervals. In contrast, the dimensionless profiles of the x-component velocity maintain a similar profile during t= 2.0~ 2.8 sec intervals because the vortices are affected by main channel flow to move downstream and then to finally disperse. In sum, the velocity field usually determines the motion of sediment, which affects the alluvial fan morphology. In next section, we discuss the morphological details of alluvial fans. 4 DISCUSSION 4.1 Centroids of alluvial fans The volume of alluvial fan is defined by the following integral: Thus, the coordinates X CG and Y CG of the centroid of alluvial fan are equal to the first moments divided by the volume: Assume that the centroids of alluvial fans can represent their location.To realize the effect of confluence angle,

Figure 11. Relation between the centroids of alluvial fans

and angles of confluence: (top) when the angle of conflu

ence is larger, the tributary encounters stronger resistance

and X CG decreases; (bottom) Y CG is similar to X CG , but Y CG

is larger than the others when the angle of confluence is

90 degrees.

we calculated the centroids of 19 alluvial fans which

have more complete shapes with different angles of

confluence (Fig. 11). Figure 11 shows that the conflu

ence angle could primarily determine the alluvial fan location. In addition, the “erosion angle” can be also defined by the alluvial fan centroid. If the longitudinal center line of the tributary, called the “axis line”, is extended to the wall of main channel, the line from the confluence point (x= 23.5, y= 0) to the centroid and axis line forms the erosion angle. Previous research indicates that a positive relation exists between erosion angle and discharge ratio (Q_m/Q_b) (Chen 2000). Our experiments show the similar results, although their relation is not significant.

4.2 Shapes of alluvial fan

We extracted the longitudinal profile and cross-section at the alluvial fan centroid (Fig. 12) to analyze shape characteristics of alluvial fans. In these profiles of alluvial fans, the shapes are markedly affected by confluence angle. For example, the peak of the longitudinal profile deflects downstream when the confluence angle is 45 degrees (Fig. 12a). In contrast, the peak of the longitudinal profile deflects upstream when the confluence angle is 135 degrees (Fig. 12c). Furthermore, when the confluence angle is 90 degrees, the shape of the longitudinal profile is shaped like a hat, and the cross-section (Fig. 12b) seems to have two peaks. The reason that there are two peaks might be

that the tributary shoots directly to hit the opposite

wall of the main channel and to deposit the sediment

on the bed.

The alluvial fan contours in different confluence

angles are illustrated in Figure 13 as an example. Figure 12a. Extracted profiles at alluvial fan centroid (X CG , Y CG) for confluence angle 45 degrees: (top) longitudinal profile; (bottom) cross-section profile (•: slope of branch= 20%, Q m = 0.66× 10 −4 cms; +: slope of branch= 20%, Q m = 1.99× 10 −4 cms; ×: slope of branch= 30%, Q m = 4.35× 10 −4 cms; density of mixture is 1.9 g/cm 3). Figure 12b. Extracted profiles at alluvial fan centroid (X CG , Y CG) for confluence angle 90 degrees: (top) longitudinal profile; (bottom) cross-section profile (•: slope of branch= 20%, Q m = 1.99× 10 −4 cms; +: slope of branch= 30%, Q m = 0.66× 10 −4 cms; ×: slope of branch= 30%, Q m = 1.99× 10 −4 cms; density of mixture is 1.6 g/cm 3). According to these contours, the outlines of alluvial fans in different confluence angles are simplified and summarized as Figure 14. The types of alluvial fan in Figure 14 are similar to the classification, i.e. partial blocks to the main river (Chen & Peng 2003a, Chen 2000). The results of this laboratory experiment can be used for preliminary assistance for numerical simulation. Using either laboratory experiment or numerical simulation, the mechanism of confluence between the tributary and main river can be clarified.

Transient hyper-concentrated flows: limits of some hypotheses in

mathematical modelling

D. Berzi & E. Larcan

Politecnico di Milano, Dept. I.I.A.R., Milan, Italy

ABSTRACT: A one-dimensional mathematical finite-difference model used for simulation of unsteady hyper

concentrated flow is described.This model is based on the SaintVenant equations, integrated via the MacCormack

method.Two mass balance equations and one momentum equation are used, thus, the model can be seen as a quasi

two phase model. In the momentum equation the resistance term is derived from a semi-empirical formulation of

shear stress in a generalized visco-plastic fluid (Chen 1996). Bed erosion and deposition effects are also included

and numerical results are experimentally verified for high

concentration flows in mild slope channel. Though the assumed hypothesis largely simplify the mathematical model, the validity of the model is confirmed, with particular attention on the role of the yield stress. A good agreement between numerical and experimental results is found, but, when the solid concentration is high and the densities of the two phases are significantly different, a quasi-two phase model seems to be unable to simulate the phenomenon. Considerations about the limits of the mathematical approach and the opportunity of more complicated models are underlined.

1 INTRODUCTION

The behaviour of a granular debris flow (flow of rigid spheres in an interstitial fluid) can be analysed through either a microscopic or a macroscopic approach. The former involves statistical mechanics, in particular the kinetic theory (Savage 1984, 1989, Jenkins 1987); the latter considers debris flow as a continuum, such as in classical fluid mechanics (McTigue 1982, Chen 1986, 1988). Anyhow, the aim of this paper is to find the constitutive equations of the liquid-solid mixture and define the relation between the resistance terms and the kinematic quantities.

This paper concerns with the mathematical simula tion of debris flows due to dam-break. Shear stresses in the mathematical model are approximated fol lowing the continuum mechanics approach. The use of formulas of uniform flow for a typical unsteady

phenomenon represents another approximation. Nev

ertheless, a simple model with an empirical approach,

such as the mathematical model presented herein,

is preferred for practical design purposes. Thus, it

seems very important to verify the rightness and

the limits of the approximations introduced; hence,

numerical results obtained with the model are com

pared with experimental data. These comparisons are

used to define the validity range of the mathematical

model, to find the limits imposed by the simplifying hypotheses and to suggest the research guidelines for its improvement. 2 EXPERIMENTAL SET-UP The parameters of the mathematical model (Section 3) have to be set experimentally; therefore, experimental work has been carried out on a laboratory rig with a 6 m long, square section (0.5× 0.5 m) flume of adjustable slope also for the validation of the results obtained with mathematical model. Failure of the dam can be simulated by means of a pneumatic rising sluice-gate (opening time t= 0.3 s). Debris flow is modeled by a water- solid mixture, the solid phase is reproduced with either common gravel (ρ= 2621 kg/m 3 , d 50 = 0.005 m) or a plastic homogeneous granular material called “vedril” (ρ= 1168 kg/m 3 , d 50 = 0.003). Tests are performed for several solid concentrations, and different channel characteristics: slope (3.2 ∘ , 5 ∘ , 10 ∘ , 15 ∘ and 20 ∘) and bottom roughness (zinc coated plate or fixed homogeneous gravel d 50 = 0.005 m). A complete list of experimental runs is reported by Bertalli et al. (2002). Sorting phenomenon are not taken into account because of the use of homogeneous solid material in the mixture. This fact appears to be very important in the dynamics of debris flows, yet too complicated to be implemented.

3 MATHEMATICAL MODEL

Usually models of dam-break waves are based on

one-dimensional and two-dimensional schemes, while

three-dimensional models are extremely rare. Some of

these models consider the liquid–solid mixture as a single phase liquid, while others, more complicated, take into account both liquid and solid phases. Some of the later suppose that solid and fluid are charac terized by the same average velocity and introduce only changes in solid concentration, caused by the erosion/deposition rate; other models involve also two different momentum equations, one for each of the two phases, defining, in a some way, the missing interaction component that closes the problem.

Herein the one-dimensional approach to the prob lem, which is the simplest one (Takahashi 1991, Egashira et al. 1997, Ghilardi et al. 1999, Berzi & Mambretti 2003), is used. The mathematical model presented is a quasi-two phase model that simulates the erosion/deposition phenomenon and uses a single momentum equation. Even if the phenomenon is typ ically impulsive, modeling is performed by numerical integration of the well-known Saint Venant equa tions through a scheme relying on shock-capturing functions.

The equations can be written in matrix notation:

where:

and x is the coordinate along the bottom of the flume; t is time; g is the gravitational acceleration; i is the

channel slope; J is the resistance term; A is the cross

section area of the flow; Q is the flow-rate; ρ M is the

mixture density; c is the solid concentration in the mix

ture; c ∗ is the solid concentration at the bed; E is the

erosion/deposition rate; L stands for the channel width

at the interface between the flow and the movable bed

layer; A d is the cross-section area of the movable bed

layer. Here, where h represents the water depth, while σ(x, η) represents the channel width at the depth η. Equations 1a, and 1b represent the mass and momentum conservation laws in the solid–liquid mixture, the mass conservation of the solid phase and the mass conservation of the solid–liquid mixture in the movable bed layer. In these equations pressure distribution is considered hydrostatic, even if the presence of solid material should change the normal stress expression (Bagnold 1954, Chen 1996). Equations 1a and 1b are integrated via a second-order precision finite-difference method (MacCormack & Baldwin 1975). The numerical scheme can be written as follows: where subscripts p and c are predictor and corrector steps respectively and n and i are the space-time step indices. In order to make computations more stable, θ= 1 as it is verified for hyper-concentrated fluids (Berzi & Mambretti 2003). Like all finite-difference schemes with second order precision, MacCormack scheme is characterized by large oscillations when the flow becomes supercritical and in presence of singularity points. In order to reduce these effects and remove non-physical shocks due to numerical integration, artificial terms simulating viscosity effects are introduced. These terms become negligible when numerical solution are stable. MacCormack scheme written with the introduction of artificial viscosity terms gives: Jameson (1982) expression is used for evaluating parameter ζ: 0 0.1 0.2 0.3 0.4 0.5 0.6 0.7 0.8 0.9 1

Figure 1. Comparison between Ritter analytical and numer

ical solution of dam-break wave (10 s after dam-break).

where:

When clear water is considered in dam-break prob

one should set α (2) = 0.5 and α (4) = 0.02. In the case

of debris flows the best values are different (see

Section 4).

The model has been tested for clear-water dam

break (using c= 0, E= 0 and the Chézy formula for

the resistance term J). Figure 1 shows the good agree

ment between numerical results and Ritter (1892)

analytical solution. The global balance of mass seems

to be verified too as it is shown in Figure 2.

When debris flow is considered, terms J and E

ought to be described for making possible the integra

tion of the equation system 1a, 1b. If the flow regime

is laminar, the resistance term J can be derived from

rheology, otherwise some empirical laws have to be

considered.

Some expressions based on Bagnold (1954) shear

stress and on a Chézy-like formula have been formerly

tested (Berzi & Mambretti 2003).

Here, Chen (1996) rheological equation for a

simple-shear granular flow is used:

where z is the coordinate normal to the flume bottom; u

is the local velocity in x-direction; s is the yield stress

equal to p sin φ; φ is the static friction angle and p

the pressure. Equation 7 is valid for an incompress

ible Stokesian fluid; thus, the solid phase density and 0
0.5 1 1.5 2.52 3 m t=0.04 s t=0.4 s t=1 s channel bottom
Figure 2. Wave at different times along the channel. the
interstitial liquid density should be the same. This
denotes a clear limit of the model. Anyhow, if η 1 = 1,
Equation 7 becomes the expression of a Bingham fluid in a
macroviscous regime and if η 1 = 2 turns into the
expression of a dilatant fluid in grain-inertia regime.
Hereafter parameters η 1 and μ 1 are defined. For uniform
flow in a wide open channel, the relation between the shear
stress τ(z) and the resistance term J is: where γ is the
specific weight of the mixture. From Equations 7, 8, under
the hypothesis of hydrostatic pressure distribution, one
can write: The transverse velocity distribution can be
obtained by integration of Equations 9: where the first of
Equations 10 is valid for J > sin φ, while the second for J
≤ sin φ. The constant C can be evaluated with the no slip
condition. Thus, when z= 0, u(z)= 0:

Finally:

where:

The flow-rate Q is:

where V is the average velocity. Substituting Equation

12 in Equation 14 and dividing by the channel width L:

so that:

Now, introducing Equations 13 in Equation 15, the

expression of the resistance term J results:

For a Newtonian fluid (μ 1 =μ, η 1 = 1,φ= 0),

Equation 16 exactly represents the resistance term in

laminar flow in an indefinite plain:

Equation 16 is valid if turbulent stresses in the inter

stitial fluid are supposed negligible. Otherwise, when the flow regime is grain-inertial, another empirical term has to be added as suggested by Bagnold (1954). Concerning μ 1 , Chen (1986, 1988) provides the following formula: where the parameter α 1 is a function of the solid material characteristics; ρ s is the solid density; d is a characteristic diameter of solid material; μ is the viscosity of the interstitial fluid; μ ∗ is the relative viscosity of the granular suspension, function of the solid concentration c (Krieger & Dougherty 1959): with K = 1/c m ; c m is the solid maximum concentration and B the intrinsic viscosity, equal to 2.5 for a suspension of very lightly-concentrated rigid uniform spheres but higher for a suspension of heavily-concentrated spheres, in particular if the channel bottom is rough. If turbulent stresses in the interstitial fluid are neglected, only this parameter takes into account the influence on the wave profile of the bottom roughness. This effect is experimentally verified as shown in Figure 3. In this Figure dam-break waves of a hyper-concentrated fluid on smooth and rough bed bottom are depicted. Both tests are performed with a water-gravel mixture (c= 0.2) and a channel slope i= 20 ∘ ; wave depth refers to a section placed 1.0 m downstream from the sluice-gate. Coefficient η 1 (Chen 1996) depends on the shear rate number N , similar to Bagnold number, ratio of the inertial stresses due to the particle collisions and the viscous stresses in the interstitial fluid. N can be expressed as (Chen 1986): 0.00 0.02 0.04 0.06 0.08 0.10 0 3 4 5 time [s] w a v e d e p t h [m] smooth bottom rough bottom 1 2 Figure 3. Influence of the bottom roughness on dam-break waves.

where D= du/dz. For N → 0 η 1 = 1 (macroviscous

regime), for N →∞ η 1 = 2 (grain-inertia regime).

Between these two asymptotic regimes, η 1 assumes

intermediate values. On the basis of the tests per

formed by Bagnold (1954) and Savage and McKeown (1983), Chen (1996) obtained the values of η 1 shown in Figure 4.

Figure 4 shows also the interpolating relation between η 1 and N used in this paper.

A similar relation between α 1 and N doesn’t exist because α 1 depends on some material constants, such as a coefficient of restitution.

The experimental tests demonstrate an important solid material exchange between the debris flow wave and the movable bed. Hence, it seems essential to introduce the erosion/deposition rate as a function of some relevant quantities.

Erosion/deposition rate E, defined by Honda & Egashira (1997) and modified by Ghilardi et al. (1999), is here used:

where:

where i b is the bed slope. θ e is the equilibrium bed slope. In uniform flow condition θ e is (Takahashi 1991):

where ρ l is interstitial fluid density. In Equation 21 the coefficient K E is introduced in order to obtain the best fitting with experimental results. y = 0.1415Ln(x) + 0.784

Figure 4. Relation between shear rate number N and

coefficient η 1 . 4 MODEL SETTING The mathematical model includes some parameters whose values have to be set. Some of these parameters are introduced in order to reduce the oscillations in the numerical solution due to non-physical shocks. Others are used to calibrate the model and their values can be defined only on the basis of field measurements and best fitting analysis. The latter has been performed by the comparisons between numerical and experimental results of six tests, taken as representative of the whole phenomenon, with different values of channel bed slope, solid concentration, solid material and bottom roughness. The value of the parameter c ∗ is chosen by measuring the solid concentration in the deposited material: for the gravel c ∗ = 0.49 and for the vedril c ∗ = 0.54. The static friction angle φ is equal to 0.5233 rad for gravel and to 0.4815 rad for vedril. The mathematical model provides good results when the solid concentration is low-medium (c= 0.2-0.4), without considering the yield stress. The yield stress has to be introduced, when the solid concentration is higher (c= 0.6).This fact influences the value of the artificial viscosity term parametersα (2) andα (4) . Best results are obtained setting α (2) = 1 and α (4) = 4 when the yield stress is neglected, while α (2) = 5 and α (4) = 2 are to be considered if the yield stress is introduced. Figure 5 shows several wave profiles for different values of the parameter α (2) . The relation between η 1 and the shear-rate number N is described in the previous Section. Assuming a triangular velocity distribution along the z-direction, Equation 21 becomes: α 1 is always positive and less than 2 (Chen 1996) but its value depends on the type of the solid material. Since a sensitivity analysis shows that the numerical solution 0.00 0.02 0.04 0.06 0.08 0.10 0.12 0.14 0 1 2 3 4 5 6 time [s] w a v e d e p t h [m] (2)=0.5 (2)=5 (2)=1 Figure 5. is weakly influenced by this parameter (Fig. 6), here α 1 is set 1.1 both for gravel and for vedril material.

The intrinsic viscosity B is important because it takes into account the influence of the bottom rough ness on the wave behaviour. A thorough study about the value of this parameter could be performed in the future.

Here, when the flume bottom is a zinc coated plate B= 3 and, as suggested by Chen (1996) for the gran

ular flow of neutrally buoyant particles, B= 4.5 when the flume bottom is an homogeneous gravel bed.

The K E parameter, introduced in Equation 21, is set equal to 0.1 as indicated by Ghilardi et al. (1999) for unsteady flow.

5 COMPARISONS WITH EXPERIMENTS

The mathematical model involves large simplifica tions; first, the solid and the liquid phases are char acterised by the same average velocity and the same density: hence a single momentum equation can be employed and the resistance term J can be expressed as described in Section 3.Thus, one can expect that a good agreement between numerical results and experimen tal data will be obtained only when the solid material is vedril, whose density is similar to water density.

Figures 7, 8 show the comparisons between experi mental and numerical results: wave depth h versus time t graphs, at a section located 1.0 m downstream from the sluice-gate are shown. Figure 7 regards the test per formed with gravel-water mixture while Figure 8 that with vedril-water mixture. The solid concentration in both cases is equal to 0.2 and the flume bottom is set rough with a 5 ◦ slope.

Figure 7 shows that numerical results of the maxi mum wave depth as well as the deposit layer thickness

(see for t≥ 3.5 s) are definitely overestimated respect

to experimental data; on the contrary, the reaching time

to the measurement section is well predicted. 0.00 0.02 0.04 0.06 0.08 0.10 0.12 0.14 0 2 4 6 time [s] w a v e d e p t h [m] experiment model 1 3 5 Figure 7. Comparison between numerical and experimental results. Test performed with gravel mixed with water (c= 0.2), a rough bottom of slope i= 5 ∘ , measurement section at 1.0 m from the gate. 0.00 0.02 0.04 0.06 0.08 0.10 0.12 0.14 0 2 4 6 time [s] w a v e d e p t h [m] 1 3 5 experiment model Figure 8. Comparison between numerical and experimental results. Test performed with vedril mixed with water (c= 0.2), a rough bottom of slope i= 5 ∘ , measurement section at 1.0 m from the gate. In Figure 8 it can be observed that the mathematical model supplies a good estimate of both the maximum wave depth and the deposit thickness. The simulated wave appears to move faster than the experimental wave (around 0.2 s), maybe because of the non-zero opening time of the sluice-gate. These considerations are valid for all the tests performed and at any section of the flume. For example, Figure 9 shows another comparison between numerical and experimental results at a section located 0.4 m downstream from the sluice-gate.The test is performed with vedril-water mixture (solid concentration equal to 0.2) and on a smooth flume bottom with a 5 ∘ slope. In this case perhaps a careful analysis of the intrinsic viscosity value B could improve the agreement between the numerical results and the experimental data. The SaintVenant equations are based on the hypothesis of mild slope; then, its foreseeable that agreement between the numerical and the experimental results should worsen when the slope increases. Indeed, Figure 10 shows the comparison between numerical and experimental results, at the same section of Figure 9

and with the same experimental conditions except that

the channel slope. This is set 15 ∘ and it can be noticed

that the wave depth peak is underestimated (around

20% less than measured one).

The comparisons shown refer to tests performed

with mixtures with low solid concentration and

neglecting in the mathematical model the yield stress

in the resistance term; thus, sin φ does not appear in

Equation 16. For high solid concentration, the yield

stress has to be introduced in order to avoid results that

do not reflect the real phenomenon.Yield stress seems

to be present only when continuous friction among the

grains develops in high concentration flows.

Figures 11, 12 show the comparisons between

numerical and experimental results, at a section

located 0.4 m downstream from the sluice-gate;

whether the yield stress in the model is included or

not. Both figures regard tests performed on a rough

bottom and a 5 ∘ slope with mixtures with a solid con

centration equal to 0.6. In Figure 11 the solid material

used is gravel, while in Figure 12 it is vedril. 0.00 0.02 0.04 0.06 0.08 0.10 0.12 0.14 0.16 0.18 0 1 2 5 time [s] w a v e d e p t h [m] experiment model with yield stress model without yield stress 3 4 6 Figure 11. Comparison between numerical and experimental results. Test performed with vedril mixed with water (c= 0.6), a rough bottom of slope i= 5 ∘ , measurement section at 0.4 m from the gate. It can be seen that the wave behaviour is completely misunderstood if the yield stress is not present in the shear stress expression used for the calculation of the resistance term in the model. Anyhow, even if the yield stress is taken into account, deposit thickness is largely underestimated (about 20-25%). 6 CONCLUSIONS The matter of the present paper is the analysis of the hypotheses upon which a one-dimensional mathematical model of granular debris flow consequent to dam-break is based. These hypotheses represent a limitation for the application of the model, although their introduction is necessary in order to simplify the problem. The model equations are integrated via a shock-capturing MacCormack scheme. The main hypotheses considered are the following: i. the solid and the liquid phase are characterised by the same average velocity;

ii. the water-solid mixture density is constant, that is

the solid material is neutrally buoyant;

iii. pressure distribution along the cross-section of the

flow is hydrostatic;

iv. the channel slope is mild;

v. the presence of the solid material does not involve

changes in the expression of the normal stresses.

The importance of the hypotheses (i) and (ii) is underlined by the comparisons between numerical and experimental results when the solid material is gravel, whose density is much larger than water den sity. The hypotheses (iii) and (iv) are used to obtain a one-dimensional version of the mathematical model, while hypothesis (v) allows a further simplification. Moreover, some parameters of the model allow its calibration and avoid oscillations in the numerical solution; the values of the parameters for best fitting with experimental data are indicated.

The comparisons between numerical and experi mental data show that the mathematical model can satisfactory predict the wave behaviour consequent to dam-break, if the solid concentration is low-medium and the solid material density is similar to the inter stitial fluid density. Concerning higher solid concen trations, the introduction of the yield stress term in the shear stress expression allows a quite satisfac tory, yet not excellent, agreement with experimental data. The density of the debris in real granular flows is much larger than the water density, therefore the mathematical model employed seems to oversimplify the problem, though it provides useful indications for a first, often safe, evaluation of the wave depths.

It seems that the correct simulation of the unsteady granular flow consequent to dam-break requires a more complex and complete approach. A first improvement can be reached removing the hypothe sis of hydrostatic pressure distributions, that means the use of at least, a two-dimensional mathematical model, which will also solve the problem of modelling the complex geometry that characterizes real debris flows. Finally, it is remarkable that only a two-phase mathematical model, employing two different momen tum equations, seems to be able to better reproduce the behaviour of a real debris flow.

Numerical simulation of hyper-concentrated flows

D. Komatina & D. Đor – devic´

Faculty of Civil Engineering, University of Belgrade,
Belgrade, Serbia & Montenegro

ABSTRACT: Numerical modelling of dam-break or dike-break flows of homogeneous non-Newtonian fluids is

presented in the paper. One of the most important tasks when formulating such a model is an estimation of friction

losses, so that a constitutive equation must be adopted for the fluid under consideration. The constitutive equation

introduced into the presented model is based on a general yield-power law (Herschel-Bulkley's rheological

model). Numerical model used herein to solve the governing equations of 1D unsteady free-surface flow is

based on the MacCormack explicit finite-difference scheme. The proposed model is verified using results of

laboratory dam-break tests of mine tailings mixed with water. The mixtures are considered homogeneous, the

material being composed mainly of silt and clay and wave propagation being considered of short duration. A

comparison between measured and calculated results is given through a number of diagrams, showing the effect

of varied parameters both on the wave propagation speed, and the flow depths.

1 INTRODUCTION

Dam-break flow of mine tailings seems to be one

of the most dangerous hazards threatening local peo

ple, property and the whole environment. Therefore,

a considerable attention has been paid to analysis of

unsteady free-surface flows of highly concentrated

solid–liquid mixtures, which have a non-Newtonian

character, such as liquefied mine tailings (Jeyapalan

et al. 1983, Komatina 1998), mud and debris (Han & Wang 1996, Huang & Garcia 1997, Hunt 1994, Jin & Fread 1999, Laigle & Coussot 1997, McArthur & Schamber 1986, O'Brien et al. 1993). Few analyti cal solutions to the problem have been given (Huang & Garcia 1997, Jeyapalan et al. 1983), applying Bingham plastic rheological model for description of mud and mine tailings flows. Examples of physical modelling of such flows have been presented as well (Coussot 1994, Komatina 1999).

Unsteady dam-break flow of highly viscous solid–liquid mixtures has been numerically studied so far using various constitutive relationships. Newtonian (Aguirre-Pe et al. 1995, Hunt 1994), Bingham (McArthur & Schamber 1986) and Herschel-Bulkley's fluid models (Laigle & Coussot 1997) have been applied to laminar flow modelling, while hybrid mod els have been employed for turbulent flow modelling – quadratic model (Bingham model, extended to account for turbulent and dispersive stresses) (Liu & Lai 2000, O'Brien et al. 1993), or a model established combining Bingham and Chezy-type relationships (Han & Wang 1996). Explicit numerical schemes of a finite-difference (Aguirre-Pe et al. 1995, Laigle & Coussot 1997) and finite-element type (McArthur & Schamber 1986) have been used in numerical treatments for 1D (Aguirre-Pe et al. 1995, Hunt 1994, McArthur & Schamber 1986) and 2D modelling (Han &Wang 1996, Laigle & Coussot 1997, McArthur & Schamber

1986, O'Brien et al. 1993). Implicit numerical scheme has not been employed to such an extent for modelling unsteady hyper-concentrated flows, due to difficulties when modelling flows having discontinuities (Fraccarollo 1997). It has been accepted as an unconditionally stable, robust and suitable for application to tasks requiring both spatially and temporally huge computational domains (Cunge et al. 1980, Meselhe & Holly 1997), which are likely to occur in nature. Additionally, it has been successfully used in the clear water dam-break subcritical flow modelling (Hicks et al. 1997). However, in a paper of the authors (Komatina & Lalovic´ 2000), where the implicit 4-point finite-difference scheme has been applied, quality of the simulation results decreased due to impossibility of a dry-bed computation – calculated longitudinal profiles of the waves were too smooth and the wave front locations were greater than those measured in laboratory. In order to improve modelling of discontinuous flows, such as the dam-break hyper-concentrated flow, an application of a shock-capturing scheme, which allows for weak solutions, is analysed in this paper. Therefore, the MacCormack explicit finite-difference

scheme, whose good performance in discontinuous

Newtonian flow modelling has been reported in lit

erature (Aguirre-Pe et al. 1995, Bellos & Sakkas

1987, Đor – devic´ 2000, Garcia-Navarro & Saviron

1992, Jovanovic´ & Đor – devic´ 1995), is used for 1D

numerical modelling of dam-break flows of lique

fied mine tailings, previously performed in laboratory

canal (Komatina 1998). Friction losses are calculated

in the model using the Herschel-Bulkley's rheological

equation.

2 FRICTION FACTOR MODELLING

A case of uniform free-surface flow of a homogeneous

time-independent incompressible non-Newtonian

fluid in a wide channel is considered. It can be

shown from momentum equation that the shear stress

distribution over the flow depth is linear, see Figure 1:

where τ is the shear stress at a distance y from the

bottom, τ o is the bottom shear stress:

ρ is the fluid density, g – gravitational acceleration, h –

flow depth, α – bottom slope angle, S o – bottom slope,

§ – dimensionless distance from the fluid surface:

and § c – non-dimensional plug flow width, given by:

where y c is the distance from the bottom where τ= τ c .

Evaluation of the friction slope is of a crucial

importance in solving the governing equations for a

non-Newtonian fluid. For this purpose, a constitutive

equation for the material under consideration has to be y c
y § . h § c . h h τ (y) τ c τ 0 u c u (y)

f l o w α

Figure 1. Shear stress (τ) and flow velocity (u)
distribution,

shown schematically. adopted. The Herschel-Bulkley's model is used in the paper: where $\dot{\gamma}$ denotes shear rate; τ c , η, and m – rheological parameters of the fluid (yield stress, consistency index and flow behaviour index, respectively). The equation comprises yield and viscous stress components and is valid in laminar flow regime only. By double integration of Equation 5 over the flow depth, the laminar flow equation can be derived in the following form (Coussot 1994): where U is the mean flow velocity, which is, for a wide channel, equal to the depth-averaged velocity, and the dimensionless function is defined by: It is well known that standard Newtonian relationships for clear water can be applied for calculation of friction factor for a non-Newtonian fluid, if the Reynolds number is expressed in an extended form, so as to include all the rheological parameters of the fluid (Wan & Wang 1994). For the Herschel-Bulkley's model, the extended Reynolds number is

defined as (Komatina 1999): where the Newtonian Reynolds number is equal to: So, the standard Moody relationship, which can be obtained from Equation 6, is applied in the laminar flow regime (Re ext < 2100), (Komatina 1999): and the Blasius formula is applied in the turbulent flow regime (Wan & Wang 1994): The bottom shear stress is then determined using the calculated value of the friction factor:

3 GOVERNING EQUATIONS

The 1D unsteady free-surface hyper-concentrated flow

is described by the De St.-Venant equations in conser

vative form:

where x and t are space coordinate and time, respec

tively; A – the flow area; Q – the discharge; S o – bottom

slope and S f – friction slope. The terms I 1 and I 2 are

related to the hydrostatic pressure force:

in which: the depth integration variable along y-axis

is denoted by ζ, the width of the cross-section at the

distance ζ from the bottom of the cross-section, which

is located at distance x along channel by b(x, ζ). In

prismatic channels I 2 = 0.

3.1 Determination of the friction slope

It is usually assumed that for unsteady flow, the bot

tom shear stress at a specific point is equal to the value

of the uniform flow with a corresponding flow dis

charge and depth (Aguirre-Pe et al. 1995, Laigle &

Coussot 1997). Consequently, application of sim

ple rheological relationships, such as Equation 5, is

possible.

The friction slope in Equation 13 is determined

using the relationship:

on the basis of the bottom shear stress, previously

calculated from Equation 12.

4 NUMERICAL MODEL

The system of partial differential hyperbolic-type

equations 12 is numerically solved using the MacCor

mack explicit finite-difference scheme. The scheme is second order accurate in both the space and time. It consists of a two step predictor-corrector sequence: Predictor: Corrector: New value: Here, subscript i defines a position of the crosssection along the x-axis, superscripts k and k + 1 denote values of the variables at the previous time level (k) and the following time level (k + 1), whereas superscripts p and c denote values in the predictor and corrector steps, respectively. The backward and forward difference operators are defined by: The operator sequence in the predictor and the corrector steps is alternated each time step, which means the operator cycle is concluded in two time steps. In order to provide numerical stability of the scheme, the Courant-Friedrichs-Lewy's criterion is used to determine the time step t in Equations 16 and 17. 5 EXPERIMENTS Mixtures of water and copper tailings taken from the Veliki Krivelj copper mine (Serbia and Montenegro) were used as experimental fluids. The mean diameter of particles is 0.025 mm, with 8% of the material finer than 0.002 mm, and 70% finer than 0.062 mm. The density is 2650 kg/m 3 , and its chemical composition: 63% SiO 2 , 14% Al 2 O 3 , 3.5% Fe, 3% K 2 O, 3% CaO, 3% MgO and 3% Na 2 O. Clayey fractions of the material are of kaolinite-illite type. Rheological parameters of the mixtures were determined using two types of measurements: in a commercial rotational viscometer and in the laboratory canal, illustrated in Figure 2. Measurement errors were estimated to 13% (viscometer) and 16% (canal), (Komatina 1999). The applied procedures provided data on rheological behaviour of the mixtures in different ranges of shear rate: small shear rates (0.5 to 20 s −1) in the case of steady-state free-surface flow experiments in the canal, and 50 to 250 s −1 , 4.5m 0.155m A A

using the rotational viscometer. For a mixture, two

linear relationships (Bingham model) were defined

for each of the shear rate ranges. Finally, a yield

power-law (Herschel-Bulkley’s model) was defined

so as to match the linear relationships. Values of the

rheological parameters, obtained in this manner, are

listed in Table 1 (where C V denotes the volumetric

concentration of the solid phase).

The dam-break flow experiments were performed

in a 4.5 m long, 0.15 m wide glass-walled laboratory

flume, with adjustable bottom slope (Fig. 2). The dam

break type of flow was initiated by releasing mixtures

from a 2 m long, 0.155 m wide reservoir, situated on

the upstream part of the flume. A sketch of the experi

ment is given in Figure 3 (H – initial reservoir depth).

Experimental parameters were varied in the following

ranges: S o = 0–1%, H = 10–30 cm, C V = 0–45.6%. 6 RESULTS AND DISCUSSION Results from the laboratory rig, depicted in Figure 2, were used to verify the results of numerical simulation of one-dimensional unsteady hyper-concentrated flow. The flow was caused by a sudden release of the mixture (induced by an abrupt removal of the gate between the reservoir and the canal), stored in the 2.0 m long and 0.155 m wide reservoir that had been formed in the upstream part of the flume. The propagation of a positive wave in an initially dry canal was filmed by a video camera with recording speed of 5 images per second. The glass walls had been covered with a square net (∆x=∆z= 1 cm), thus it was possible to “read” the records – read the flow depths along the canal. Settling of particles during the propagation was neglected, as the propagation time was short relatively to the settling time of the material composed mainly of silt and clay. The evolution of the measured and the calculated flow depth profiles of four experiments with different mixtures, in which the initial depth in the reservoir was H = 0.3 m and the bottom canal slope 1%, are shown in Figures 4–7. The properties of the mixtures are given in Table 1. The initial condition at the opening was defined according to the theoretical Ritter’s solution for the one-dimensional dam-break problem: h= (4/9)H , u= (8/17) √ gH , while for numerical reasons, the initial depth downstream from the reservoir was set to 0.001 m. No artificial viscosity was used. For the sake of easier comparison with the measurements, the time step, used in this simulation, was kept constant ∆t= 0.01 s, which resulted in the maximum Courant’s number values of 0.6 for lower concentration mixtures and 0.4 for higher concentration mixtures. It can be noticed (Figs 4–7), that the wave front propagation speed is generally well reproduced for all the mixtures – the differences between the calculated and the measured wave front locations are less then ±3%. However, discrepancies between the calculated and the measured flow depth profiles expressed in reference to the measured flow depths are somewhat greater for the mixtures with lower concentration of solids

(Figs 4-5), than those pertaining to the mixtures with higher concentration of solids (Figs 6-7).The discrepancies for the former mixtures are as high as 45% at the steep front, where it was not possible to read the flow depths from the video tapes accurately. The flow depths were too small to recognize and read easily from the recordings. On the other hand, discrepancies between the calculated and the measured flow depth profiles for the mixtures with higher concentrations of solids (Figs 6-7) are much lesser, since the wave front heights were much greater for these mixtures. Discrepancies for about 90% of the results are within ±15%. Furthermore, the effect of slowing down the advancing front is readily noticeable for the mixture Distance [m] h [m] 0.00 0.00 0.50 0.50 1.00 1.00 1.50 1.50 2.00 2.00 2.50 2.50 3.00 3.00 3.50 3.50 4.00 4.00 4.50 4.50 0.00 0.00 0.10 0.10 0.20 0.20 0.30 0.30 0.40 0.40 calculated measured t = 0.6 s Distance [m] h [m] 0.00 0.00 0.50 0.50 1.00 1.00 1.50 1.50 2.00 2.00 2.50 2.50 3.00 3.00 3.50 3.50 4.00 4.00 4.50 4.50 0.00 0.00 0.10 0.10 0.20 0.20 0.30 0.30 0.40 0.40 calculated measured t = 0.8 s Distance [m] h [m] 0.00 0.00 0.50 0.50 1.00 1.00 1.50 1.50 2.00 2.00 2.50 2.50 3.00 3.00 3.50 3.50 4.00 4.00 4.50 4.50 0.00 0.00 0.10 0.10 0.20 0.20 0.30 0.30 0.40 0.40 calculated measured t = 1.0 s

with the highest concentration of solids (C V =

36.4%) – Figure 7, which is another very important

feature of the proposed model. The influence of the

concentration of the solid phase on the wave propaga

tion speed is presented in the Figure 8. The higher the

concentration, the lower the propagation speed, which

is in agreement with the laboratory observations.

As previously explained, the rheological parameters

of the Herschel-Bulkley’s model were determined by

matching the Bingham linear relationships obtained

from two different procedures (viscometer and canal).

Although the authors are aware of inconsistency of the

procedure, it gave good results in this particular case,

as can be seen from the plots of advancing fronts of

all the mixtures (Figs 4–7). This justifies the applied

procedure for determination of the parameters.

With the rheological parameters obtained in this

manner, the calculated flow regime was laminar for

all the analysed mixtures released from the reser

voir, except the one with the lowest concentration of

solids (C V = 13.8%), see Table 2. For the mixture hav

ing C V = 13.8%, it can be seen that Re ext < 10000.

According to the findings of Wan & Wang (1994), this means that the flow conditions have not achieved fully developed turbulence, which justifies application of the Blasius formula in the turbulent flow regime. 7 CONCLUSIONS Dam-break flow computation is a complex task, affected by a number of factors, such as availability and reliability of boundary and initial conditions, and capability of a numerical scheme to reproduce steep front without introduction of additional algorithms for bore tracking. The computation becomes even more complicated when modelling unsteady flows of highly concentrated solid–liquid mixtures. In such a case, estimation of rheological parameters of the mixture, as well as calculation of the friction slope, appear as new sources of errors. In this paper, a 1D numerical model for hyperconcentrated dam-break flows is illustrated. The main intention is to reproduce numerically dam-break flows already observed in nature or laboratory. As a further objective, prediction of flows due to dam failure or dike

failure on mineor ash-tailings deposit sites is planned.

The MacCormack explicit finite-difference scheme is used for numerical modelling. As it belongs to the group of shock-capturing methods, it is particularly suitable for solving problems of the main interest to the authors – simulation of flows with a steep front.

Simulation results have shown that the wave front propagation speed is generally well reproduced for all the mixtures. This means that the initial condi tion at the gate opening, derived for the clear water case, is equally applicable in the case of the hyper concentrated flow. In addition, the observed effect of slowing down the wave front propagation speed with the increase in the concentration of solid par ticles is successfully reproduced with the proposed

model, which makes it a good predictive tool for solv
ing dam-break or dike-break hyper-concentrated flow
problems.

Further, discrepancies between the calculated and
the measured flow depth profiles are acceptable. For
the mixture with the lowest concentration of solids, the
discrepancies at the steep front are high due to the
difficulties in reading small depths from the video
tapes.

Determination of the rheological parameters of the
Hershel-Bulkley's model by matching the Bingham
linear relationships obtained from two different pro
cedures (viscometer and canal) is not consistent.
However, results from the plots of advancing fronts
of all the mixtures justify the applied procedure for
determination of the parameters.

With the parameters obtained in this manner, the
calculated flow regime was laminar for all the mix
tures, except for the one with the lowest concentration
of solids (C V = 13.8%). The values of the extended
Reynolds number for this mixture show that fully
developed turbulence has not been achieved, which
justifies application of the Blasius formula.

The proposed model in its present form gives satis
factory results in simulation of flows of homogeneous,

hyper-concentrated mixtures in regular channel geom

etry. In order to extend its application to real problems

occurring in industry and nature, improvement of

the model by allowing for computations in irregular

Probabilistic estimation of debris-flow discharge by Monte Carlo simulation method

J.C. Chen

Disaster Prevention Research Center, National Cheng Kung University, Tainan, Taiwan

C.D. Jan & M.H. Lee

Dept. of Hydraulic and Ocean Engineering, National Cheng Kung University, Tainan, Taiwan

ABSTRACT: Equation of debris-flow discharge contains hydrogeological and topographical parameters. Considering the uncertainty of the parameters and using the Monte Carlo simulation method (MCSM), a debris-flow design discharge versus reliability probability at various return period is developed. The method proposed in this paper is used to estimate the debris-flow design discharge in fushing village, Hualien county, Taiwan. The results also compare with that by First-order second-moment method (FOSM).

1 INTRODUCTION

Reliability modeling and other probabilistic techniques are becoming increasingly important tools in design of debris-flow hazard countermeasures. As an example, a discharge design may be based on reliability to assist the engineering in deciding on the most appropriate design parameters under a variety of uncertainties. Once the design discharge was underestimated, the reliability of debris-flow mitigation plan or structures would be doubtable.

Methods in deterministically calculating debris flow discharge have been proposed by some investigators, such as Takahashi (1978), Kang (1985), Wang & Chang (1985), Chen et al. (2002), among others.

Assume that the debris flow peak discharge can be

directly related to the peak discharge of the water stream, a semi-empirical relation of debris-flow dis charge for a specified return period is given as (Chen et al. 2002)

in which C = runoff coefficient; A m =watershed area in hectares (ha); T = rainfall return period in years; L= stream length in km; H = elevation difference of stream length in km. C v = sediment volumetric con centration. The values of C v for debris flow are in the range of 0.15<C v < 0.9(1- n) in which n is porosity of sediment layer; l= the length of over land flow in km; v= the overland flow velocity in km/hr. Generally, the values of v are in the range of 1.08~ 2.16 km/hr (SWCTC 2000) ; I r = reference of rainfall intensity (mm/hr) that is the rainfall intensity at return period of 25 years and duration of 60 minutes; k 0 is a constant and equals 55. The other coefficients (k 1 , k 2 , k 3 , k 4) and the reference rainfall intensity I r are directly related to the annual rainfall in the concerned watershed, as indicated in Appendix I. The above equation is a deterministic equation if all parameters involved in the equation are evaluated by their mean values. However, the parameters have some kinds of uncertainties. Considering the uncertainties of the random variables in Eq. (1) and using the firstorder second-moment method (FOSM), Chen et al. (2002) have been developed a probabilistic equation of debris-flow discharge. For the FOSM, no distribution is required, but the underlying assumption is that the variables are all normally distributed and the function being analyzed is linear. This assumption can present large errors in some cases where the function or equation is highly nonlinear. Therefore, an exact method, the Monte Carlo simulation method (MCSM), in this paper is used to estimate the debris-flow discharge for different reliability probability, and the result is compared with that by FOSM. 2 UNCERTAINTY OF PARAMETERS The uncertainty of parameters may result from the facts that (1) the topographical parameters, A m , l, L and H , measured from

a topographic map of watershed have inconsistent values for difference persons (engineers)

Table 1. Statistical properties of seven parameters at Fushing village.

Variables x i	Samples N	Ranges values	Mean μ xi	Variance CV xi (%)
A m (ha)	31	310.4~ 396.6	355.6	6.81
l (km)	31	1.36~1.73	1.55	5.22
L (km)	31	1.47~1.90	1.69	5.01
H (km)	31	0.21~0.22	0.216	1.64
C v	-	0.15~0.56	0.355	28.87
C	-	0.5~0.8	0.65	11.54
v (km/hr)	-	1.08~2.16	1.62	16.67

due to their different experiences on drawing the watershed boundary and the initial point of river upstream; (2) the soil properties, the vegetation and topographic properties vary in space and are highly non-homogeneous, and therefore the overland flow velocity v and the runoff coefficient C are random variables; (3) the sediment concentration C v of debris flow has high uncertainty also, depending on the property of sediment, slope and the amount of sediment and water. The uncertainties of the above mentioned parameters could be quantified by using statistical parameters, such as the mean value, the standard deviation, the coefficient of variation and probability distribution.

Table 1 lists the statistical result of topographi cal parameters (A_m, l, L and H) at Fushing village in Taiwan (Jan et al. 2003), basing on the measured data individually conducted by 31 graduate students using same kind of map of watershed. One can see that the variances of the parameters A_m, l and L all are larger than 5%, while variance of H is 1.64%. The mean values and the coefficients of variation for other parameters, C_v, C and v, are estimated from the range of possible values owing to the absence of field data. Given the range of possible values of a random vari able, the mean value of the variable and the underlying uncertainty may be evaluated by prescribing a suitable distribution within the range (Ang and Tang, 1984). If the given limits are assumed to be ±cover 2 standard deviations in the normal distribution, the mean val ues and the corresponding coefficient of variation for parameters C_v, C, v, are also summarized in Table 1.

All the seven parameters in Eq. (1), A_m, l, L, H, C_v, C, and v, are treated as random variables and assumed fol lowing normal distributions while the rest parameters are treated as deterministic parameters in the present paper.

3 MONTE CARLO SIMULATION METHOD

Many methods have been developed for uncertainty

assessment (Harr 1987, Ang & Tang 1984, Rubinstein

1981). Generally, these methods can be classified into
Input: Statistical distribution for each component variable
Select a random value from each of these distributions
Calculate the value of system performance for a system
composed of components with the values obtained in the
previous step Output: Summarize and plot resulting values
of system performance. This provides an approximation of
the distribution of system performance Repeat many times
Figure 1. Flow chart of Monte Carlo simulation method.
approximate and exact. The approximate methods are usually
of the moment type, e.g. the first-order secondmoment
method (FOSM) and the advanced-secondmoment method (ASM).
The exact methods involve a comprehensive analysis using
the probability distribution of all component variables,
e.g. direct integration method and Monte Carlo simulation
method (MCSM). In this study Monte Carlo Simulation (MCSM)
is used to generate random samples of parameters in Eq. (1)
based on the specified coefficients of variation and
distributions.The probabilistic equation of debris-flow
discharge based on FOSM (Chen et al. 2002) is also used for
comparison in this paper. Monte Carlo simulation is a
method for obtaining information about system performance
from component data. This method has also been referred to
as synthetic sampling or empirical sampling. The procedure
of Monte Carlo simulation is shown graphically in Figure 1.
To obtain a probabilistic debris-flow discharge, the
following steps were followed: 1. Values for each of random
variables in Eq. (1), including (C, C v , A m , l, v, L, H
), were generated from their respective distributions for
each of N= 1000 simulation cycles. All the variables were
assumed to be normal with means and standard deviations of
Table 1. 2. The debris-flow discharge Q t was calculated
from Eq. (1) based on the generated random variables. This
process was repeated for N simulation cycles. Figure 2
shows a frequency histogram of the N= 1,000 simulated
debris-flow discharge Q t . 0 40 80 120 160 200 240 Q t

4 PROBABILISTIC ESTIMATION OF DEBRIS FLOW DISCHARGE IN FUSHIHG VILLAGE

Fushing village is located at Hualien county in eastern

Taiwan. There were several severe debris flow events

in the village during past five years. Figure 4 shows the

debris flow hazard in Fushing village on July 31 2001,
Figure 4. During typhoon Troaji period, a large amount of
boulders deposited in the village upstream and damaged the
road due to insufficient of bridge crossing section (DPRC
2001). after typhoon Troaji attacked. A large amount of
boulders deposited in the village upstream and damaged the
road due to insufficient of bridge crossing section. Hence,

how to estimate the debris-flow discharge and determine the design cross section reasonably is an important work in this area. Given the rainfall coefficients (i.e., I r = 92.332 mm, k 1 = 0.551, k 2 = 0.305, k 3 = 18.206 and k 4 = 0.594), a specified return period T and the parameters listed in Table 1, the reliability probability p s for a certain value of debris-flow design discharge Q d which exceed Q t , i.e. G=Q d -Q t > 0, in Fushing village can be determined by MCSM. Figure 5 shows the relationship of the design debris-flow discharge Q d against reliability probability p s for various return period T .The relationship shows that the debris-flow discharge Q d increases with the increase of T and p s . This result implies that the larger Q d is needed if we choose the larger rainfall return period and higher reliability index in design work. The probabilities of debris-flow design discharge at various return period are also estimated by FOSM (Chen et al. 2002), and indicated in Figure 5 for comparison. Figure 5 shows that Q d determined by FOSM is trifle greater than that by MCSM in most ranges of reliability probability (0.2< p s < 0.6). For example, Q d = 108 cms by FOSM and Q d = 103 cms by MCSM if we give p s = 0.5 and T = 50 years. That is, the determined debris-flow design discharge from FOSM is 0 0.1 0.2 0.3 0.4 0.5 0.6 0.7 0.8 0.9 1 Reliability Probability p s 40 60 80 100 120 140 160 180 200 220 240

more conservative or safety than that from MCSM.

Anyway, the debris-flow design discharge determined by FOSM is close to that by MCSM. The relative error is less than 10%. In general, the MCSM may obtain better results than the FOSM, since the MCSM is an exact method. However, the evaluation of p f by FOSM is much faster than that by MCSM. The comparison in Figure 5 reveals that the debris-flow design discharge obtained by FOSM is indeed a good approximation to that obtained by MCSM.

5 CONCLUSIONS

A debris-flow discharge equation contains three hydro geological parameters, such as the runoff coefficient, sediment concentration and overland flow velocity, and four topographical parameters, such as the water shed area, the length of overland flow, the horizontal stream length and elevation difference of stream. The uncertainties of the seven parameters in Fushing vil lage in the eastern Taiwan are analyzed and evaluated. Taking into consideration of the parameters uncertain ties, we have developed a relationship of debris-flow

design discharge versus reliability probability at vari

ous return periods by using Monte Carlo simulation

method (MCSM). This result obtained by MCSM

is also compared with that from previous study by

First-order second-moment method (FOSM). These

comparisons show that the debris-flow design dis

charge determined by MCSM is close to that by

Concentrated mud suspensions flowing in open channels

G.F. Maciel & F.L. Santos

Department of Civil Engineering, São Paulo State University, Ilha Solteira, São Paulo, Brazil

ABSTRACT: Mixtures of clay and water exhibit, in general, non-Newtonian property to be up to solid con

centration. The purpose of this article is, first, to characterize these mixtures of the physical and rheological

point of view. Under controlled conditions, the temperature, pH, and volumetric concentration influence on flow

curve of this mixtures, were determined. Second, to carry out dynamic experiments in open channel in order

to determine empirical wall stress formula (friction laws) from depths and discharges measured. It can also be

obtained, from a global quantity analysis, behavior laws of several rheological parameters due to volumetric

concentration. The fitted rheological model was Herschel-Bulkley, $\tau = \tau_c + k(\dot{\gamma})^n$ where τ_c : critical shear stress

(yield stress), k: apparent viscosity; n: index of flow; and $\dot{\gamma}$ is shear rate.

Finally, due to rheological properties of material and the dynamic characterization of flow, it was determined

the friction law to the hyper-concentrated fluids flowing in wide inclined long channel.

1 INTRODUCTION

Resulting mixtures of Newtonian fluids behavior and solid particle appear with frequency in the nature and industry. Those mixtures exhibit, as a rule, non Newtonian properties (COUSSOT, 1997). In general, when we approach these mixtures, we identify, first, flows such as wastewater (sewage sludge), slurry coals, mud proceeding of oil explotation, fresh con crete, agroalimentary fluids. Second, we identified phenomena related to sedimentation process in reser voirs, deposition in irrigation channels, transport and finally, the landslides, sand liquefaction, erosive actions and torrential lavas – this real “mud sea” and debris which have banned the life of hundred of people at the world.

From those motivation, came up interests in diag nose, to a better refined way, and with engineering point of view, physic properties of non-Newtonian matrix (water+ clay mixture), once characterized, would be insert to flowing studies with laminar behav ior (mudflows) or turbulent (mud fronts, urban floods) according to friction laws.

2 WATER+CLAY MIXTURE RHEOLOGICAL CHARACTERIZATION

To the mixtures rheological characterization, R/S

rheometer (Figure 2a) was used for controlling shear Figure 1a. Mud flowing in a river.

Figure 1b. Mud flowing in small channels at FEIS/UNESP

laboratory.

stress and shear rate. The chosen geometry is the kind

of that uses coaxial cylinder (Figure 2b) equipped

with temperature control (circulating water bath). Sup

ported by Rheo2000 software, could be gauged, to a

better refined way, the Herschel-Bulkley parameters,

as well the flow curves to each material essayed.

The following results aimed to explain some char

acteristics of essayed mixtures (water+ kaolin clay)

related to temperature variation, pH, and volume

concentration.

2.1 Temperature changing analysis

As it was analyzed (Figure 3), the temperature chang

ing at the sample did not seem to influence to a

significant on the flow curve, above all if we consider

a zone of temperature that comprises the ambient Figure 2a. R/S Rheometer. Figure 2b. Coaxial cylinders geometry and spindles. temperature (0 ∘ C<T< 30 ∘ C). So, we can reassure ourselves when the temperature control at the moment of rheometry tests. 2.2 Ph variation analysis It was noticed, as showed results Figure 4, that the pH influence of the mixture at the rheological curve is small in this study. However, the variation of these Cv = 10%

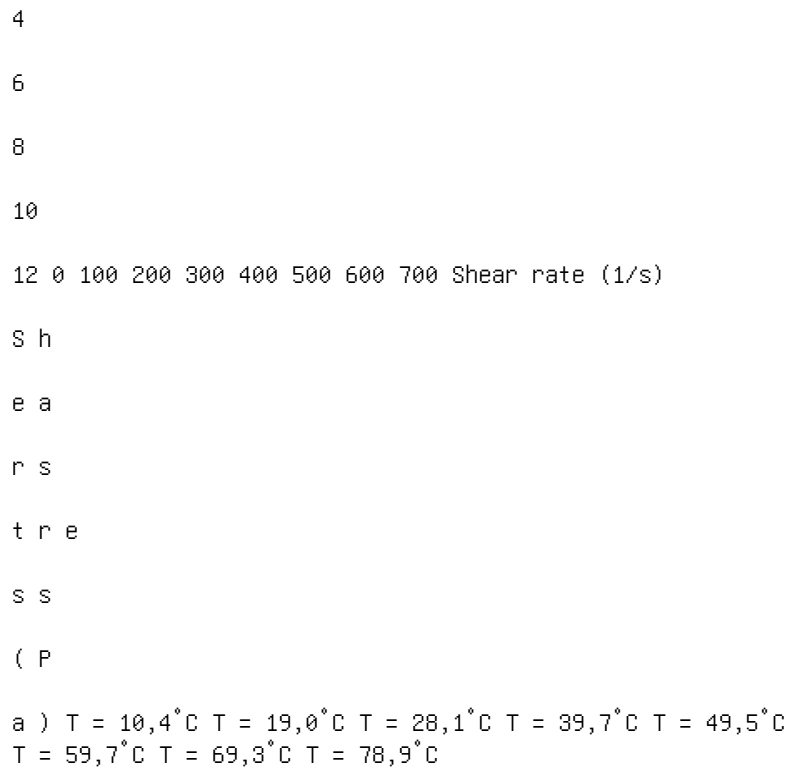

Figure 3. Flow curves in function of temperature.

Figure 4. Flow curves in function of pH.

parameters showed itself being more significant than the temperature effect over the shear stress.

2.3 Concentration variation in volume (Cv) analysis

It is noticed that hyper-concentrated fluid viscosity goes up due to solid concentration existent to the mix tures. This carry out because as much bigger takes the solid material amount, bigger will be the friction of flowing material, and consequently, it will be larger the stress to produce a certain shear rate.

This way, it also can be noticed that critical stress of fluid increases with the concentration, and, con

sequently, the minimum stress necessary to produce

a deformation is also bigger. Such fact is attested at

Figure 5.

2.4 Comparative global analysis to other rheological models

Which follows, we show some rheological behavior

to some concentrations in volume trying to compare

Newtonian, Binghamian and Herschel-Bulkley rheo

logical models to the experimental data. An example

of fitting and good adaptability of Herschel-Bulkley

is shown at Figure 6, whose data are listed in Table 1. 0 20 40 60 80 100 120 140 160 180 200 0 100 200 300 400 500 Shear rate (1/s) S h e a r s t r e s s (P a) Cv = 5% Cv = 10% Cv = 15% Cv = 20% Figure 5. Flow curves in function of Cv variation. 0 20 40 60 80 100 0 200 400 600 800 1000 Shear rate (1/s) S h e a r S t r e s s (P a) Experiments Bingham Newton Herschel - Bulkley Figure 6. Flow curve of water+ kaolin clay – Cv= 15%. Table 1. Rheological models parameters to water+ kaolin clay mixtures. Herschel-Bulkley model Cv (%) τ c (Pa) k (Pa.s n) n R 2 10 1,26 0,22 0,47 0,99 15 29,45 1,3 0,46 0,98 20 192,27 46,29 0,27 0,98 Newton model Bingham model (τ c = 0en= 1) Cv (%) τ c μ B (Pa.s) R 2 μ (Pa.s) R 2 10 1,7529 0,01 0,96 0,027 – 15 35,818 0,029 0,929 0,094 – 20 211,66 0,152 0,95 0,515 – 2.5 Global quantitative analysis of rheological parameters due to Cv variation Some scientific works point out that the parameters of rheological model proposed by Herschel-Bulkley follow, to kaoline clays, the following pattern: τ c values (critical stress) and k (apparent viscosity)

increases exponentially with the solid mixture vol

ume concentration. On the other hand, (flowing index

n) value lessens to the concentration, obeying to a

power law.

From the data of WAN (1982), HUANG &

GARCIA (1998), COUSSOT (1992) and MACIEL

et al. (2002), we took the following relation:

Those relations above all introduce good coeffi

cients of correlation (R 2 > 0.90), comprised a large

range of concentration in volume (5%< Cv< 20%),

that includes and explains well the results of other

authors.

3 DYNAMIC CHARACTERIZATION OF

FLOWING IN CHANNELS

Based on works of COUSSOT (1998) and starting

by hypothesis of uniform, steady, laminar and incom

pressible flow, flowing in an infinitely wide inclined

plan, we obtained an expression of specific discharge,

that is extremely useful at the dynamic characterization

to this kind of flowing.

with:

sin θ: declivity of channel; ρ: volumetric mass;

τ c , k, n: rheological parameters (Herschel-Bulkley);

q: specific discharge.

For calculating the friction coefficient, from a

dimensional analysis (using convenient scale), we

could determine G and H b dimensionless numbers that

show themselves essential to this study as follow:

with:

h: normal depth u= q h The friction at the channel bottom
is given according SANTOS (2003) by: Equation to be gauged

through experimental data, or in addition; Theoretical friction law – it does not depend on the channel geometry, in this stage. 4 EXPERIMENTAL RESULTS IN ORDER TO DETERMINE FRICTION LAW 4.1 Experimental apparatus description and methodology of essays The experimental apparatus (Figure 7) consists to a 10 meter length channel, with variable width (until 0.60 m), and with declivity until 30%. There is a recirculating system where the hyper-concentred flow is warranted by a 7.5 CV motorpump that transport mud to the superior reservoir of constant level. A frequency invertor does the control of discharge. The normal depths were measured with a metallic ruler and ultrasonic sensors in 3 different points of channel. The discharges vary from 1.0 to 10.0 l/s. From characteristic equation of specific discharge, Equation 1, we prepared a sample with concentration in volume Cv= 13% and we put it to flow on the experimental channel. The essay was done for three declivity of channel, around 6.3 ∘ , 12.2 ∘ and 17.4 ∘ . In Figure 7. Mud flowing in channel.

each declivity, there was five variation of discharge.

At the same time that took place the flowing essay, it

was collected a sample to a rheological test.

All the information obtained at related flow, as well

the gauged rheological parameters with Brook-field

R/S rheometer, are shown at Table 2.

With: n: flowing index; τ c : critical shear stress,

k: apparent viscosity; Cv: Volume concentration; ρ0:

Volumetric specific mass mixture; sin θ: Declivity of

channel; h: Normal depth; q (theoric):Theoretical spe

cific discharge (semi-experimental, so it depends of h

measure and rheological parameters); L: Width chan

nel; q (exp): Experimental specific discharge; error:

Relative error among experimental and theoretical

specific discharge.

We can notice that the results present, most of the cases, high errors to the discharges. These errors can be explained by great sensibility of some parameters. Even the normal depth (h), showed at Table 2 be an average took out from several measuring done along the channel, such as, any lack of precision at its mea suring, produces a considerable error, so this parameter interferes significantly to the calculus of the theoreti cal specific discharge (Equation 1). Other procedures of essay have being improved for trying to solve this uncertain.

4.2 Discussing experimental results

To the analysis of experimental data, the dimension less numbers (G- 1)×H b are illustrated in Figure 8. This way, from comparison among adjusted equa tion to theoretical points (semi-experimental) obtained through this figure and Equation 5, we can analyze the conformity between the theoretical development and experimental results.

Theoretical (semi-experimental) and experimental

friction values estimated to 0.60 m channel of width

are presented in Table 3.

5 CONCLUSIONS

The rheological characterization of mixtures and flow ing dynamic mud mixture were inferred with success and showed the following conclusions:

- The water+ clay essayed showed themselves, such prediction, non-expansible, they did not show thixotropic phenomena (not showed at this arti cle) and changing the basic rheological properties, such as critical shear stress (τ c), flowing index (n) and apparent viscosity (k) due to volume concentration (Cv);
- The experimental results fitted well to the Herschel Bulkley rheological model, noticeable at the deter mining of critical shear stress and to the large shear rates range ($\dot{\gamma}$ ~ 100 s −1 : shear rate observed at field to the mudflow phenomena);
- However, it was also verified a good adaptability to Binghamian model to high shear rates.

This way, based on experimental results obtained at FEIS/UNESP, a new database was established. From this, it was obtained evolution laws of several rheo logical parameters, according to that was presented at item 2.5 of this article.

- The obtained results for friction of wall at the exper

iments taken at the channel, showed them-selves

highlighting. However, the percentual errors over

Numerical simulation and field observation of debris roll

waves in the Illgraben torrent, Switzerland

B. Zanuttigh

University of Bologna, Dipartimento di Ingegneria delle Infrastrutture, Strade, Trasporti, Acque, Rilevamento e Territorio, Bologna, Italy

B.W. McArdell

WSL Swiss Federal Research Institute, Department of Water, Soil, and Rock Movements, Zuerich, Switzerland

ABSTRACT: In natural debris flows, even if the critical Froude number is almost always exceeded, the formation of waves, which eventually develop into surges, is not always observed. This contribution numerically represent a debris flow event occurred in the Illgraben torrent, Swiss Alps, which consisted of a single surge and of about 28 roll waves on the surge tail. Simulations are carried out with two 1-D codes based on Shallow-Water equations and a wide variety of rheological laws (Herschel Bulkley, Bingham, Dilatant Inertial, Generalised Visco-Plastic, Voellmy).

The analysis of flow depth in time, maximum flow depths and velocities along the debris channel shows that a good representation of the main debris features can be obtained with a proper calibration of rheological parameters. More difficult appears to be the representation of flow tail instabilities.

The causes of debris wave development based on literature and interpretation of the model results are examined and an original interpretation is provided.

1 INTRODUCTION

The formation of instabilities in debris or mud flows

has been investigated by several authors, among the others Chun (1982), who determined the stability curve for generalised Newtonian flows; Trowbridge (1987), who carried out the same analysis using shal low water equations; Lanzoni and Seminara (1993) experienced that a granular flow becomes unstable for Froude numbers around 1.0; Coussot (1994) showed that for a Herschel-Bulkley fluid the critical Froude number drops to 0.25 or less; Lamberti & Zanuttigh (2003) extendedTrowbridge's method to a Generalised Visco-Plastic flow.

In several cases instabilities should be evident according to theory but do not show-up in nature; moreover, the mechanism of formation of multiple surge events is still unclear and the possibility to predict such features is still uncertain.

This contribution aims to examine through numer ical simulations and field observations wave develop ment in debris flows. The numerical model is based on Shallow-Water equations, which are able to cap ture the position and to reproduce the intensity but not the shape of the debris front. An accurate analytical solution for representing the flow profile at the front as well as at the tail, of two-dimensional unsteady nonuniform Bingham and Herschel-Bulkley flows down a steep slope can be found in Huang and Garcia (1997) and (1998) respectively. This contribution is divided in four main

parts. The first part presents the numerical models adopted. The 1D numerical formulation is adopted since reflections, diffractions and refractions, which are clear in water flows, do not seem to substantially affect debris flows, as it is proven by field surveys (Berti et al., 1999; Mortara et al., 1994; Rickenmann et al., 2001) and several video registrations (Arattano & Trebbo, 2000; Lamberti, 1999; Rickenmann, 2000). The second part presents the catchment under analysis from a hydro-morpho-geological point of view and the debris flow events, a single-peak and a multiple-surge event. The third part compares numerical results to available flow depth and velocity registrations for different rheological laws and calibrations of the rheological parameters. Finally, an interpretation for the formation and development of instabilities is provided, based on the analysis of numerical simulations and on hydrographs measured during debris events (Arattano et al., 1997).

2 NUMERICAL MODELS

2.1 Numerical scheme

Both numerical models applied in this study are based on one-dimensional solutions to the conservative form of the shallow water equations, where the frictional resistance term typically used for open channel flow (e.g. a Chézy flow resistance law) has been replaced with flow laws which have been proposed to describe debris flow behavior. The primary unknowns are flow depth and specific discharge. Only the main features are summarized here because both models have been described elsewhere.

The DFEM model from WSL is a finite element solution of the shallow water equations in one dimen sion and is based on the Finite Element MethodTOOL box (FEMTOOL) libraries developed by Rutschmann

(1993). Many research problems using the 1-D, 2-D, and 2-D extended shallow water equations have been addressed using the FEMTOOL codes (Näf, 1997, Krüger, 2001) and a 2-D version of the code for debris flows is under development at WSL. The main modifications for application to debris flow routing are the inclusion of debris flow laws and a treatment of the transition from wet-to-dry cells involving simple cut off velocities and depths. When the predicted velocity or depth is below some small user-specified value (a few cm for the flow depth) the bed is assumed to be dry. To increase the numerical stability, it was necessary to introduce an upwind scheme (e.g. Katopodes, 1984).

TheWAF-DF model from the University of Bologna (Zanuttigh & Lamberti, 2002) solves the equations using the weighted average flux (WAF) method ofToro (1997). This method is 'shock-capturing' in the sense that discontinuities are automatically treated correctly without the need for a special tracking algorithm. For this reason, the code has been especially useful in interpreting the propagation of roll waves in debris flow surges using data from the Acquabona torrent in Italy (Zanuttigh & Lamberti, 2003).

2.2 Rheological laws

Single-phase flow laws can be divided into three major

categories (Iverson, 1997), turbulent flow laws (e.g. theVoellmy flow law, Bartelt et al., 1999), laminar flow laws (e.g. the Herschel-Bulkley formulation, Coussot, 1997), and grain-shearing flow laws (e.g. the dilatant inertial formulations, Takahashi, 1991).

The DFEM model has been designed to allow for systematic comparisons of the major categories of flow laws and combinations of flow laws when appropri ate (O'Brien et al., 1993). For this paper, one example from each of the three categories of resistance relations has been applied, the Voellmy Fluid (VF), Dilatant Inertial or Grain Shearing (DI), and Simplified Bing ham relations (SB). The relations are incorporated into the model in the friction term and are therefore expressed here in terms of the friction slope, S f . The Voellmy Fluid (VF) resistance relation (Hungr 1995) consists of a Chézy-type turbulent friction term and a Coulomb-type dry friction term: where q is the specific discharge, h is the flow depth, h r the hydraulic radius, C (m 1/2 s −1) is the Chézy flow resistance coefficient, α is the slope angle of the channel and δ is the angle of internal friction. The Voellmy relation was developed to describe flow-type snow avalanches (Bartelt et al. 1999) and with the Coulomb term allows the flow to stop on inclined surfaces. The Dilatant-Inertial (DI) law can be stated in a simple form: where ζ is a roughness parameter (m −1/2 s −1). The laminar flow relation is the simplified version of the Bingham flow (SB) law (Hungr 1995, Rickenmann 1990). We use the following relation to incorporate the Bingham flow law: where g is the acceleration due to gravity and ρ is the bulk density of the flowing debris, and τ 0 , the shear stress, is given by the solution to the cubic equation from the Bingham relation: In the DFEM code, the cubic term may be dropped and leading to: where τ C is the yield stress,μ B is the viscosity. For the case where the stress ratio τ C /τ 0 is smaller than 0.5, the error in the mean flow velocity is on the order of 6% (Rickenamm 1990). The

rheological behavior of the WAF-DF model is alternatively supposed to follow: 1) the Herschel-Bulkley (HB) model, which is given by: where τ c is the cohesion or yield stress parameter, K is the consistency index and γ is the shear rate;

2) the Bingham (B) model

where μ b is the consistency index;

where μ 1 is the consistency index and η is the law's

exponent. The sum of the first two terms at the second

member of (8) represents the yield stress τ y whereas

the third term is the stress τ ′ due to shear rate.

B and HB models are trivial special cases of the

GVP model: φ= 0 and η= 1.0 or 1/3 respectively. The

GVP model is characterised by two more degrees of

freedom than the HB or B models and thus by two more

parameters to be calibrated: the exponent of the rheol

ogy law η and the friction angle φ. Details on the pro

cedure for evaluating flow resistance for this general

case can be found in Zanuttigh and Lamberti, 2003.

In both models, the magnitude of the flow resis

tance term is limited to enhance numerical stability

and provide more realistic results. In the DFEM model

the magnitude of the friction term (expressed in units

of energy) is not allowed to exceed the local kinetic

energy of the flow. One implication of this limitation

is that the vibrational kinetic energy of a debris flow

cannot be converted into translational kinetic energy.

In theWAF-DF model the flow resistance for the debris flow is assumed to be not less than turbulent fluid with an appropriate value of the Chézy coefficient, which is assumed equal to 22 m 1/2 s −1 following Rickenmann (1999).

3 ILLGRABEN CATCHMENT

The Illgraben catchment (10.5 km 2 above the fan apex) contains an unusually large proportion of unvege tated, steep, unstable slopes with abundant colluvium derived from weak carbonate and greywacke bedrock. The channel downstream of the fan apex is 2.6 km long, has a mean slope of 10%, and is presently deeply incised.

No information on the geometry of recent debris flow deposits on the alluvial fan is available because all debris flows in the last few years have traveled into the Rhone River where they are immediately reworked by the river flow. In order to stabilize the torrent bed after an avalanche occurred in 1960s, a nearly 50 m high sediment retention dam was installed upstream of the fan apex and many check dams were built up downstream this structure.

Several debris flows per year occur generally fol lowing intense rainfall in the catchment (Rickenmann et al., 2001) and some presented (McArdell et al.,

2003) multiple peak hydrograph that can be interpreted Figure 1. Debris flow observation station at the Illgraben torrent with the location of the geophones (Geo) video camera (VC), radar (RD) and rain gages. as the result of instability of uniform debris flow conditions. The downstream 850 m of the channel has been instrumented with 3 geophones, a radar flow depth sensor, and a video camera, with data logging triggered automatically by the upstream-most geophone (Figure 1). Observations consist of flow velocities estimated from the travel time between the geophones and a radar sensor and flow depths from the radar. The videos provide additional velocity and depth estimates as well as qualitative observations of the flow behaviour and maximum grain size.An independentlyoperated network of three rain gages was installed in the upper catchment in 2000. 4 NUMERICAL SIMULATIONS 4.1 The event of June, 2000 The event of 28 June 2000 was selected because of the availability of several field data as independent field observations of surface velocity, cross section and mud traces collected after the event to reconstruct maximum flow depths and wetted areas. From the front travel time between the instruments, the flow depth estimated at the radar and the analysis of video images, the total volume of this event can be evaluated around 35,000 m 3 ; the maximum discharge was 125 m 3 s −1 , the front velocity arose 3.9 ms −1 and the peak flow depth was close to 3 m. The flow was observed to have a single coarse granular surge moving over an initially dry bed (Figure 2) carrying boulders more than 2 m in diameter. The tail of the debris flow was muddy and low-amplitude roll waves were observed starting about 600 seconds after the passage of the front. Numerical simulations were carried out on the topography obtained by a field survey performed in

Figure 2. Debris flow front for the 28 June 2000 event from

the video tape. The base width of the check dam is about

10 m. Mud traces from an earlier event in summer 2000 are

still visible immediately downstream of the front.

2000; the channel cross sections were approximated

for simplicity to rectangle with variable-width and

the base of the sediment retention dam was used as

starting point. As no rainfall data was collected, a sim

ple triangular hydrograph was assumed as upstream boundary condition. Based on the downstream obser vations of total volume, mean flow velocity and depth, the hydrograph is built up so that after 14 s flow dis charge reaches the maximum value of 14 m 2 s −1 and after 236 s returns to zero. Other hydrographs were tested, but in general the differences from plausible alternatives tend to be damped by the development of near-uniform flow over the more than 3000 m long reach from the base of the retention dam to the observa tion station, so a detailed parametric analysis of input conditions is not included here.

The models were run with incremental changes of the parameters until a “best fit” was achieved. For com parison with the field data, the results are presented by comparing model results with the front velocity measured between instruments in the field and the flow depth determined from the radar. The results can be difficult to interpret because there may not be a unique combination of parameters that allow one to match both the front velocity and the flow depth. The following ‘best’ calibrations were adopted in this contribution:

- for the DFEM: SB, μ b = 130 Pa·s, τ b = 100 Pa, ρ= 2200 kg/m 3 ; DI, ζ= 14 m −1/2 s −1 ; VF, C =

22 m 1/2 /s, δ= 2.5 ∘ ;

- for the WAF-DF: HB, K/τ c = 0.1 s 1/3 , τ c /ρ=

0.1 m 2 s −2 ; B, μ b /τ c = 0.6 s, τ c /ρ= 0.1 m 2 s −2 ;

GVP, η= 0.5, μ b /τ c = 1.3 s, τ c /ρ= 0.2 m 2 s −2 ,

Comparison of front position with field data. Dashed lines indicateWAF-DF results and solid lines indicate DFEM results. The comparison of front velocity between geophone 2 and the radar (Figure 3) shows a wide variety of flow behaviors for the different flow resistance laws. The curves for the WAF-DF model show a uniform velocity (similar to that observed in the videos), but the flow is too rapid in comparison with the field data for the Bingham and Herschel-Bulkley flow laws. These relatively large velocities are similar to what one would calculate with a Chézy model using C = 22 m 1/2 s −1 , suggesting that the value chosen to limit the magnitude of the friction term may be influencing the results for the flow laws using WAF-DF. However, the slope of the simplified Bingham model during periods of flow, which was run with the exact same set of parameters, is quite similar, so the apparent match with a Chézy model may be a coincidence. The curves for the DFEM model show good agreement for the dilatant and Voellmy resistance laws, but the surge-stop behavior of the simplified Bingham model is probably due to numerical instability and may have no meaningful physical interpretation. An exact match with the dilatant-inertial model was not possible because numerical instabilities. Additional pairs of simplified Bingham viscosities and yield stress values are also capable of matching the front trajectory; in the absence of flow deposits where one can estimate the yield stress, it is difficult to choose one “best fit” set of parameters. The slopes of the simplified Bingham model, when it is flowing, are similar to the Bingham law predicted with theWAF-DF model, suggesting that a different set of yield stress values (in particular a larger yield stress) may provide a better match with the data. The Voellmy fluid law is always numerically stable with this field case. A comparison of modeled flow depth with the field data (Figure 4) shows that most of the resistance laws predict too shallow depths compared with field observations. the stop-surge behavior may explain why the simplified Bingham model best reproduces the flow depth near the upstream end of the computational domain (Figure 4). However eyewitnesses did not observe the stop-start behavior and it is not apparent in the video images, suggesting that this is not a reliable numerical result. Perhaps the main difference between the field and model is the downstream diffusion of the wave resulting in lower flow depths downstream. This may be an artifact of simplifying the complex behavior of the debris flow using simple single-phase rheologies with one set of parameters to characterize the entire debris flow wave.

A comparison of the Bingham model results between the two models shows a striking difference in their predicted flow behavior in spite of the fact that the parameters used in the models are identical. Part of the discrepancy can be explained by each model's method of limiting the magnitude of the friction term; another possible explanation is that the Bingham model is inappropriate for such a granular flow. A Bingham Reynolds number, defined as $R_{eB} = 4Vh\rho/\mu_B$, where V = the flow velocity, h= the flow depth, ρ= the bulk 0 10

This suggests that laminar-type flow law (e.g. the SB, B, HB, and GVP models) does not contradict the simulated flow behavior. An analysis of a boulder motion shows roughly 2/3 of the particles showing periods of both rolling and non-rolling behavior over the 50 m section upstream of the video camera, suggesting that the qualitative description of a laminar fluid is an oversimplification for this granular debris flow. The comparison of observed and modeled hydrograph shape shows a generally poor agreement between flow depths or areas, with all numerical simulations failing to match the observed flow depths by nearly a factor of 2. The comparison with wetted flow area at the radar location yields a better match with the tail of the debris flow (Figure 5). All the ‘best’ calibrations obtained with the WAFDF model predict an onset of roll wave activity at flow tail that is characterized by different wave periods and heights depending on the rheological law and calibration, as it clearly appears by Figure 6. Table 1 compares the summary of numerical and measured wave statistics, showing that the calibration with GVP is the only one that reproduce the period of the onset of roll wave activity observed in nature, whereas none of the calibrations adopted is able to accurately represent roll-waves amplitudes. 4.2 Discussion One major problem with the Illgraben data set is a lack of good data on the cessation of motion of the flow – most debris flows that remain in the channel, like this event, continue moving until they reach the Rhone River downstream where they are destroyed. 0 50 100 150 200 0

Without information on the stopping angle or location

of the debris flows, in many cases it may be impos

sible to find a unique pair of parameters to match

the field results. In the case of the Voellmy model,

the practical upper limit on the value of the Coulomb

dry friction can be determined by the angle of the

channel bed, and the best fit envelope of parameters

varies linearly between C = 14 m 1/2 s −1 , δ= 0.6 ◦ and

C = 22 m 1/2 s −1 , δ= 2.5 ∘ .

In general the parameters from the model are realistic in that they are similar for values observed in the Acquabona torrent (Zanuttigh & Lamberti, 2003). The Voellmy parameters are also similar to those calculated for a smaller granular debris flow in the Schipfenbach torrent, Switzerland (Hürlimann et al., 2003), using a snow avalanche simulation program was used (with the density adjusted to represent debris instead of snow). The range of Chézy C values is in agreement with empirical values plotted as a function of peak discharge (Rickenmann, 1999).

Regarding the inaccurate representation of roll waves at flow tail for this event and in general the possibility of validated numerical models to accurately reproduce surges and secondary waves in natural events, an important role seems to be played by the upstream input hydrograph. In the case of Acquabona, for which the upstream hydrograph was reconstructed based on available rainfall measurements, it was possible to achieve, by calibrating the rheological parameters, a good match to field data both of wave periods and wave heights (Zanuttigh & Lamberti, 2003).

5 AN INTERPRETATION FOR WAVE DEVELOPMENT IN NATURAL EVENTS

In some cases, debris waves do not develop in nature even if the critical Fr is exceeded, as for the event of June 2000 in the Illgraben. Among basins in which development of surges in debris events is well documented from measurements and observations, we can consider the Illgraben events already shown and the case of the Moscardo

torrent, Northern Italy. The Rio Moscardo generates at least one event per year and has been since ten years object of a continuous and accurate monitoring (Arattano et al., 1997). Hydrographs measured along the channel during some events are reported at the left hand-side in Figure 7. Effects of the channel length cannot be appreciated, because the two hydrographs are measured in correspondence of two stations located at a distance of 300 m. In all cases, a first surge is present and secondary waves develop during recession and become more evident with increasing effective duration of the event (top-down in Figure 7), independently on peak discharge. The first surge, mainly composed by boulders and coarser fractions, has an almost symmetrical shape and do last for a relevant time; depending on the event duration, instabilities can show-up as small waves in the descending reach of this first surge or as independent muddy secondary waves with asymmetrical shape, similar to water roll waves in the overtaking phase. On the basis of these field observations and on numerical analysis (Zanuttigh and Lamberti, 2003) performed along Acquabona channel (Northern Italy), the interpretation sketched at the right hand-side in Figure 7 has been developed. Debris flows tend almost always to develop in theoretically unstable conditions, but debris waves are not always observed. In facts, the front of the event moves with the velocity of masses by which is composed (dx/dt= u c), whereas the unstable perturbations are associated to celerities dx/dt= u+ c, which are higher than front velocity u c near the peak of the event.The space allowed for waves to develop is therefore larger the later they origin after peak crossing.When instabilities are not evident, space (length of the channel) and time (duration of the event) are insufficient to allow their development. 6 CONCLUSIONS Debris waves do frequently develop in nature, whenever a critical Froude number Fr cr is exceeded, causing

Figure 7. At the left hand side, measured hydrographs at two

channel sections (300 m distant) of some events occurred in

the Moscardo torrent (original plots in Arattano et al., 1997),

on which the real duration of the event is highlighted: with

increasing duration, instabilities do develop.At the right hand

side, the sketch in the x-t plane graphically represents the

interpretation by the authors for debris wave formation and development in space and time.

a significant increase in peak flow depth and par ticularly in peak thrust. Debris events are generally composed by a first surge and secondary waves that develop during recession and become more evident with increasing effective duration of the event, inde pendently on peak discharge. When instabilities in nature are not evident, space (length of the channel) and time (duration of the event) may be insufficient to allow their development.

Several flow laws incorporated into two 1D dif ferent numerical models, DFEM and WAF-DF, have been compared to field data obtained from a well documented debris flow event in the Swiss Alps.

The two models, both based on shallow-water

Some features of distribution of turbulence parameters of a

jet flow in the river mouth

R. Khanbilvardi, B. Shteinman & V. Khazin

International Center for Water Resources and Environmental Research and Department of Civil Engineering,

City College of CUNY, USA

O. Ozkurt

The Graduate Center and University Center of CUNY, USA

ABSTRACT: The objective of the study was measurement of the turbulence parameters of a jet flow and estab

lishment of some common patterns of their distribution along the current and in the cross section of the flow. In the

river mouth, the jet current is an inertial flow smoothly spreading out in the liquid medium, without a direct contact

with the bottom or the banks.The most characteristic feature of such flows is gradual attenuation of the runoff cur

rent, accompanied by the corresponding decrease in its kinetic energy. Another remarkable feature is intense tur

bulent mixing of the two water masses – that of the river and that of the receiving water body. The very retardation

of the river jet on its boundaries, along with the diminishing flow gradient, are the main causes of its attenuation.

1 BACKGROUND

River mouth areas are specific natural objects that

enclose zones of transition of the river hydrological

regime to the hydrological regime of the receiv

ing reservoir (seas and lakes). The most important

character of this process is a significant change of

hydrodynamic, hydrophysical, chemical and biolog

ical parameters of the water masses within a compar

atively short distance. An external evidence of these

river-mouth processes is the formation of rather stable

forms of relief, such as the above-water and underwa

ter deltas, the mouth bar and spits. In the river mouth,

the jet current is an inertial flow smoothly spreading

out in the liquid medium, without a direct contact with

the bottom or the banks. The most characteristic fea

ture of such flows is gradual attenuation of the runoff

current, accompanied by the corresponding decrease

in its kinetic energy. Another remarkable feature is

intense turbulent mixing of the two water masses –

that of the river and that of the receiving water body.

The very retardation of the river jet on its boundaries,

along with the diminishing flow gradient, are the main

causes of its attenuation (Mikhailov 1971, Mikhailov

1996, Mikhailov et al. 1986, Shteinman & Kamenir

1998, Shteinman et al. 2000).

A number of empirical, semi-empirical and the

oretical methods and models were worked out as

an essential part of the assessment of river mouth resources. The publications mentioned deal mainly with the study of mean velocities attenuation along the jet flow in river mouth areas (Mikhailov 1996, Shteinman & Kamenir 1998, Shteinman et al. 2000). Much less studied is the distribution of turbulence characteristics in the jet flows within river mouth areas. The existing theoretical methods to describe free turbulence observed in jet currents within the river mouths are based on the hypothesis of self-modeling of the respective currents, and on using semi-empirical theories of turbulence. The self-modeling theories are based on some general properties of liquid currents and can also be justified by means of similarity and dimensionality methods. Semi-empirical theories of free turbulence utilize, besides general laws of hydrodynamics, some additional, more specific hypotheses (Monin & Yaglom 1965, 1967, Hintze 1963). There have been attempts at mathematical simulation when studying turbulence of jet currents (Miligeyev & Sokolov 1986, Svanidze et al. 1984). In these models, in order to choose boundary conditions that would combine turbulence irregularity and statistical orderliness of the averaged motion, boundary conditions from the experiment are introduced (usually the velocities obtained by using quick-response devices). Although in some cases the theoretical models provide a satisfactory description of the turbulence structure of a river jet flowing into the receiving water body,

they do not take into account a number of important

effects occurring on the boundaries of water masses of

different density. These effects are caused by thinning

out of the flow of fresh river water onto the surface

of the receiving water body (sea or lake). In such double-circulation conditions, the flows' turbulence structure has a number of essential features that are not described by theoretical and mathematical models.

Here, taking as a sample the measurements per formed in the mouth of the Kura River flowing into the Caspian Sea, some features are established of the turbulence structure of a river jet flowing into a sea.

2 SITE DESCRIPTION

The Kura River mouth area is located on the Western coast of the Caspian Sea (Fig. 1), in the Repub lic of Azerbaijan. The Kura River, by its length (1,515 km), watershed area (188,000 km 2) and average annual discharge (about 16 km 3) is the largest river in Transcaucasia.

The total area of the Kura's delta amounts now to some 75 sq. km. The river bifurcates, within its delta, into two branches – northern and southern, and the bulk of river runoff (up to 80%) is entering the sea through the southern one.

The average annual discharge of suspended sedi ments in the mouth of the southern branch is 280 kg per sec. The predominant grain size in the suspended sediments is <0.05 mm, and it is the biggest in the period of high water (April–June), when up to 75% of

the annual runoff enters the sea.

The river sediments coming to the mouth coastal

waters have formed a crescent-shaped sand bar and

mouth spits. The bar crest is at an average distance of

about 1 km from the mouth, experiencing insignificant

seasonal oscillations corresponding to the sediment

balance at different stages of the hydrological regime.

At the stage of rising high waters, the bar moves

seaward, the water depth at its crest falling down to

0.7–0.5 m. At the low water stage, the bar is being

gradually eroded from its seaward slope.

Figure 1. Schematic map of the Kura River Mouth area. Current velocities at the mouth reach 1.5–2.5 m/s in the high-water periods, while in low-water periods they are 0.5 m/s on the average. 3 FIELD MEASUREMENTS Because of the complexity of the process of mixture of the river and sea waters, and accordingly – the restructuring of the river turbulence, the goal of field measurements in the first stage was rather simple: to reveal main physical properties of turbulence – its space-time and spectral characteristics. The measuring tool used in this stage was a micropropeller that records the longitudinal component of flow velocity. This measuring tool is described in Nikora et al. (1994) and Nikora & Shteinman (1996). The first stage of studies resulted in an information base on statistical characteristics of pulsation of the longitudinal component of velocity at different distances from the mouth section, which allowed making a very general conclusion on the process of restructuring of turbulence of the river flow as it was moving into the sea. In the following stages of experiments, the tasks became more sophisticated. Now the goal was to obtain information on the flow’s velocity structure for 3-D plotting. The measurement system used to record the three velocity components included the threedimensional velocity fluctuation meter consisting of 3 circular piezoelectric slabs (radius 1 m) mounted on a 5 cm× 5 cm× 5 cm cubic frame interfaced with a computer to give real-time readout. Using this system allows obtaining valuable data on the

structure of turbulence (Shteinman et al. 1993, Khanbilvardi et al. 2003a, Ozkurt et al. 2003), and substantially expanding the goals of experiments. It is worth emphasizing that all measurements were done in calm waters, with almost no waves or alongshore movement of sediments, which made it possible to research various models of free spreading of the river jet on the river mouth area in its pure form. Measurements were conducted under steady hydraulic conditions and embraced the entire cross section of the flow. The duration of measurements in each point was 15 min., so background hydrological and hydraulic conditions were practically unchanged during each experiment. Measurements were performed at the river mouth cross section and at distances of 25, 50, 75, 100, 150, 200, 300, 400, and 500 m from it along the jet's dynamic axis, at its boundaries, as well as in the area of its free spreading beyond the bar. 4 DATA PROCESSING Quantization of the continuous records of velocity pulsations was done with the step of 1 s, and in some

cases the quantization step was 0.25 s and 0.1 s. In

accordance with this, the upper frequency of analy

sis, determined by the quantization step, was accepted

as 31.4 rad/s.

The main mechanisms used to describe the results

were the theory of random processes, the method of

structural averaging when studying coherent struc

tures, and the theory of random functions and

fields when studying hydrodynamic fields (Grin

vald & Nikora 1988, Grinvald 1974, Nikora 1991,

Sukhodolov et al. 1998).

When considering jointly the three velocity compo

nents, that is the vector fields of velocity, the vector

algebraic method of analysis was used (Rozhkov

1979), which provides important information under

conditions of commensurability of the three veloc
ity components. The main element of this analysis is
analyzing the correlation tensor of the vector process
which is a dyadic tensor function of the arguments
(t, τ). This function characterizes the interrelation of
the directional changes of the flow velocity vectors at
the moments of time t, t+ τ , and provides numerical
assessment of the intensity of these changes and of
their orientation in the given system of coordinates.
The invariant D of the skew-symmetric part of the
tensor K v , called by Rozhkov (1979) the indicator of
spinning (rotational movement of turbulent eddies),
can be determined by the relation
It is composed of the orthogonal components of
the vectors v(t) and v(t+ τ). If D> 0, then the vector
v(t+ τ) is predominantly oriented to the right of the
vector v(t), and if D> 0, then to the left. This means
that in the first case the vector's rotation is clockwise,
while in the second case it is counterclockwise.
In the equation (2), the basis unit vectors of the ten
sor K v depend on the arguments (t, τ) and are oriented,
with respect to the reference system of coordinates, in
the direction
In our experiments, the spatial structure of the cor
relation characteristics is conducted successively for

the vertical (u, v), horizontal (u, w), and transversal (v, w) planes in the left system of coordinates (the X-axis goes with the current, theY-axis is oriented perpendicular to the gravity vector in the direction of the right edge of the current, and the positive Z-semiaxis goes upward, perpendicular to the bottom plane). The invariants D i,j characterize the intensity of spinning of the velocity vector in various planes. For a more complete analysis, the so-called linear invariant J was considered, which can be determined by the equation composed of the collinear vector components ⃗v(t) and ⃗v(t+ τ). If J > 0, the collinear vector components are unidirectional, if J < 0, they have opposite directions, and if J = 0, the vectors are orthogonal. A joint analysis of the invariants J and D allows researching, regardless of the chosen system of coordinates, the structure of collinear and orthogonal alterations of the flow velocity vectors, and finally the intensity of spinning of the turbulent eddies in various planes, as well as the spatial orientation of the axes of such spinning. 5 RESULTS 5.1 Pulsations of the velocity module and the intensity of turbulence As a result of multiple theoretical and experimental studies, it has been established that the intensity of turbulence on rectilinear portions of the river channels with a smooth, poorly erodible bottom is evenly increasing from the water surface to the bottom of the flow, where main generation of the turbulence energy takes place. At the area of inflow of a jet river flow into a receiving water body, the main factor determining the changes in turbulence intensity is the intensity of dissipation of the longitudinal current velocity (Fig. 2). Turbulence intensity grows the fastest at the river mouth section, where the flow is abruptly getting wider. The farther from the mouth, relative dissipation of velocity being equal, turbulence intensity is growing slower. It should be emphasized that we are talking only about the longitudinal component of velocity.The type of relationship shown in Figure 2 is caused by the fact that, the farther from the mouth and the wider the flow, the greater part of the pulsations energy falls on the transversal (between the mouth and the bar) and vertical (beyond the bar crest) components of velocity. Pulsations of the longitudinal component of velocity in the jet flow first grow with the distance from the mouth. At a distance equal to the width of the river channel, the intensity of longitudinal turbulence on the jet axis is

about the same as in the channel, and then grows in the areas of increased longitudinal gradients of velocity. Levels of turbulence in the diffusion current are significantly higher than in the steady one because of a higher velocity gradient, and, accordingly, higher ** * * * ** * * * ** * * * * * * * * * * K u 0.30 0.26 0.06 0.10 0.14 0.18 0.22 0.02 ΔU/U 0.1 0.2 0.3 0.4 0.5 1 2 3 4 * 1 2 3 4 0

Figure 2. Relationship between turbulence and intensity of

attenuation of the longitudinal velocity along the axis of the

jet. Flow at various distances from the mouth (1 – 200 m, 2 –

500 m, 3 – 800 m, 4 – 1,400 m)

generation of turbulence. Within the area, 2–3 widths

of the river long, in the river mouth, where abrupt flow

deceleration occurs, the level of pulsations is observed

to grow considerably.

The greater the river water discharge and, accord

ingly, the flow velocities, the farther from the river

mouth gauge occurs the zone of highest turbulent

pulsations.

Multiple studies have established the intensity of

turbulence in the river flow is getting higher from the

water surface to the bottom. However, in the condi

tions of free spreading of the jet flow, starting from the

bar crest where the jet detaches itself from the bottom

(so-called detached flow), the highest intensity of tur

bulence is observed within the contact zone between

the upper layer of fresh river water and the underlying

layer of denser sea water mass (Fig. 3). As the veloc

ity of the river jet increases, the layer of maximum

turbulence is shifting deeper.

The influence of the bottom topography on the

velocity pulsations and on the distribution of turbu

lence intensity is felt in the jet flow in the same manner

as in the river channel. As proven by observations

(Ozkurt et al. 2003, Khanbilvardi et al. 2003b), in the

area between the river mouth gauge and the bar crest,

the linear dimensions of the bottom ridges are rapidly

diminishing along the flow.

This leads, first, to the faster decrease in the

standard deviation of the longitudinal pulsations of

velocity, and second, to a more uniform distribution

of turbulence intensity over the depth of the flow.

The mouth bar has also the shape of a large ridge

composed of river sediments. According to labora

tory studies (Petrosyan 1984), maximum values of the a b 5 4 3 2 1 0 5 4 3 2 1 0 h,m h,m 5 10 15 20 25 0 2 4 6 8 10 c 0 5 10 15 2 0 1 2 3 ε, % ε, % Figure 3. Variability of the intensity of turbulence with the jet flow depth at various distances from the mouth (a – mouth gauge, b – bar crest (500 m from the mouth), c – deeping beyond the bar (800 m from the mouth – zone of detachment of the river jet from the bottom). Curves 1, 2 and 3 correspond to the flow velocities in the mouth equal to 1.58, 2.10, and 2.46 m/s respectively). standard deviation of pulsations on the vertical lines beyond the bar crest occur at the crest level, and here we see similarity with the channel flow having a ridged bottom. At the same time, the conclusion that the character of changes in turbulence intensity beyond the bar is similar to that of the area below the bar of a moving sand wave, cannot be extrapolated to the field

conditions. In laboratory conditions, an unstratified flow is observed beyond the bar, while in natural river mouths fresh waters are pinching out to the flow surface as the river jet is moving into the sea. This is why the distribution of velocity pulsations and turbulence intensity on the vertical lines beyond the bar crest has specific features as shown in Figure 3 and the river mouth bar, from the point of view of its influence on turbulence, can be considered not as a bottom ridge characteristic of a river, but as a practically immobile large bottom ridge generating a detached current. Examples of the distribution of turbulence intensity over the cross section of a jet flow at various distances from the river mouth are given in Figure 4. 5.2 Velocity vector pulsations Pulsations of the transversal (w ′) and vertical (v ′) velocity differ from the pulsations of the longitudinal component (u ′). Within the river area, the ratio u ′2 /v ′2 generally displays regular growth from the bottom to the flow surface; the ratio u ′2 /w ′2 is also growing, being greater than u ′2 /v ′2 .

Figure 4. Distribution of Turbulence Intensity over the

Cross Section of the Jet Flow at Various Distances from the

River Mouth: (1 – mouth gage, 2 – 200 m, 3 – 500 m, 4 –

800 m, 5 – 1,100 m)

In the river mouth jet flow, spatial distribution of

the velocity components has some specific features.

In the jet flow, at the distance from the mouth equal

to the width of the river, u ′2 starts its regular growth

with the distance from the bottom. This is related

to the fact that friction at the side boundaries of the

jet is 6–9 times higher than friction at the bottom

(Mikhailov et al. 1986). For this reason, when the river

flow exits the mouth gauge, its surface layer acquires intense additional turbulization as compared to the near-bottom layers experiencing basic friction on the bottom because here the transversal velocity gradient is the smallest. For the same reason, is also growing in the surface layer.

Beyond the bar, where the river jet, possessing insignificant energy, is detaching from the bottom and spreading freely, all three components of velocity have the highest values of pulsation in the surface layer. However, if the jet has significant energy, the u ′2 , v ′2 and w ′2 are decreasing from the bottom to the surface, which is due to high vertical gradients of velocity in the near-bottom zone.

Eddy zones on the jet boundaries are the sources of the elevated turbulence, with the velocity of trans lational motion 5–10 times lower than the velocity in the main body of the jet. Here we observe the high est values of turbulent pulsation and commensurable components u ′ , v ′ and w'. The intensity of transversal pulsations can be here as high as 60%, while the inten sity of longitudinal pulsations is only 25–35%. The transversal pulsations of velocity at a distance equal to 5–6 river widths are 10–20 times higher than those in the jet axis. -8 0 8 16 24 I (τ). 10 2 , cm 2 s 2 D (τ). 10 2 , cm 2 s 2 0 8 16 -8 -16 -20 40 α°(τ) α° uw

(τ) D uv (τ) D uw (τ) D vw (τ) α° uv (τ) 30 20 10 0 0 2 4 6 8 10 12 14 16 18 Figure 5. Example of the autocorrelation tensor function invariants. The above regularities of distribution of the velocity pulsations are the reflection and result of the eddy structure of the flow and of the turbulent eddies spinning in it. Figure 5 presents examples of calculation of the correlation tensor function invariants I and D superposed on various sections of the jet flow. For functions D uv (τ), D uw (τ) and D vw (τ), corresponding to the channel section, both positive and negative values are present, and lesser than I (τ) amplitudes of oscillation, the highest ones pertaining to D uv (spinning in a vertical plane), and the smallest to D vw . On the bar, the component D uw dominates other components, testifying to the restructuring of the flow from spinning predominantly in the verticallongitudinal plane (u, v) to spinning predominantly in the horizontal-transversal plane (u, w). Beyond the bar, the component D uv is close to zero (spinning in the (u, v) plane is negligible compared to spinning in other planes), powerful spinning occurring in the horizontal plane (u, w).

Analysis of indicators of spinning in different planes

has shown that in experiments within the river channel

it was in the form of right screw (clockwise), while

within the jet part of the flow, as it approaches the

bar, toppling and surfacing of eddies occur, with spin

ning beyond the bar predominantly counterclockwise

(in the horizontal plane). Judging by the values of the

angleα 0 (τ) given in Figure 5, the direction of the major

axis of the tensor curve (direction of the predominant

variability of the velocity vector) does not stay con

stant but is cyclically changing with respect to τ : in

the river flow mainly in the plane (u, v), in the jet sec

tion up to the bar in the plane (u, w), beyond the bar

again in the plane (u, v) because here intense mixing

of river and sea water masses occurs.

Comparison of the values of the correlation func

tion I (τ) of the collinear components of the pulsation

velocity vector with the function D(τ) of the orthogo

nal components shows that I (τ)>D(τ) before the bar,

and I (τ)<D(τ) on the bar. This means that while at

the beginning of the jet the interrelation of the collinear

components is predominant, around the bar the inter

relation of the orthogonal components is stronger,

that is the influence of the changing flow direction

is greater than the influence of the changing velocity

module.

6 CONCLUSIONS

Analysis of the distribution of the standard deviations

of the components of the river jet velocity vector at

its inflow into the sea has shown that the structure of

channel turbulence is rapidly degenerating. Turbulent

eddies change their orientation from the predomi

nantly vertical-longitudinal spinning with a horizontal

axis to the predominantly horizontal-transversal spin

ning with a vertical axis. At the same time, substantial

additional turbulent energy is being generated in the

zones of contact between the jet flow and the adjacent

mass of seawater.

ABSTRACT: In the National Operative Programme (P.O.N.), called AQUATEC “Control, treatment and main

tenance innovating technology for water emergency solving”, the objective entitled “System for prevention of

pollution due to waste waters into rivers” proposes to implement a system for the control and valuation of the

effects into the rivers produced by waste waters derived from industrial, human or agricultural activities.

The innovative idea of the project consists in the use, in conjunction with traditional technology of qualitative

and quantitative river monitoring and simulation of the pollutants dispersion, of an expert system realized

through archives containing both available measurements and simulations of reference scenarios or “classes” of

situations. So the system is able to “extrapolate/interpolate” in an intelligent way data in archives to formulate

a forecast cause/effect connection of continuous or accidental waste waters.

1 INTRODUCTION

In the last years water ecosystems biotic integrity con

cept has had a growing importance till to be considered

official by Italian regulation 152/99.

This regulation defines general rules for water pro

tection. Its objectives are “to prevent and to reduce

water pollution, to recover and to improve water state,

to defend special water uses, to assure sustainable uses

of the resource and to preserve natural capability of

river self-purification, necessary to support wide and

well diversified animal and vegetable communities".

"Quality objectives" and "protection plans" are the

prescribed tools for these aims.

The use of the presented methodology supposes

a continuous monitoring, with all benefits short and

long term, for territorial planning, for river quality

state evolution control, waste waters delivered into

river management, for prevision of impacts, as well

as for the possibility of quick decision and prompt

intervention in situations of emergency.

To reduce the physical complexity of the continu

ous survey and data transmission net, we use a virtual

sensor system implemented with a fuzzy logic. The present article describes design and implementation phases in a sample basin of decision support system which consents to interpret qualitative and quantitative data from the river monitoring net. In this way it is possible to analyze causes of the present situation and to interprete short and long term effects into river caused by input of waste waters from industrial, human or agricultural activities. This objective, focusing attention on the river, is in perfect line with the above-mentioned regulation 152/99, in which the imposition logic respect of the single waste waters or area to protect respect of the quality is exceeded. The problem is dealed within a general hydrogeologic context, according to which environmental quality of river is to be reached in a global way, searching balance between natural water flow and the external contribution due to human presence, avoiding causing qualitative and quantitative irreparable damages. The balance is reached when natural capability of river self-purification remains and so the possibility of supporting wide and well diversified animal and vegetable communities, without pollution processes. The system we want to realize needs continuous monitoring with data acquisition in a

S.I.T. from which we get information to execute simu

lations on different temporal scales. The possibility to get on-line data relative to river state besides assuring real time signalling about critical or warning situations arising, to operate (do) a quick intervention, consents to define initial conditions of the physical environ ment from which to leave, to get prevision of future scenarios.

2 STATUS OF THE RESEARCH

2.1 Sensors

In the last years research in sensors field has had a notable development providing [11] a great number of components suitable for chemical-physical interest ing parameters on-line survey. They are founded on potentiometric techniques, for example to measure the oxygen, ph, etc. or colorimetric ones, for example for determination of nitrogen and phosphorus com pounds. Parameters considered for the rivers are typ ically: temperature, dissolved oxygen, conductivity, redox potential, ph, turbidity, suspended and gravity driver-position solids, ammonia. Automatic sampler which consent to evaluate the pollution stress are available. Moreover they are studying both analyti cal data validation technics and real-time adjournment methods, with communication systems using wire less techniques (GSM), of the data bank of territorial

information systems.

To reduce the physical complexity of the continuous survey and in way to make it more similar data trans mission net and to evaluate parameters which don't lend oneself to on-line valutation (BOD), we use a vir tual sensor system implemented with a fuzzy logic.

The fuzzy logic objective is to generalize classic logic to human thinking way. Some intermediate values which can characterize in a more precise way the real situations are added to the two typical values "true" and "false". The logic inference rules used in this case are calibrated on the particular application field. However they operate simulating the typical "good sense" of the field expert. Moreover virtual sensors [2] consent to estimate the trend of simple and complex parameters on the base of only simple parameter measure acqui sitions (flow rate, level, dissolved oxygen, ph, etc.).

The system is based on analysis of measures historical knowledge and consents to estimate temporal trend of not directly monitored parameters on the base of others monitored ones. Parameters which we want to estimate temporal evolution must be correlated (fuzzy function) to automatically controlled ones. But it is not required correlation between monitored parame ters and estimated ones as, on the contrary, it is required

for physically founded models. The use of fuzzy logic

for the definition of virtual sensors has as objective to

explicit the dependence rules among parameters. This individuation process of inferences between input and estimated ones becomes an explicit knowledge patrimony, and consents to value and control by an expert operator (typical characteristic of an expert system). 2.2 Quality models Fluently river quality study is made by formulation of a mathematical model of the real system to employ with a computer. Model must have the ability to describe in quantitative terms space-time real system evolution, and to give system reply to external solicitations considering internal dynamics. Usually in a software implementing a river quality model the whole of elaborations is organized by functional strictly related modules, which we can usually schematise as follows: - hydraulic model, which describes water flow field and concentration's distribution of dissolved substances; - chemical model, which describes inorganic substances kinetics degradation in the river; - biochemical model, which describes organic substances kinetics degradation; - ecological model, which reproduces photosynthesis mechanics and dynamic of the river ecosystem food chain; - thermal model, which describes temperature field into river. As regard to research, hydraulic models have reached a good maturity and three-dimensional software are available giving reliable results. As regard water quality models, since very complex phenomena are described, the research is always in evolution for realizing more complete and reliable models. Now many river quality models are available [10] where we notice the difficulty to realize optimum integration between hydraulic and quality models. Some well-known river quality models are: QUAL2E (EPA, 1995), MIKE11 (Danish Hydraulic Institute), WEST (Wastewater Treatment Plant Engine for Simulation and Training, made in Belgium). River quality models are used to produce single elaborations concerning specific environmental conditions; at present it seems that in Italy, except for specific situations, appliances integrating river quality models with on-line obtained data from a territorial scale monitoring net are not available for describing temporal evolutions of phenomena and then to go up to incidental event causes, or to support choice of reclamation actions. 2.3 Expert systems The project wants to realize a decision support system which gives output of simulation with monitoring net data to consent a result interpretation and a prediction of consequent effects. This system cannot use traditional mathematical models whose

elaboration

time are incompatible with a real-time system, but has

to use Artificial Intelligence techniques.

Some expert systems applications are known within

the limits of very specific sectors of water treatment,

in particular:

- research to establish biological efficiency in active

sludge depuration plants [5];

- exploitation well safe yeld control, iron and man

ganese control in potable water, hydraulic net

efficiency control [6];

- nitrogen removal from sludge control [7];

- on-line monitoring of waste waters from purifica

tion plant [8];

- optimization of chrome fragmentation in industrial

water [9].

Research on Artificial Intelligence gave enquiry

tools which are over traditional monitoring limits, con

senting to use, with monitoring data, also qualitative,

dubious or incomplete information as they are used by

an expert of the field. Systems operating in this way

are called expert systems. They are founded on the use

of “Knowledge Base” considered as a whole of highly

structured information and association of concepts and

rules.

The central element of an expert system is infer
ential motor which can be synthetized as a whole of
rules and strategies of knowledge elaboration to reach
a deduction for the problem solution. But data aren't
precise, so the operative logic can't be Boolean, but it
must consider dubiousnesses and the many shadings
of original data; the logic which uses these standards
is "Fuzzy Logic".

3 PROJECT PRESENTATION

3.1 System structure

The system is essentially composed by two modules
based on a common techniques, and precisely [4]:
System for simulation and prevision of short, mid
dle and long term effects due to incidental waste or
continuous ones into rivers or sensitive backwater
areas. This system wants to estimate, for incidental
sources or continuous waste, river areas interested by
waste water, to give in short, middle and long terms
a prevision of effects in terms of quality and the pos
sible water recycle. It can also give indication about
possible recovery intervention which we can suppose,
for example an use of solvents, drawn work closing.
Reconstruction and locating of the original scenar
ios in connection with water quality control systems.
This system wants to elaborate, on the base of monitor

ing indications, (for example on the confluence in the

main river) possible scenarios on the origin of mea

sured values, giving indications on the possible risk

areas or letting in zones not in norm. Input data Input data Field data GIS PREVISION AND CONTROL SYSTEM Environmental data Control net Forecasts conditions. Original scenarios research. Numerical simulators Scenarios archive Dynamic flow of waste waters Water quality indicator Training Self-training Measures Results mapping Signals Figure 1. Block scheme of information flux among modules. Both indicated systems depend on river and territorial characteristics, so we forecast their integration in a GIS from which they will take territorial information, and to which they will give elaboration results for a their mapping in connection with territorial data (waste position, drawn works, effects on bypasses, etc.). Moreover we analyse the possibility to connect the systems with environmental tools (meteo gages flow and/or level meter, current meters, water quality sensors, etc.). All the systems will be “trained” by a series of numerically simulated scenarios able to cover all the possible hydrodynamic situations which depend on environmental and seasonal parameters, and will increase its knowledge in connection with monitoring date. 3.2 Choice of the experimental site Sarno river basin, considered since many years as a social-economic and environmental emergency area, has been chosen as investigation site for this project. This choice is justified by many factors. First of all at present studies and data are available on Sarno basin and we can use them to study pollution evolution, to have knowledge of the present quality status, as well as to the efficacy of renewal interventions [3]. ARPA Campania, an Institutional Organization employed to environmental controls began two years

Figure 2. Quality state of Sarno River.

ago sampler and analysis activities for studying quality

of rivers in Campania.

Sarno analytical data relative to years 2001 and

2002 have consented operating river first classification

according to regulation 152/99. Even if environmental

state wasn’t defined but pollution level expressed by macro-descripting, it was defined only (LIM). Addi tional parameters research as organic and inorganic pollutants so far has been limited to metals, measured in all the seven monitoring stations, and to pesticide only in same stations. Since wasn’t possible to mea sure IBE index, the ecological state value (SECA) is strongly conditioned by pollution level expressed by LIM.

From monitoring data analysis and from their elab oration, it is rather clear how strong the Sarno basin decay is, independently from IBE index values and step levels of most important chemical pollutants.

The application of mathematical models to study river system behaviour is used whether for the simulation of flow conditions or evaluation of pollutants con centration in the river for convection, dispersive and diffusive transport phenomena. The project forecasts the implementation of mathematical water quality model formed by hydrodynamic, chemical and bio chemical modules, open to subsequent integration of ecological and thermal modules. Moreover we forecast to detect, for the realization of a prototype, a part of the river with significant length which is delimited, above and below, by continuous qualitative monitoring sta

tion of chemical and physical parameters. The selected

zone has a considerable waste inside as pollution load

contribution, e.g. the waste of one of the purification

of plants of middle Sarno districts. The part which

has such characteristics is included between mouth

and confluence of Alveo Comune Nocerino, measur

ing 10 km, where effluent of district n ∘ 3 purification

plant discharges.

3.3 Choice of the continuous monitoring parameters and qualitative modeling hypothesis

By considerations made on results of statistics elab

orations realized by ARPA Campania, the pollution

which causes high BOD and COD values has an industrial origin prevalently. It is caused by heavy metals as nickel, chrome, plumb and mercury, rather then biochemical origin caused by alimentary industries discharge. The method used for Factor Analysis is the Principal Components one (A.C.P.) followed by varimax rotation; Table 1 reports the factor loadings for each parameter, eigen values and the variance percent explained for the first five factors. First of all the analysis has showed that a large part of informations is contained in the first five factors (56.7% of represented variance). Moreover in the table we can notice that: - 1st factor (16.3% of explained variance) is strongly related to dissolved oxygen, BOD and COD. It essentially expresses the river organic component. It is thought that the organic load represented by this factor comes from industries owing to unimportant correlation with the classical parameters which indicate civil pollution (ammoniacal nitrogen, total phosphorus, Escherichia coli, etc.). - 2nd factor (15.8% of explained variance) is related to total chrome, mercury, nickel and lead. We can say that this factor represents industrial pollution parameters. - 3rd factor (10.3% of explained variance) is characterized by total and ammoniacal nitrogen. We can say that this factor represents nitrogen pollution and it represents reduction state of the system. - 4th factor (7.5% of explained variance) is related to nitrates and

total phosphorus. We can suppose that these correlations are due to photosynthesis and nitrification processes and they are representative of system eutrophication. - 5th factor (6.8% of explained variance), difficult to interpret, it seems not containing any directly interpretable information. Besides we will monitor: dissolved oxygen, BOD, COD, organic, ammoniacal, nitroso and nitric nitrogen, organic and dissolved phosphorus, chromium as organic and conservative substance, Escherichia coli, to consider also biological pollution effects. For each of described parameter their correspondent modules operate the integration of convective-dispersive one-dimensional transport equation in which the space-temporal variation of concentration is due to longitudinal dispersion phenomenon, to dilution with other affluents, to the contribution of other outside distributed and concentrated pollutant loads, to the chemical and physical relations that may influence the examined substance concentration in relation to other state variables (temperature, concentration of other present substances, BOD, dissolved oxygen). In a subsequent phase it is made sensitivity analysis and calibration of the model, assignating to parameters in the model equations values obtained by a monitoring activity. Practically from the sensitivity analysis we can detect parameters whose values influence more Table 1. Factor loadings. the answers of the model in particular initial and con

tour conditions. On the other hand, from planning of

data acquisition activities, which characterize the real

system behaviour, we go on to the mathematical model

calibration of the system. It is possible to forecast mak

ing the model calibration using previously obtained

data, supposing stationary contour conditions con

cerning to the temporal contexts in which data acquisi

tion and model calibration were made and completing

our data with a special analytical monitoring activity.

3.4 Assumptions of hydraulic modelling

Hydraulic model uses one-dimension equations of a

slow stream in variable motion resorting to:

- geometry knowledge any 300 meters of water

sections, inclination and roughness of Sarno river;

- water level staff measurements in shallow water; - the
knowledge of waste water localization, tipology and

diameter; - the definition of flow time state in upstream or first section of experimental site and water level in downstream or final section of experimental site. The river quality model used for tests is arranged in 1997 by ISMES (Mancusi, Barbanti) to study quality of river Serio [1]. In hydraulic and biochemical submodel there is one dimension spatial description. Variable values are averaged or integrated on section. Equation of mass balance of a general quantity, liquid weight or variable is: where t= time; c= pollutant concentration; l= spatial coordinate; v= average rate of liquid in cross section; A= cross section area; D= longitudinal dispersion

coefficient; S = source term which is addition of two

terms: S L = external contribution or drawing; S c =

contribution by internal dynamics to concentration

variations.

Hydraulic submodel

It is made by equations resulting from (1), replacing

by respectively water density ρ (mass balance equa

tion and motion quantity density ρv (motion quantity

balance equation).

Biochemical submodel

It is made joining conservation equation of water mass

and considered compound. In any case there will be a

type of equation:

where S q c/A describes concentration diluition due to

water source S q (dimensionally flow on unit of length).

Model is composed by type (2) equations system,

one for any inquired compound. In the S c term the

dynamics of variables are cointained. For any chemical

agent can be produced source terms as function of

physical and chemical kinetics which control different

degradation or concentration addition.

3.4.1 Nitrogen

Organic nitrogen N 4

where α 1 = nitrogen fraction present in algae biomass;

τ= algae breathing rate; A(t)= algae biomass con

centration; β 3 = organic and ammoniacal nitrogen

hydrolisis rate; σ 4 = sedimentation rate.

Ammoniacal nitrogen N 1

where β 1 = ammonia oxidation rate; σ 3 = benthic

generation (σ 3 > 0) or consumption (σ 3 < 0) of

ammoniacal nitrogen; μ(t)= specific growth rate;

r N = ammoniacal nitrogen fraction in α 1 ·μ(t) ·A(t)

nitrogen used for new algae biomass; α 3 = oxygen

photosynthetic production rate; d(t)= stream average

depth.

Nitroso nitrogen N 2

where β 2 = nitrites oxidization rate. Nitric nitrogen N 3 where α 1 ·μ(t) ·A(t)= nitrogen used for new algae biomass. 3.4.2 Phosphorous Organic phosphorous P 1 where β 4 = organic phosphorous degradation rate; σ 5 = sedimentation rate; α 2 = algae phosphorous fraction. Dissolved inorganic phosphorous P 2 where σ 2 = benthic generation (σ 2 > 0) or consumption (σ 2 < 0) of dissolved phosphorous. 3.4.3 Algae where A(t)= algae biomass concentration;μ(t)= specific growth rate; τ= breathing rate; σ 1 = sedimentation rate; d(t)= stream average depth. 3.4.4 BOD Carbonic BOD is regulated by degradation and sedimentation processes, described in the following relation: where k 1 and k 3 are respectively BOD degradation and sedimentation rate; B(t)=BOD concentration. 3.4.5 Oxygen Oxygen is consumed by a lot of processes already presented and is produced by

superficial areation and photosynthesis; dynamics can be described by relation: where α 5 ,α 6 = oxygen consumption rate on unity of respectively oxidized NH 4 ·NO 2 concentration; k 2 = aeration rate; C S = saturation concentration; C(t)= oxygen concentration; α 3 = oxygen photosynthetic production rate; α 4 = algae breathing rate; k 4 = oxygen demand (k 4 > 0) or production (k 4 < 0) from sediments.

3.4.6 Fecial coliforms

where k 5 = death rate; E(t)= colibatteri fecali

concentration.

3.4.7 Non conservative indicators X nc

Equation, which is used to describe non conservative

general polluting dynamics X nc , is:

where k i = degration rate; σ j = sedimentation rate;

σ k = benthic consumption (σ k > 0) or generation

(σ k < 0) of agent; X nc (t)= non conservative indicators

concentration.

Among non conservative indicators phyto-drugs

kinetics is modelled by this form equation.

3.4.8 Conservative indicators X c

Equation, which is used to describe conservative

general polluting dynamics X c is:

where σ j = sedimentation rate; X c (t)= conservative

indicators concentration.

Chlorine and boron kinetics is modelled by this

form equation.

For all considered pollutants is supposed that they

behave like dissolved solids and that their diluition

don’t change water density. In the case of heavy met

als the behaviour inside water matrix was described

by conservative kinetics, with concentration distri

bution varying only because of adsorption on col

loidal particles and other suspended solid in stream,

sedimentation and probable suspension again of dregs:

whereσ j = parameter sedimentation rate;σ i = suspen

sion again rate, function of cross section average

velocity; M c (t)= heavy metals concentration.

3.5 Expert system

Data acquisition of a traditional monitoring system,

which works in a stand-alone way, usually gives a lot of

measures and alarms, but it doesn’t give an explanation

to the operator about the cause of signals or a general

analysis of the situations to suggest the most suitable

actions. To pass these limits, the present project uses

an expert system, implemented with neural network,

A random walk approach for investigating nearand far-field transport

phenomena in rivers with groin fields

Volker Weitbrecht 1 , Wim Uijttewaal 2 & Gerhard H. Jirka 1

1 Institute for Hydromechanics, University of Karlsruhe, Germany

2 Environmental Fluid Mechanics Section, Faculty of Civil Engineering and Geosciences,

Delft University of Technology, The Netherlands

ABSTRACT: Dead-water-zones in rivers formed by groin fields strongly influence the dispersive mass trans

port of dissolved pollutants. The cause for this influence is the exchange process between groin fields and main

stream. With the help of laboratory experiments the most important parameters, such as storage time, velocity

distribution and distribution of the diffusivity have been investigated. A transport model using a Lagrangian

Particle-Tracking-Method (LPTM) has been developed, to transfer the locally obtained experimental results for a

single dead-water-zone into the global parameters of a one-dimensional far field model that comprises the action

of many dead water zones. It is shown that in the presence of large dead water zones at the river banks, an equi

librium between longitudinal dispersion and transverse diffusion can be reached if the morphologic conditions

do not change. The simulations result in a cross sectional averaged concentration distribution that converges

asymptotically to a Gaussian distribution over the longitudinal coordinate. Due to the presence of dead water

zones the distribution of tracer material becomes inhomogeneous in transverse direction.

1 INTRODUCTION

Predicting the transport of dissolved pollutants in rivers is difficult, because of the various effects of the morphological conditions. In rivers with strong morphological heterogeneities, like extensive dead waterzones, the prediction of transport velocities, maximum concentration and skewness contains strong uncertainties that need to be reduced. The River Rhine-Alarm-Model (Spreafico and van Mazijk 1993) has been developed by the “International Commission for the Hydrology of the River Rhine” (CHR) and the “International Commission for the Protection of the Rhine” (ICPR). For this kind of predictive mod els, much effort and money is spent on calibration by means of extensive in-situ tracer measurements (van Mazijk 2002). In the case of the River Rhine Alarm Model, which uses a one-dimensional analyti cal approximation for the travel time and concentration curve, a dispersion coefficient and a lag coefficient have to be calibrated. The model works well for cases of similar hydrological situations. However, variations in discharge, and thus, changes in water surface levels, lead to increased errors if the same calibrated para

meters are used for different hydrological situations.

Insufficient knowledge about the relation between river morphology and transport processes are the reason for these uncertainties. Hence, predictive methods that are appropriate for variable flows and changing morphological conditions are needed. With the present work we focus on the influence of dead water zones, such as groin fields, on the dispersive mass transport in the far field of pollutant releases. Longitudinal dispersion in rivers that can be treated as shallow flows is controlled by two processes. First, the longitudinal stretching due to the horizontal shear, and second, transverse homogenization by turbulent diffusion (Fischer et al. 1979). Detailed velocity and concentration measurements have been performed in the laboratory in order to determine typical flow patterns and local mass transport phenomena. Direct measurements of dispersion coefficients are problematic because the dispersive character of a transport phenomena reaches its final behavior only after a very long travel time (Fischer et al. 1979), which is determined by the width of the flow and the intensity of the transverse turbulent diffusion. In most cases laboratory flumes are far too short, to examine longitudinal dispersion in the far field. To address this problem, laboratory and numerical experiments have been combined in such a way that the effect of local phenomena that have been measured, are translated into the

behavior of tracer clouds in the far field with the help

of Lagrangian-Particle-TrackingMethod (LPTM).

2 EXPERIMENTS

In the present study the experiments have been per

formed in a laboratory flume of 20 m length and 1.8 m

width, which has an adjustable bottom slope. In all the

experiments only half of the channel width has been

modelled, which means that only on one side of the

flume groins have been placed.The shape of the groins

was chosen to be very simple due to the fact that ear

lier investigations suggest that there is no significant

effect of the groin shape on the exchange processes (Lehmann 1999). Using a simple geometry leads to a small number of parameters, which allows clear under standing of the basic relations between geometry and flow or transport phenomena, respectively.

The flume bottom consists of a plastic laminate with small roughness elements <0.2 mm. Level changes in xand y-direction (Fig. 1) of the flume bottom are smaller than 0.2 mm. The flume is connected to a system of a water storage tank and a constant head tank, which is supplied by three different pumps, enabling discharges up to 100 !/s. The discharge is controlled by an inductive-flow-meter together with an PC controlled gate valve. In the present case, only very small discharges of up to 10 !/s are needed. Therefore, the gate valve is equipped with a pentagonal regulating orifice, which leads to constant discharges (changes smaller than 0.5%), even if the valve is opened only 5%.

In order to simulate flow patterns under the influ ence of dead-water zones, respectively groin fields, a series of 15 schematized groins made of PVC with a heavy core were built, so that these elements could be placed at variable positions. The outline of a single groin was chosen to be a combination

of a rectangular box (0.45 m× 0.05 m× 0.05 m) with

an attached half cylinder (diameter= 0.05 m). In the

present study experiments have been performed with

varying groin field aspect ratio W/L (0.17–3.5) and

different inclination angles of the groins (Fig. 2).

The velocity measurements were performed using

Particle-Image-Velocimetry at the water surface, using

the PIV package DaVis from LaVision (Weit-brecht

et al. 2002). With the help of a particle dispenser the 20 m 1.82 m PC-controlled 3-D positioning system Diffusor D a m p i n g s c r e e n Groins Lamella weir Sieve α x L W B/2 y

Figure 1. Schematic top view of the laboratory flume show

ing the groins placed on one side. water surface is seeded with black Polypropylene particles, such that homogeneous particle distribution on the water surface is achieved. The flow field in the main stream and in the groin field is then recorded with a digital camera at a temporal resolution of 7 Hz. The vector fields are obtained by using a crosscorrelation technique, leading to spatial resolution of 2 cm× 2 cm. In Fig. 3 the measured mean velocity profiles are plotted for the different aspect ratios in the case of the standard groins. W/L = 0.35 W/L = 0.17 0.25 0.40 L W 0.59 W/L = 0.40 W/L = 1.00 Flow direction α = 64°, 116° α α α α = 90° 0.77 1.12 2.00 3.35 0.40 0.48 α α Standard Groins Short Groins Inclined Groins Figure 2. Comparison of the mean velocity profiles for the different W /L aspect ratios. The plotted velocities are averaged in space over the length L of the groin fields, and normalized with the maximum velocity at the water surface U S .

The comparison in Fig. 3 shows that, the aspect ratio

of the groin field has limited influence on the mean

flow properties in the main stream. Above the groin field boundary no significant differences between the normalized velocity profiles can be observed. The velocity profile in Fig. 3 in the main stream part of the flow has the typical shape of a mixing layer velocity profile and can be approximated using a hyperbolic tangent function of the form

where a, b and c are constants that have to be adapted. In the present case the profile for the reference case W /L= 0.4 leads to the following values: a= 0.82, b= 0.24 and c= 0.17. h S is the water depth in the main stream. This equation represents the velocity profile that is responsible for the stretching mechanism of a tracer cloud in the main stream.

In Fig. 4 the normalized rms-velocities of the transverse component v ′ /u ∗ measured with the PIV system are plotted. These values indicate the strength of the transverse turbulent mixing, which is the second important parameter influencing longitudinal dispersion.

Additional concentration measurements have been performed to measure the mean residence time T D of tracer material in the dead-water-zones (Kurzke et al. 2002) using a depth averaged adsorptive technique. With the help of a multi-port injection-device tracer

has been injected instantaneously into one groin field.

The evolution of concentration distribution has been

recorded with a CCD-camera. Gray scale analysis,

which takes into account inhomogeneous illumination

and changing background intensities, finally leads to

an exponential decay function for every groin field

Figure 4. Comparison of the normalized strength of the

velocity fluctuations v ′ /u ∗ for the different aspect ratios W/L. where C is the spatial averaged concentration in the dead zone, C o the initial concentration. The residence time T D is used in the LPTM transport model to parameterize the influence of dead-water zones on the mass transport in the river. T D can be normalized with the width of the groin field W and the main stream velocity U to give a dimensionless exchange coefficient k The resulting exchange coefficients k for the different groin field setups are shown in Fig. 5. Figure 5 shows that k reduces with increasing W/L, which means that the residence time T D is longer in the very narrow cases of groin fields. Another results is the increased mass exchange for backward inclined groins compared to downward inclined or regular groins. For short groins Fig. 5 shows also the tendency towards smaller exchange values with increasing W/L. However, the k-values for short groins are noticeably smaller for the same aspect ratio W/L than in the standard case. This shows, that the groin field volume has to be taken into account for the prediction of k . A slight modification of the scaling factor W/L into WL/(W +L), which can be interpreted as a kind of hydraulic radius R D of the dead-water-zone, leads to a better normalization

shown in Fig. 6. Why the exchange coefficients should scale with the hydraulic radius R D can be explained by the following: In the case of very long groin fields with L →∞ the expression WL/(W +L) tends to W . Therefore, in the case of very long groin fields the recirculating flow is only determined by the width W of the groin field. In the other extreme case for W →∞ the hydraulic radius R D tends to L, which means that the mass exchange in this case is only determined by the length of the mixing layer. 0 0.5 1 1.5 2 2.5 3 3.5 0 0.005 0.01 0.015 0.02 0.025 0.03 0.035 0.04 k W/L Standard groins Backward inclined groins Forward inclined groins Short groins Figure 5. 3 LAGRANGIAN PARTICLE TRACKING

METHOD

A transport model based on a two-dimensional

Lagrangian-Particle-Tracking-Method (LPTM) has

been developed to transfer the local results of the

laboratory experiments for a single dead-water-zone

into the global parameters of a one-dimensional far field model that comprises the action of many dead waterzones. The method represents a random walk approach as has been used, for example, by Sullivan (1971) to model turbulent shear flow based on statistical mechanical transport theories presented by Taylor (1921).

As the present transport problem is basically a problem of longitudinal dispersion, we assume that the dominating processes in this case are longitudinal shear and transverse diffusion. Thus, the behavior of discrete particles under the influence of advection in longitudinal direction and of transverse diffusion is determined in a two-dimensional domain. The idea is to initiate a cloud of particles that is advected within a known mean flow profile. This advective movement is superimposed on a random movement in transverse direction, representing turbulent diffusion.

The characteristic transport parameters, like dispersion coefficient, transport velocity and skewness coefficient, can be determined by analyzing the statistics of such a particle cloud at any position of the simulation. In addition to one-dimensional information this method yields concentration distributions in transverse direction, in order to describe near-field

phenomena.

The influences of dead-water zones are included

with the help of extra boundary conditions that rep

resent the mean retention time of particles in the area

of dead-water zones. Herewith, the influence of dif

ferent groin field geometries on the mass transport, y x t t+Δt u(y) u(y)Δt v'Δt Figure 7. Particle velocity in a two-dimensional flow field with mean velocity in x-direction and turbulent velocities in y-direction. especially on the mass dispersion, in the far-field of a pollutant spill can be predicted. The method has been verified with the aid of the analytical solution presented for the AdvectionDiffusion-Equation for a Couette-Flow problem (Fischer et al. 1979) and turbulent unbounded vertical shear flow given by Elder (1959). Dispersion coefficients obtained from these solutions are compared with the transport characteristics using the LPTM (Weitbrecht et al. 2003). In the next step the transport model is used to predict the transport parameters for the flow conditions, taken from the experiments. Mean flow quantities and turbulence intensities are determined in pure channel flow and are adapted to the LPTM. Finally the influence of dead-zones (groin fields) is implemented. A random walk simulation can be understood as the tracking of discrete particles, under the influence of the governing flow processes. Typically, the particle displacement dX i is described by a deterministic and a stochastic part, leading to the so called Langevin equation (Gardiner 1985) where X i is the position x, y and z. f (X i , t) represents the advective or drift component, which can be interpreted as the mean flow velocity field. The expression g(x i , t) describes the diffusive or noise component of the particle movement that describes the strength of the turbulent diffusion in space. The stochastic part is represented by the Langevin force Z , which is a Gaussian distributed variate with a mean value of zero and a variance equal to one. In the present case the governing processes are advection in x-direction and diffusion in transverse direction (Fig. 7), which implies that we can neglect the drift component in y-direction and the noise component in x-direction in Eq. 4. An important part of such a model is the link between the diffusive step

size and the length of the time step. Here we use

the approach given by Taylor (1921) who stated that the spreading of a particle ensemble measured with the standard can be treated as a Fickian type of diffusion, where σ ~ √ 2Dt. The diffusive step size for a single particle at a certain time step in y-direction is therefore given with

where D y is the turbulent diffusion coefficient in y-direction. Using these assumptions, the position of the particles in every time step Δt can be described by a simplified two-dimensional version of Eq. 4.

where x old , y old and x new , y new are the spatial locations at times t and t+Δt respectively, and D y is the transverse component of the turbulent diffusion coefficient. The function u(y) denotes the mean flow velocity in relation to the position in transverse direction. Consequently, in every time step, a particle moves convectively in x-direction depending on the velocity profile and does a positive or negative diffusive step in transverse y-direction.

The reason why there is no diffusive step in the x-direction needed (Eq. 6), can be explained by the fact, that turbulent diffusion in x-direction and longitudinal dispersion are additive processes (Aris 1959), which means that the final dispersion coefficient can be adjusted by adding the turbulent diffusion coeffi

cient. Fischer et al. (1979) showed that in natural rivers the coefficient of longitudinal dispersion D L lies in the range of 30<D L /(u ∗ h)< 3000, while the longitudinal turbulent diffusion coefficient D x is considerably smaller. A typical approximation of the turbulent diffusion coefficient is given by D x ≈ (0.6u ∗ h), which means that in this approach turbulent diffusion in longitudinal direction can be neglected in comparison to longitudinal dispersion. An advantage of this simplification is a shorter computing time.

Flows with inhomogeneous turbulent diffusion coefficients are treated here, which means that D y is a function of y. A problem in performing LPTM simulations is given by the fact that particles segregate into regions of low diffusivity (Hunter et al. 1993). In the stochastic model particles move independently from regions with high diffusivity into regions with low diffusivity. As a consequence the probability of a particle to move from a region of high diffusivity into a region of low diffusivity is higher than vice versa. In order to satisfy continuity an extra advection term in y-direction has to be included, to achieve consistency with the governing Advection-Diffusion-Equation. This extra term is called the noisedrift component. By matching the resulting stochastic transport equations with the Advection-DiffusionEquation Dunsbergen (1994) showed, that in this case, the noise-induced drift component y n can be formulated as follows If Eq. 7 is extended with the given expression for the noise-induced drift component (Eq. 8), the transport problem with varying diffusivity is described consistently with the Advection-Diffusion-Equation. Also

the boundaries of the calculation domain and their effect on the particles are important. The inflow and outflow boundaries do not affect the particles as in our case the domain has an infinite length. In case of horizontal shear the boundaries representing the channel bank and channel centre line act as reflective walls. Particles which would cross the left or right boundary at a certain time step are reflected into the calculation domain. Consequently, a particle with a calculated y-position outside the calculation domain y< 0 is re-introduced as follows where y calc is the calculated y-position at a certain time step. With the given equations and boundary conditions transport in open channel flow can be simulated with a depth-averaged velocity profile in transverse direction and a certain distribution of the diffusivity. The next step is to include the influence of dead-water zones (Fig. 8) into the LPTM. The mean residence time of tracer material in the dead-water zone is the most important parameter to describe the behavior of a dead-water zone. Therefore, it should be possible to model the influence of the mass transport by including this parameter into the LPTM. A possibility is to include the residence time into the boundary condition, such that this boundary simulates the behavior of mass trapping and mass release. Thus, the interface between main channel and dead-water zone has to act as a transient-adhesion boundary, which means that particles that reach such a boundary are fixed to that position until T D has passed. This mimics to the real dead-zone behavior. A particle that enters a dead-water zone because of turbulent motion in the mixing layer, does not move on average in x-direction, assuming that the longitudinal extension

of the dead-water zone is small compared to the length of the modeled river section. The particle remains in the dead-water zone on average for time period given by the mean residence time T D , and after that period it gets back into the main stream.

The outcome of a LPTM simulation are x and y-positions of every single particle at every time step. By analyzing the statistics of the particle posi tions, information about the transport characteristics can be determined. The one-dimensional longitudinal dispersion coefficient D L , as a measure of the spa tially averaged spreading rate of a tracer cloud, can be determined by calculating the time change of the longitudinal variance σ 2 x of the particle distribution (Rutherford 1994) as follows

A second result will be the skewness G t of the par ticle cloud. The skewness is defined as the relation between the quotient of the third moment about and

the third power of the standard deviation where n is the number of particles at the positions x i with mean position $\bar{x}$ and σ x is the standard deviation of the particle distribution. The skewness of a certain distribution describes the degree of asymmetry of a distribution. The skewness can be used as an indicator for the length of the advective zone, in order to define when it is acceptable to apply the Taylor solution to a pollutant transport problem. Another parameter of interest is the transport velocity c of the tracer cloud, defined as the velocity of the center of mass of a particle ensemble. In the case of regular channel flow with ordinary reflective boundary conditions c is equal to the mean velocity if the particles are

homogeneously distributed over the river cross section. In case of point sources this can be reached after the tracer has passed the advective zone. The transport velocity can be determined as follows where $\bar{x}$ represents the center of mass of a particle cloud. 4 APPLICATION AND RESULTS In this section the LPTM is applied to different flow fields, that have been investigated in the laboratory in order to determine the influence of river heterogeneities on the mass transport properties of a river. Three different cases will be analyzed in detail. First the behavior of the dispersive character of pure channel flow without the influence of groin fields is investigated. In a second step groin fields are implemented, and finally the influence of different residence times on the transport characteristics is determined. 4.1 Straight open channel flow A LPTM-simulation has been performed, in order to analyze transport phenomena in regular channels without groin fields. Therefore the measured velocity distribution has been approximated with an analytical function, that can be seen in Fig. 9(i). The diffusion coefficient in this case has been chosen to be constant over the whole river cross section, with a value according to Fischer et al. (1979) for regular channels. In Table 1 the properties of the flow and the settings of the 2D-LPTM-simulation for the case of a straight channel flow are listed. The equilibrium between longitudinal stretching and transverse diffusion, where the dispersion coefficient does not change any more is reached after about 0 0.5 1

D L /(u ∗ h) is 177, and is much larger (30 times) than the

dispersion found in a channel with a laterally uniform

velocity (Elder 1959).

4.2 Channel flow with groin fields

The influence of groin fields is simulated with the

transient-adhesion boundary condition (Sec. 3), that

represents the mean residence time of a particle in

the groin field. These mean residence times have been

measured in this study with two different approaches.

Concentration measurements have been performed,

where concentration decay in a single groin field has

been tracked with digital video analysis. Starting with

a known homogeneous concentration in the groin field

and zero concentration in the main stream an exponen

tial decay could be observed, leading to a typical time

scale T a describing the mean residence time. These

experiments are in principle analogous to the measure

ments that have been performed by Uijttewaal et al. (2001). An improvement could be achieved by the development of a multi-port injection device, that is able to produce reproducible homogeneous concentration fields as initial condition for the concentration measurement (Kurzke et al. 2002). Another possibility to determine the residence times is given by using the velocity fields for the determination of the mass exchange rate between groin field and main stream (Kurzke et al. 2002). In order to determine the influence of groin fields, a LPTM-simulation has been performed with the same flow properties as in the described case above (Table 1). The difference lies in the transient-adhesion boundary condition at the channel wall. This simulation represents groin fields, where the ratio between the width W of a groin field divided by the length L is 0.4 (Fig. 2). These conditions correspond to laboratory measurements with a groin field length 1.25 m and a width of 0.5 m. As the water depth in the groin field and the main stream is the same, the ratio between the cross sectional area of the dead water zone and the main stream is 0.5. The mean residence time T a of a tracer particle has been set to 90 seconds, which corresponds to the measured dimensionless exchange coefficient where W is the width of the groin field and U represents the mean flow velocity in the main channel. In the case of channel flow with groin fields the velocity profile is slightly changed compared to the pure channel flow, because in the presence of groin fields the velocity profile has to represent the mixing layer between groin field and main stream and can be approximated with a tanh function, where the velocity is still positive at y= 0. The distribution of the diffusivity in that case is not constant over the channel cross section, see Fig. 4. Turbulence measurements showed, that the velocity fluctuations in the region of the mixing layer between groin field and main channel are much stronger than in the undisturbed main channel. Therefore the diffusivity given by Eq. 14 is amplified in the region of the mixing layer, proportional to the increasing transverse velocity fluctuations. This has been done, by fitting a gaussian curve to the transverse rms-values of the channel flow, such, that the diffusivity in the mixing layer is three times larger than in the main channel (Weitbrecht et al. 2002). In Fig. 10 the LPTM-simulation with groin fields is visualized after 200 time steps. The main difference with respect to pure channel flow is found in the particle clouds that travel far behind the main tracer cloud, a

phenomenon that is also observed in the laboratory flume. These small particle clouds arise by the effect of the dead water zones. Particles that have crossed the 0 5 10 15 20 25 30 35 40

lower boundary layer during the simulation, remain at the same x-position for the mean residence time T a . After T a has elapsed the particles get back to the flow. The mean distance between those clouds corresponds to the mean residence time T a .

The final stage of mixing in the case with groins shows again, that after a long period the tracer cloud approximates a Gaussian distribution in longitudinal direction Fig. 11.

The interesting properties of this simulation are the evolution of the dispersion coefficient and of the skewness, as visualized in Fig. 12. The final value of D L /(u * h) is in that case approximately 24.800 which is a factor 140 higher than in the case of pure chan nel flow, and about ten times higher than the values common for natural rivers without groin fields. This can be explained by the exaggerated ratio between the cross sectional area of the dead water zone and the cross sectional area of the main channel, which is 0.5 for this experiment, a value rather high compared to natural rivers.

The equilibrium between longitudinal stretching

and transverse diffusion is achieved after approxi

mately 800 times the channel width (Fig. 12), which 0 1000 2000 3000 4000 5000 6000 -3 -2 -1 0 1 2 3 x/h G t D L / u ∗ h 1 0 4 D L G t Figure 12. Evolution of transport velocity c of a tracer cloud normalized with mean velocity of the main channel. indicates that the advective zone has the same length irrespective of the presence of groins. In the case of a straight channel flow, the transport velocity c, which is defined as the translation velocity of the center of mass of the tracer cloud Eq. 13, always equals the mean flow velocity in the channel. In the case with groin fields the transport velocity of the tracer cloud decreases in time until an equilibrium distribution between the particles in the dead water zones and in the main channel is established, see Fig. 13. In this simulation the transport velocity does not change further after the tracer cloud has travelled approximately 1000 times the channel half width. The final transport velocity is 64% of the mean flow velocity in the main channel. According to the one-dimensional dead-zonemodels by Valentine and Wood (1979, van Mazijk (2002), the transport velocity in the far field can be estimated from the ratio between the cross sectional area of the dead water zone A d and the cross sectional area of the main stream A s In the presented case this relation would provide a value of 67% of the mean flow velocity, which is close to the result of the LPTM-simulation. Considering the particle distribution in transverse direction of the river cross section, it can be stated that the initial homogeneous distribution (Fig. 14i) remains homogeneous in the case of a pure channel flow. The distribution is affected in the presence of groin fields 0 0.5 0

(Fig. 14ii, iii, iv). A substantial part of the particles accumulate in the dead-zone area during the LPTM simulation. In the final stage of mixing (Fig. 14iv) almost 40% of the tracer material is found in the region of the dead water zones. The remaining 60% of the material is travelling in the main stream.

4.3 Groin fields with different exchange rates

The dimensionless exchange coefficient k (Eq. 15), can be found in the literature to be in the order 0.02± 0.01 (Valentine and Wood 1979; Uijttewaal et al. 2001), with no clear dependency to the shape of the dead water zone. With our laboratory experi ments, we could demonstrate that k varies with the width to length ratio of the groin fields within the range of 0.015–0.035. Here the longest groin fields (W /L= 0.3) are leading to the highest k-values and the shortest groin fields (W /L= 3.5) correspond to the lowest k-value (Weitbrecht and Jirka 2001). In all cases the groin field width W was constant. Accord ing to Eq. 16 the transport velocity is supposed to be

the same in those cases. In order to explore the pos

sible influences of the changing k-values, two extra

LPTM -simulations have been performed, where the

mean residence time has been set to 75, 95 and 130

seconds, respectively. Consequently, the respective

k-values used, are 0.035, 0.028 and 0.020.

In Table 2 the results of the simulations with chang

ing k-values are summarized. It can be seen that the

dimensionless dispersion coefficient D L /(u ∗ h) is pro

portional to the residence time T a . The longer the

residence time, the higher the stretching rate of the

tracer cloud.

It can be seen that the influence of the different

k-values on the transport velocities is at maximum 10% for the presented configuration. According to these simulations, the results of the one-dimensional dead-zone-model mentioned above predicts the transport velocity correctly, for a k-value of about 0.035, which corresponds to groin fields with an aspect ratio of about W /L= 0.33. An equilibrium between longitudinal stretching and transverse diffusion is reached in all cases after approximately 800 times the channel's half width B. That again indicates that the dominant time scale is not T a , but the diffusive time scale B 2 /(2D y) associated with the time needed for a particle to cross B. If we determine the length x/B that corresponds to this time, we get which corresponds very well to the observed behavior of the particle clouds in the LPTM-simulations. 5 CONCLUSIONS Our approach in which laboratory experiments and LPTM are combined, creates the possibility to determine transport characteristics in the far field of a pollutant spill in shallow, predominantly two-dimensional river flows. Detailed velocity and concentration measurements are used to determine local flow and transport phenomena in the presence of groin fields. A translation is made via the LPTM , to convert these findings into transport velocities,

longitudinal dispersion and skewness coefficients of the cross sectional averaged pollutant cloud in the far field. This information can be used to improve the accuracy of onedimensional alarm-models, and to reduce the need for calibration with tracer experiments. The finding, that the transverse tracer distribution is influenced by the presence of dead water zones should be taken into account for the planning of future field experiments, and for the interpretation of existing data. In addition to the concentration distribution it is likely that other properties depend also on the lateral coordinate. The computationally simple two-dimensional approach allows for studying near field effects as well. Point releases of contaminants near one of the banks and not fully mixed states are impossible to predict with a one-dimensional approach. The same holds for strongly varying flow geometries with confluences, weirs, bends etc.

ABSTRACT: The paper looks at a vertical round buoyant jet issued in a cross flow and investigates the effect

of turbulence in the cross flow upon the structure of the jet. This general problem of the influence of ambient

turbulence has been investigated for the case of cross flow turbulence associated with flow over a rough bottom

boundary. The results of laboratory investigations of this problem are described and it is shown that the influence

of the roughness of the bottom surface is manifested by significant modifications to the buoyant jet trajectory

(as compared to the smooth boundary reference case). Preliminary attempts to quantify and parameterize these

modifications are presented.

1 INTRODUCTION

One crucial problem in hydraulic engineering con

cerns the dilution of turbulent thermal discharges in a cross flow. The effects of cross flow turbulence (gener ated, as in this case, by the presence of a rough bottom boundary) upon the structure of the discharge flow is an important aspect of this problem. The study of a heated water discharge in the form of a turbulent buoy ant jet into a channel with a flat bottom and with a cross current is well established in the literature (e.g. Lee, 1984; Il Won Seo et al., 2001; Young Do Kim et al., 2002). The flow dynamics of the thermal discharge in the near field are governed purely by the momentum source represented by the high velocity injection. In the far field, instead, mixing is governed by ambient currents and stratification. Moreover, processes at the air-water interface, such as heat exchange towards the atmosphere and wind stress, can further affect the heat distribution. As regards the ambient turbulence, the visualization study of Grass et al. (1991) revealed that powerful vortical structures with a general horseshoe type configuration occur over smooth surfaces as well as in the turbulent boundary layer near rough walls and that they are similarly linked to bursting events in both the smooth and rough bed cases. The nature of coher ent structures and their processes of development over rough surfaces, therefore, appear to be similar to those

originating over smooth walls. Furthermore, Grass et al. (1991) and Grass & Mansour-Tehrani (1996) observed that a remarkable feature of the rough wall flow is its apparent ability to order itself very rapidly in a small vertical distance above the tops of the roughness elements. Their measurements indicated that for fully rough wall conditions, the near-wall turbulence structures are directly proportional to the bed roughness size for geometrically similar roughness elements and the packing used in their tests. In order to clarify the dependence of the buoyant jet upon the background turbulence and to improve knowledge of the physical processes that determine its dilution, an experimental study was conducted. Localized background turbulence was generated within the ambient flow by means of two different corrugated plastic surfaces of known “wavelength” λ and “amplitude” ε, fixed at the bottom of a rectangular channel. During this experimental work, the characteristics of the turbulence field produced in the surrounding flow by particular combinations of λ and ε were analyzed, with the aim of finding a typical characteristic length scale of the turbulent eddies associated with flow over the rough boundary and its effect upon the structure of the buoyant jet. Since the study consisted of a three-dimensional buoyant jet interacting with a three-dimensional “patch” of shear turbulence, measurements of velocity and temperature fields were assessed at different vertical levels to obtain the spatial structure of the temperature and the velocity profile

of the cross flow. Such an approach required a long

time for each run, especially because relevant differ

ences were observed at a distance of mms, and accurate

and appropriate techniques to collect data, as described

below were necessary.

For each configuration, the objectives of the exper

iments were (i) to compare the mixing of a buoyant

jet discharged into a cross flow with a smooth and

rough boundary, (ii) to identify a distortion of the jet

structure by the presence of the background turbulence

generated by the rough bottom and (iii) to quantify this distortion and parameterize it in terms of buoyant jet and corrugated surfaces characteristics.

2 EXPERIMENTAL WORK

2.1 Experimental set-up

The laboratory model was constructed in the Coastal Engineering Laboratory of the Technical University, Bari, Italy (Fig. 1). The system consists of a rectangular steel channel 15 m long, 4 m wide and 0.4 m deep, with lateral walls and base made of transparent glass material (Saint Gobain), 15 mm thick. To create a current inside the channel a closed hydraulic circuit was constructed. The fresh water at ambient temperature was supplied from a big metallic tank downstream by a Flygt centrifugal electro-pump, which sucked the water into a steel pipe with diameter 200 mm and then discharged the same water into the upstream steel tank. Into the upstream tank a side-channel spillway with adjustable height was fitted, being made from different plates mounted together.The water that overflowed was directed into a pipe like the one for the water supply and parallel to it, with a 250 mm diameter and finally discharged into the tank downstream of the channel. Two different electromagnetic flow meters were mounted on the two parallel pipes described

above in order to measure the flow rate in the channel

Figure 1. A view of the channel. as the difference of the two discharge measurements. The free surface level of the water into the channel, H a , was maintained at a constant level with a depth of 26 cm for all of the experiments, to ensure that the discharge into the channel was constant. The second part of the laboratory model consisted of a buoyant jet thermal-hydraulic system. The discharged heated water generating the turbulent buoyant jet was pumped into the channel through a round steel tube mounted at the bottom of the channel and within the central longitudinal section.The tube was mounted vertically and it passed through the glass base. The source diameter D= 5.0 mm of the jet was chosen to satisfy different conditions. Firstly, in all cases to ensure that the jet was fully turbulent, i.e. to have the Reynolds number Re, defined for a round jet as Re= 4Q 0 /πDν, with ν the kinematic viscosity of the fluid and Q 0 the source discharge, sufficiently high (Re> 2000). Secondly, the value of D was fixed taking into consideration the length scale l M , defined in terms of the source momentum (J 0) and buoyancy (B 0) fluxes as for a three-dimensional buoyant jet and which represents the distance from the source within which momentum effects are dynamically significant and beyond which the dynamics are dominated by buoyancy. Therefore, when the value of the length scale l M is high, the momentum flux (J 0) plays a dominant and destabilizing role on the buoyant jet, causing recirculating eddies or mixing over the entire water depth, while when the value of the l M is low, the buoyancy flux (B 0) is the main and stabilizing element that fosters a stable field in which a buoyant surface layer is formed that does not communicate with the initial buoyant jet zone (Jirka et al., 1982). Furthermore, because an ambient cross flow existed in the direction of the channel, its momentum flux, defined as where S is the transverse surface area of the ambient flow into the channel and u a is the velocity of the cross flow, was taken into consideration, as destabilizing effect on the buoyant jet development. The values of these three parameters and the relations among them were considered to have a stable flow field; that is, a low value of the length scale l M was planned so that buoyancy effects were comparable with momentum effects, and a low value of the cross flow momentum flux J a was chosen so that the position of the free surface level and a cross flow velocity were as low as possible. In particular, for the experiments with

a smooth bottom boundary, and with the source dia
meter D= 5 mm of the buoyant jet defined, the length
scale l M assumed values between 0.26 m and 0.44 m,
whereas the values of the flow ambient momentum
flux J a was 7.5 · 10 −3 m 4 /s 2 for all the experimental
configurations. For the fresh water supply and its heat
ing, a galvanized iron tank was used, which inside
were four resistances of 12,500 W for the heating of
the water till the fixed temperature (with maximum
value 90 ∘ C), each one protected by a thermostat, and a
temperature transducer for the water temperature mea
surement. A pump of 1 Hp, equipped with manometer
and interception key, transferred the hot water from
this supply reservoir to a second tank, positioned on
a lifting platform, whose different levels were able
to define the fixed source discharge. A comprehen
sive view of all of the buoyant jet generation system
described is showed in Figure 2.

A Process Computer and a control software (which
task was to store the test data and, if decided by the
operator, to supervise all the system) was used to con
trol and manage the buoyant jet system. It was able
to generate the discharge of a flow with prefixed and
constant pressure, flow rate and temperature into the
channel described, and all of the facilities connected

with the channel and the jet generation system.

Figure 2. The tanks of the hydraulic circuit of the buoy

ant jet. To create a particular turbulence in the ambient cross flow, corrugated plastic elements were positioned on the bottom of the channel, forming a rough bottom boundary (Fig. 3). Three different kinds of roughness elements were used.The first one, was a roll of 10 m length and 3 m width, made of polyester resin strengthened with glass fiber, with a “wavelength” λ of 76 mm and an “amplitude” ε of 18 mm. A hole was made in the center longitudinal section, 6 m from the upstream channel section and 4 m from the downstream section, located in the trough of the bottom boundary “wave” surface. Each of the other kinds of corrugated elements used during the following experimental configurations, was formed by 11 panels of same dimensions, and with same material and technical characteristics of the previous kind, differing only by the values of λ and ε. Experimental cases and conditions for vertical round buoyant jet issued in a cross flow with rough bottom boundary are listed in Table 1. In order to cover as wide a range of conditions as possible, experiments were conducted using several different values and U(z) Dz T 0 U 0 U 0 Z = z 0 Z = 0 Z = H z x x y SIDE VIEW PLAN VIEW at z = z 0 temperature contours: ∆T(x,y,z) ∆T 0 Q 0 (T 0 + DT 0) Figure 3. combinations of the buoyant jet and bed-form param

eters. Nevertheless, the experiments used the same

working fluid (fresh tap water) throughout and the jet

source diameter D was kept fixed (5.0 mm) for all runs.

Different buoyant jet flow conditions were therefore

created by changes in Q 0 and T 0 . In particular, the

jet temperature was changed for each configuration to

have two fixed temperature differences ΔT = (T a −T 0 , with T a the ambient temperature) of 25 ∘ C and 35 ∘ C between the ambient and the jet. The first configura tion provided a smooth flat bottom boundary, while the following three configurations have adopted the differ ent panels with different values of the parameters λ and ε, described above. Eight different thermocouple sen sors were utilised to measure the mixing of the heated water into the cross flow, with and without the rough bottom, whereas for the measurement of the velocity theADV system was used, together with CollectV soft ware for the data acquisition and ExploreV software for the data analysis, both of them products of Nortek, like the ADV.

2.2 Laboratory results

2.2.1 Velocity field

In order to study the turbulence effect upon the jet structure, a set of experiments was investigated with different configuration.The purpose of the experiment is to measure the three-velocity components (U , V , W) at different positions around the jet, where, U =mean stream-wise velocity, V =mean transverse velocity and W =mean vertical velocity, the measurement was determined by using an Acoustic Doppler Velocimeter (ADV). Figures 4–6 illustrate some of the experimen

tal tests velocity vector map. It is to be noted that measurements shown in the three figures were made with the same channel discharge, the same source dis charge and the same temperature excess at the source, the difference between theme being the nature of the channel bottom, which was a smooth surface bottom

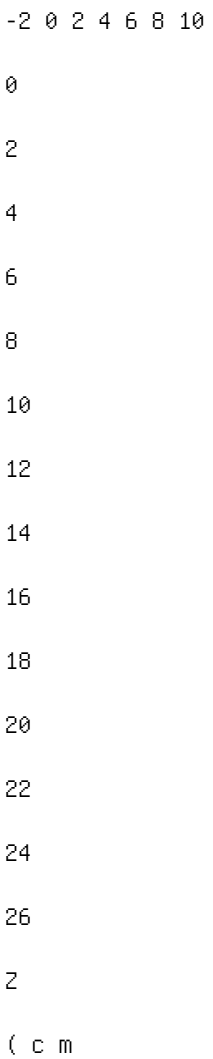

Figure 4. Near field velocity distribution for T1. Side view

(y= 0). for Figure 4, corrugated surface bottom of “wavelength” λ= 76 mm and “amplitude” ε= 18 mm for Figure 5 and corrugated surface bottom of “wavelength” λ= 146 mm and “amplitude” ε= 48 mm for Figure 6. The flow velocity vectors shown in those figures represent the mean velocity modules of the streamwise and the vertical flow velocity components which were measured along the channel axes where y= 0. As shown in Figures 4–6, it can be seen that the flow velocity vector directions and modules around the jet vary spatially. This variation is considered very rapid and more turbulent. Just for 1 or 2 cm in the upstream of the source, the velocity vectors keep the same direction along the vertical axes z and have a uniform distribution for the three bottom configurations. Over the source nozzle and going toward the downstream end of the channel, the velocity vectors appear to have an upward moving flow area, through which they change their characteristics strongly. Increasing the spatial coordinates (x, z), the velocity vectors for the three configurations change their -2 0 2 4 6 8 10 12 14 16 18 20 22 24 26 X (cm) 2 4 6 8 10 12 14 16 18 20 22 24 26 Z (c m) = 10 cm/s jet Figure 5. Near field velocity distribution for T9. Side view (y= 0).

characteristics step by step, reaching a uniform profile

similar to that of the ambient flow.

The other hand, Figures 4–6 show that the ability

of the jet to become more vertical depends upon the

nature of the channel bottom. In the case when the

channel bottom surface was smooth, the jet velocity

vectors are deviated more toward the horizontal than

the other configurations with the presence of a corru

gated channel bottom surface. It can been seen that the

velocity vectors direction are influenced by the “wave

length” λ and “amplitude” ε of the corrugated surface.

When λ and ε increase the jet velocity vectors become

more vertical. This is due to the fact that the jet is

confined between the wave crests of the bottom.

2.2.2 Stress distribution

As indicated in the previous paragraph, the channel

bottom surface nature has a big effect upon the jet

structure. In order to study this phenomenon in depth,

a Reynolds stress analysis was established. As is well

known, the statistical description of a turbulence flow

starts by dividing the flow velocity into mean and

fluctuating components. So, at each point the three

instantaneous velocity components are written as:

where u, v, w are the streamwise, transverse and ver

tical instantaneous flow velocity components, respec

tively, and u ′ , v ′ and w ′ are the streamwise, transverse

and vertical flow velocity fluctuation components,

respectively.

The quantities u ′ v ′ , u ′ w ′ and v ′ w ′ are the time

averaged streamwise-transverse, streamwise-vertical

and transverse-vertical Reynolds shear stresses.

T9. Side view (y= 0).

Test 1 was a configuration with smooth surface chan

nel bottom, Test 7 was a configuration with corrugated

surface channel bottom of “wavelength” λ= 76 mm

and “amplitude” ε= 18 mm, and Test 9 was a configu

ration of corrugated surface channel bottom of “wave

length” λ= 146 mm and “amplitude” ε= 48 mm.

From the figures, it is possible to highlight that the

strong u ′ v ′ , u ′ w ′ and v ′ w ′ Reynolds stresses are present

in the area localized near the jet source, where the

velocity vectors change their characteristics strongly,

as written in the previous paragraph. Furthermore,

both positive and negative values of the Reynolds

stresses were present in the same plan. In the measure

ment points far from the jet source, it was highlighted

that the Reynolds shear stresses become small for all

configurations. This is due to the small velocity fluc

tuations in these areas and the dominance of the cross

flow velocity components with an absence of the jet

stream effects. -1 0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24 X (cm) 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20 Z (c m) Figure 13. Figure 17. Longitudinal temperature distribution for Test 8.

Furthermore, one can see that there is a difference

of the stress distribution between the analysed con

figurations, depending on the channel bottom surface.

The absolute values of $u' v'$, $u' w'$ and $v' w'$ Reynolds

shear stresses of the configuration with the smooth

channel bottom are generally smaller than those of

the other two configurations with corrugated channel

bottom, as shown in Table 2. The same table shows

also that $u' w'$ Reynolds stress component of Test 9 is

greater than the ones of Test 1 and Test 7. In addition,

it can be seen that Test 9 shows a positive shear stress

distribution larger than the negative one, as shown in

Figure 12. On the contrary, the $v' w'$ Reynolds shear

stress component is largely negative.

Examining the different figures, it can be seen

clearly that the Reynolds shear stress distributions are

more vertical when λ and ε increase. -4 0 4 8 12 16 20 24 28 32 36 40 44 48 X/D 12 16 20 24 28 32 36 40 Z / D 0 0.05 0.1 0.15 0.2 0.25 0.3 0.35 0.4 0.45 0.5 0.55 0.6 0.65 0.7 0.75 0.8 0.85 Figure 18. Longitudinal temperature distribution for Test 9. 2.2.3 Temperature

field In the present study, another aim was the measurements of the temperature field. The survey was run in a three-dimensional form, taking data at different levels and distances from the source orifice of the heated discharge. Among the twelve experimental cases, seven typical temperature profiles, at the centre longitudinal section of the channel, are shown in Figures 16-22. In these figures, the ratio∆T/∆T 0 is reported, where∆T is the difference between the time-averaged temperature in the measurement point and the average ambient temperature, whereas∆T 0 is the time-averaged excess

temperature at the jet nozzle. In other words, this ratio represents the dilution of the buoyant jet into the cross flow. For the sake of brevity, Figures 16–22 were chosen taking into account (i) the three different bottom boundary conditions, which are smooth flat bottom, rough bottom with λ= 76 mm and ε= 18 mm, and rough bottom with λ= 146 mm and ε= 48 mm, and (ii) two different buoyant jets with different den sity, generated by different own temperatures, and different flow rates Q_0 . The purpose is to show the different behaviour of the buoyant jet related to param eters such as λ and ε, and to its own characteristics. Attention was paid also to the horizontal distribu tion of the temperatures into the ambient, so the measurements were assessed also at different vertical layers.

The analysis of the figures show that the jet is more vertical (i.e. is less deviated towards the cross flow

direction) in the case of rough bottom. Furthermore,

the jet is less deviated in the case of rough bottom with

Shallowness and longitudinal dispersion in rivers

Robert Booij

Faculty of Civil Engineering and Geosciences, Delft University of Technology, The Netherlands

ABSTRACT: The longitudinal dispersion determines the extent of and the concentration in the cloud of

pollutant that descends the river after an accidental spill. It is strongly influenced by the presence of dead water

zones along the river. The slow exchange of water and hence of dissolved pollutants between river and dead

water zone results in very large values of longitudinal dispersion coefficients. It even leads to the large tails

that are often found in the distributions of pollutants. Measurements in a laboratory model of square harbours

along a river show that the aspect ratio of dead water zones is important for the residence time of the pollutant

in dead water zones. For very shallow dead water zones as common along rivers, with aspect ratios of 20 or

more, the flow hardly enters the centre of the zones, leading to very long residence times for the pollutant there.

Laboratory models of dead zones along rivers are nearly never deep enough to account for this effect and are

hence not useful for the validation of numerical models of longitudinal dispersion.

1 LONGITUDINAL DISPERSION

The spreading of dissolved matter in rivers proceeds

in different phases, depending on the distance to

the source of the dissolved matter. Because of the

shallowness of rivers turbulent mixing over the ver
tical is the most important process near the source
of the dissolved matter. In the next phase turbulent
spreading over the width becomes the predominant
process. Meanwhile the cloud of dissolved matter
undergoes downstream convection by the mean flow
and spreading in the longitudinal direction. This longi
tudinal spreading is more difficult to describe. It hardly
depends on direct turbulent diffusion in longitudinal
direction, but is mainly due to different convection
velocities over the cross-section (e.g. caused by dif
ferences in water depth or curvature effects in river
bends), and transverse mixing (Fischer et al., 1979).
When the dissolved matter is sufficiently mixed
over the width a relatively simple description of
the transport in longitudinal direction, based on the
method of Taylor (1953), is possible. In this phase,
often called the longitudinal mixing phase, the spread
ing of the cloud of dissolved matter can be described
with a longitudinal dispersion coefficient, while the
cloud is displaced downstream by convection with the
mean flow velocity averaged over the cross-section,
u_{av}. Knowledge of the longitudinal dispersion of
pollutants in rivers is important, in particular after
accidental spills of harmful matter. The longitudinal

undistorted distorted Figure 1. Comparison of a non-distorted plot of the cross-section of a river bend, with a realistic aspect ratio of about 50 (top) and the usual distorted plot of the same bend (bottom). dispersion determines the extent of and the concentration in the cloud of pollutant that descends the river. The longitudinal dispersion coefficient depends on the transversal exchange of pollutant over the river width and the flow velocity differences over the width. The flow in a river is a shallow free surface flow. In such a flow the important horizontal length scales of the flow are one or more orders of magnitude larger than the flow depth, h. In rivers aspect ratios W /h, where W is the width of the river, of at least 50 up to a few hundred are observed. This is not always directly obvious from the usual distorted plots of cross-sections of rivers (see Figure 1). Approximate expressions for the vertical diffusion coefficient, D v , the transverse mixing coefficient, D t ,

and the longitudinal dispersion coefficient, D L , in

rivers are respectively (Fischer et al., 1979)

where u ∗ is the average bed shear velocity. For a river

with for example

this leads to

The times required for a fair mixing of the dissolved

matter over the vertical T v and over the width T t are

respectively (Fischer et al., 1979)

and the distances the cloud is displaced downstream

by convection in these mixing times are respectively

For our example river this means

Concluding, the longitudinal dispersion coefficient

is very large compared to the vertical and transverse

mixing coefficients. The vertical mixing is fast, but

the transverse mixing takes much more time, because

of the large aspect ratio involved. Important for the

discussion here is that the transverse mixing takes

place more or less within the distance over which the

river changes appreciably, e.g. by confluences with

tributaries. This would mean that the longitudinal dis

tribution of the concentration of a cloud of dissolved

matter would always be more or less Gaussian.

2 INFLUENCE OF DEAD WATER ZONES

In practice many measured concentration distributions

even far downstream of the sources of dissolved mat

ter are found to deviate appreciably from a Gaussian

distribution. Often a large tail is observed on the

upstream side. As most concentration measurements

are executed at a fixed position this leads to a tail for

the measurement of the concentration ϕ over time as Figure 2. Measured distribution of tracer concentration ϕ at Maximiliansau at Rhine-kilometer 362 during the tracer experiment 04/89 (from Mazijk, 1996). seen in Figure 2. Such a tail points to an insufficient transverse mixing and shows that the description of the longitudinal dispersion as Fickian diffusion is not correct. Such tails are caused by the so-called dead water zones, or stagnant zones, along the river: groyne fields, local broadenings, bordering harbours and lakes, old river branches, etc. These are zones with slow flowing water with low exchange with the main channel of the river.TheTaylor method and the resulting approximate expression for the longitudinal dispersion coefficient work well for a river without appreciable stagnant zones. However, when dead water zones are present, then the low exchange with the dead water zones leads to very long transverse mixing times, T_t, and lengths, L_t. When dead zones are present, the mixing length becomes easily much larger than the distance between the important tributaries and the Taylor method is not applicable anymore. A much used approach, the dead zone model, uses in that case a longitudinal dispersion coefficient for the flow in the main channel only and

accounts separately for the dead zones (Mazijk, 1996). To account for the dead zones requires a good knowledge of the exchange flow between dead zones and main channel and of the exchanged concentration. Generally for simplicity well-mixed dead zones are assumed, but more realistic models require knowledge of the flow in the dead zone to compute the concentration of the exchanged water. In principle it is possible to consider the river-dead zones system as a black box. Sufficient measurements of the development of the concentration distributions after earlier spills and tracer experiments may give enough information to predict the concentration development after a new spill. This is however only useful for well-monitored rivers as the Rhine. For other rivers the knowledge will have to be obtained mainly from laboratory experiments where the exchanges between 30 m Main stream (0.35 m/s) 3 m 2 m 3rd groyne field 5th groyne field 4th groyne field g r o y n e 4.5 m x y Mixing layer Sec. gyre Prim. gyre PTV-area g r o y n e

river and dead zones and the flow in dead zones is

investigated, or by computations with numerical mod

els that in their turn have to be validated with data from

such experiments.

3 EXPERIMENTS IN SHALLOW FLOWS

Experimental investigations of shallow flows require

large flumes because of the contradictory conditions

that play a role in such physical models. The flow has

to be turbulent, even in the dead water zones, which

requires a sufficiently large Reynolds number. More

over the value of the Froude number has to remain much below 1 to ensure that the flow is not affected by surface disturbances, e.g. around the tip of groynes or at the corners of a harbour entrance. These two con ditions lead to a maximum velocity and a minimum depth, depending on the kind of flow to be modelled. The most severe condition is the aspect ratio of the shallow flow that has to be observed. Together with the minimum depth from the Froude and Reynolds conditions this leads to very wide (and long) flumes. An example is the flume used by Uijttewaal (2003) for the investigation of the effects of groyne shapes on the flow around the groynes and in the groyne fields and on the exchanges with the river (see Figure 3). The dimensions of this flume are:

W = 5 m, h= 25 cm, length= 30 m. The average velocity in the main stream channel is u av = 0.35 m/s. An important measure, the ratio of the width of the groyne fields to the mean flow depth between the groynes is between 10 and 15 for the different cases investigated. Flumes of these dimensions are expensive and hence do not abound. In the chosen compromise between price and performance the aspect ratio is the usual victim. Several experiments in flumes with groyne fields are reported, where the width of the groyne fields is but a few times larger than the flow depth. It is obvious that because of 3-dimensional effects e.g. around the tip of the groynes the flow field will strongly deviate from the shallow flow in a real river. Hence results obtained from those experiments are hardly useful for practical purposes. In this paper shallow flow experiments in laboratory models of harbours along a river are discussed that suggest that even many experimental flows in wide shallow flumes are not sufficiently shallow. The flow in a shallow harbour along a river resembles in many respects the flow in a groyne field. 4 EXPERIMENTAL

SETUP FOR SHALLOW HARBOUR FLOW Several years ago a series of experiments was executed in a laboratory model of shallow harbours along 6m 3m 1m basin outflow harbour inflow river 18 m

Figure 4. Shallow flume for harbour experiments of Delft University of Technology. The inflow is at the right side, the

outflow at the left side. The straight river part has a length of 18 m. Along the river a rectangular basin of 3 m× 6 m allows

the construction of different harbours. 1 . 0 m 1 . 1.0 m 0 m 1 . 0 m harbour mixing laye r

sured with floats.

a flume to investigate the influence of shallowness and

of the layout of harbours and harbour entrances on the

flow in the harbours and in the harbour entrance, the

exchange through the harbour entrance, etc. (Booij,

1986). A straight flume served as a model for the river.

Along this river a basin was made in which several

harbours could be constructed (see Figure 4).

The flow in the harbours was driven by momen

tum transport through the mixing layer in the harbour

entrance between river flow and harbour flow. As an

example the flow in and around a square harbour

with sides of 1 m (the 1 m× 1 m harbour) is shown in

Figure 5. In this case the velocities were obtained by

measuring the displacements of floats that remained

just free from the bottom, in order to yield depth

averaged velocities (see Figure 6).The floats are 10 cm f l u m e b o t t o m 1 0 c m w e i g h t p o l y s t y r e n e b o d y 1 c m 1 c m water surface p a p e r h a t s t e e l Figure 6. Deep reaching floats, extending to just above the bottom to yield depth-averaged velocities. long, while the harbours and the river are kept at a depth of just above 10 cm. Another velocity measuring method used was by means of micro-impellers. The micro-impellers were placed at half depth where the velocity is not very far from the depth-averaged velocity. 5 EXPERIMENTAL RESULTS The aspect ratio of rivers W /h is of the order of 50 to several hundreds generally. Most dead water zones are

Figure 7. The flow in square harbour models of different shallowness, driven by the river flow. At left the velocity profiles

halfway the harbour are plotted. At right the layout and legenda are given.

Figure 8. Sketch of the secondary flow vortices restricted

to the near wall regions in shallow harbour flow.

equally shallow. Hence we concentrate on the shallow

est harbours in the investigation (W /h up to 30, where

W is the minimum value of length or width here). The

shallowest harbour is a square harbour with W = 3 m

hence with an aspect ratio W /h≈ 30.To investigate the

influence of shallowness this harbour is compared with

two square harbours with smaller widths, W = 1 m and

2 m (or aspects ratios 10 and 20) respectively.

For the investigation of the influence of shallow ness the micro-impellers placed at half depth were used. The measurements show that above an aspect ratio of 10 the character of the flow changes consider ably (Booij, 2003). From the measured velocities in a cross-section it can be concluded that in the 1 m× 1 m harbour the water rotates as a whole, which is also obvious from the results of the float measurements reproduced in Figure 5. On the contrary in the larger harbours the flow is concentrated along the sides and the centre is hardly affected, see Figure 7. This is due to the suppression of large-scale horizontal coherent structures because of the bottom influence, and to a phenomenon called differential advection (explained in chapter 6), which is connected with the secondary flow in the cross-sections. Both lead to a contain ment of the wall boundary jet and the secondary flow vortex, see Figure 8. 6 DIFFERENTIAL ADVECTION Differential advection makes its appearance in curved shallow flow. Its best known effect is in gentle river bends where the largest velocity is found at the outside bend. The same mechanism drives the curved flow in harbours to the near wall regions. Generally, the largest flow velocities in mildly curved shallow flow are found at the outside of the curved flow, e.g. the outer bend in curved river flow. The mechanism that makes the flow velocity at the outside of the curvature increase at the expense of the velocity at the inside is differential advection, which can be understood as follows. In mildly curved shallow flow the main flow velocity profile over the vertical is almost logarithmic. Hence the centrifugal force due to the curvature of the flow is larger in the upper part of the flow than near the bottom. On the average this centrifugal

force is compensated by the pressure gradient due to a surface slope towards the outer bend. The resulting force is directed to the outward side in the upper part of the flow and to the inward side near the bottom and hence leads to a secondary flow to the outside in the upper part and to the inside near the bottom (see Figure 9). The main flow and the secondary flow together form the helical flow observed in curved shallow flow. In mildly curved shallow flow the amount of water flowing outward is more or less equal to the amount of water flowing inward. However the main flow velocity is larger in the upper part of the flow than in the lower part, hence more main flow momentum is transported outwards in the upper part of the flow than inwards in

Figure 9. Mechanism of the origin of secondary flow in

mildly curved shallow flow and the resulting helical flow.

the lower part.This leads to a net transport of main flow

momentum in outward direction and consequently to

higher flow velocities at the outer bend.

In the harbour this differential advection leads to a

transport of the highest velocities to the outer walls.

This counteracts and suppresses the turbulent struc

tures that transport the high velocity from the wall to

the centre. This leads to the creation and a containment

of a wall boundary jet.

An interesting consequence of differential advec

tion is the poor reproduction of shallow curved flow

by 2-dimensional numerical models. In view of the

shallowness of rivers and tidal channels the preference

for 2-D horizontal models is understandable. However,

the momentum transport by differential advection (i.e.

from the region of low velocity at the inside bend to

the region with high velocity near the outside bend)

requires the implementation of a negative eddy vis

cosity, which will lead to stability problems. In 3-D

computations the secondary flow is computed and

hence its advection effects are included, without the

necessity of a negative eddy viscosity.

7 BEHAVIOUR OF THE HARBOUR CENTRE

In chapter 5 it was observed that the flow veloci

ties in the centre of the shallower harbours are very

low. This means that there is hardly an exchange of

water and hence dissolved matter between the centre

of the harbour and the outer region.This is also evident

from a dye experiment in the 3 m× 3 m harbour. This

experiment started with a more or less homogeneous

dye concentration in the harbour. After some time the

outer region had exchanged all its dye with the river,
Figure 10. Remaining dye patch in the centre region of the 3 m× 3 m harbour. The river part of the flume is at the top. The river flows from left to right. whereas the centre region was still strongly coloured see Figure 10. In less angular harbours the transition from a fully rotating harbour to a harbour with a hardly moving centre appears at slightly lower dimensions, as can be seen in Figure 11. Here a flow in a partly circular harbour is shown, measured with floats. Obvious is the slowly moving centre, although the diameter of the circular part of the harbour is slightly less than the width of a square harbour with corresponding velocity pattern. The angles of the square harbour appear to intensify turbulent disturbances that increase the exchange between centre and outer region. 8 INFLUENCE ON THE LONGITUDINAL DISPERSION The low exchange of the centre of shallow dead zones with the outer region and hence with the river harbour can have important consequences for the longitudinal dispersion and the tails

in the distribution of the dissolved matter. A dead zone influences the convection and the spreading of the dissolved matter by taking in a part of the dissolved matter as the cloud passes and releasing it gradually over the time, depending on the residence time of the water in the dead zone. In this way it decreases the (average) convection velocity of the cloud, increase the longitudinal spreading and may lead to a tail in the distribution. For a shallow dead zone the intake of dissolved matter from the passing cloud will be less, as the increase of the concentration of the centre lags behind, because of the low exchange. For a shallow dead zone this will lead to a lower increase of the longitudinal spreading by the fast exchanging outer region of the dead zone. As the dissolved matter from the centre is exchanged back more slowly, this exchange will last much longer and lead to a larger longitudinal spreading and a long tail in the distribution. The magnitude of these

Figure 11. Flow in a partly circular harbour, measured with floats. The river is at right. The flow direction in the river is from

top to bottom. Obvious is the slowly moving centre.

different effects depends on the extent of the different

parts of the dead zone and of the residence times of

those parts in relation to the passing time of the cloud.

Numerical models of the very shallow flow in rivers

with dead water zones require ample validation by

measurements, for which measurements in laboratory

models are used generally. This validation is needed

because 2-D models lack a few mechanisms as e.g.

differential advection and 3-D models require different

momentum exchange coefficients for different direc

tions that are at present not easily predicted. However,

the dead water zones in most laboratory models are not

sufficiently shallow. Hence the validation is based on

too deep flows generally. Consequently most numeri

cal models do not model the flow in the centre of the

dead water zones correctly, leading to too short res

idence times and hence incorrect predictions of the

longitudinal dispersion.

9 CONCLUSIONS

• Knowledge of longitudinal dispersion of pollutants

in rivers is important, in particular after accidental

spills of harmful matter.The longitudinal dispersion

determines the extent of and the concentration in the

cloud of pollutant that descends the river.

• The longitudinal dispersion is strongly influenced

by the presence of slowly moving (so called dead water) zones along the river, as are present between groynes, in old river branches, harbours, lakes or other bodies of water alongside the river. • The slow exchange of water and hence of dissolved pollutants between river and dead water zone results in very large values of longitudinal dispersion coefficients. • Dead water zones also lead to the large tails that are often found in the distributions of pollutants, which show that the description of the longitudinal dispersion as Fickian diffusion is not correct. • Measurements in a laboratory model of square harbours along a river show that above an aspect ratio of 10 the character of the flow changes considerably. For aspect ratios up to 10 the flow in the harbour rotates more or less as a whole.The flow in shallower harbours, or other dead zones, is more concentrated along the sides and the fluid in the centre moves hardly. • The low velocity in the centre of shallow dead zones leads to very long residence times and hence much higher values of the longitudinal dispersion coefficients and to long tails in the concentration distributions. • Laboratory models of dead zones along rivers, even those in wide, shallow flumes, are generally not shallow enough to observe this stagnant centre effect, and hence show a behaviour that is quite different from the shallower dead zones found mostly in

practice.

• Measurements in flumes with insufficiently shal

low dead zones are not useful for the validation of

numerical models of longitudinal dispersion.

Pollution transport in the lagoon of Grado and Marano: a two dimensional

modelling approach

M. Petti & S. Bosa

Dipartimento di Georisorse e Territorio, University of Udine, Italy

ABSTRACT: Pollution and water quality in lagoon areas represent a problem for human health and for the

local economy particularly felt by people living nearby. In Italy the lagoon of Grado and Marano, located in the

Northeast part of the Adriatic Sea, is subject to mercury pollution. It is held by some that the source of pollution

is the river Isonzo that drains polluted sediments from a Slovenian region and partly feeds the lagoon. Others

believe that the source of pollutants should be looked for elsewhere, for example in some industrial establishments

which, in the past, are believed to have introduced concentrations of polluting material into channels that flow

into the lagoon. In this paper a 2D finite volume model is proposed for studying the dispersion of a dissolved

pollutant in the lagoon environment and the results obtained in applying the model to the lagoon of Grado and

Marano are illustrated.

1 INTRODUCTION

The transport of pollutants is a very complicated envi

ronmental problem that involves many disciplines such

as ecology, chemistry, toxicology, sedimentology and

fluid mechanics. One of the roles of fluid mechanics is

to develop hydrodynamic models able to interpret as

well as possible the propagation of pollutants in free

surface water environments.

A numerical approach to pollutant transport can

be based on the classical advection-diffusion equation

founded on the passive tracer concept and suitable for

a widely dispersed substance. This equation may be

integrated by a Lagrangian or Eulerian approach. The

first one, known also as particle tracking, is a natu

ral approach in the presence of point sources, but a

huge number of particles may be necessary to repre

sent the concentration in each grid box. In the Eulerian approach the concentration equation describes the motion of a substance by numerical advection schemes, but care must be taken over these to control numerical diffusion or oscillations in the presence of sharp gradient (James 2002). The relative importance of advection and diffusion in the dispersion of a tracer is represented by the Péclet number $P_e = U_0 L_0 / D_0$, where U_0 is a horizontal velocity scale, L_0 the length scale and D_0 the horizontal diffusivity scale. As observed by Prandle et al. (1993) in southern North Sea studies, in lagoon basins the Péclet number is very high thus the advective transport prevails on the diffusive. To simulate an advection problem it is very important to have an efficient hydrodynamic and transport model, and care must be taken in the treatment of the advective terms in non-linear hydrodynamic equations (Dragoslav 2001). In the present work we propose a numerical model based on the Eulerian approach for the simulation of 2D solute transport with unsteady advection-diffusion. A finite volume method is used to solve non linear equations by a Godunov approach supported by a robust and efficient approximate solver proposed by Harten, Lax and van Leer (HLLC) (Toro 1999). The resulting scheme is second-order accurate in space and time and satisfies the Total Variation Diminishing (TVD) condition. After a number of tests done to check its validity the model was applied to pollution transport in the lagoon of Grado and Marano, affected by serious forms of mercury pollution. Various scenarios of possible sources of mercury pollution have been studied, also keeping in mind the wind, a meteorological factor which is very important in the lagoon dynamics of Grado and Marano. A discussion is reported on the results obtained simulating those considered to be the principal sources of immission of such a pollutant. Finally, some conclusions are given, along with a very

brief account on ongoing and future work. 2 MODEL EQUATIONS Two-dimensional unsteady solute transport can be described by the depth-averaged equations in the

vectorial and conservative form:

obtained coupling well-known shallow water equa

tions with the advection-diffusion transport equation

(Ligget 1994). Here (x, y) are Cartesian coordinates,

U(x, y, t) is the vector of conserved variables, F c , G c ,

F d and G d the advective and diffusive fluxes respec

tively in the xand y-directions and S(U) the source

term. Thus:

where U and V are the depth averaged velocities

respectively in the xand y-directions, D xx and D yy the

diffusion coefficients of the pollutant, h is the water

depth, C the depth averaged pollution concentration,

and g the acceleration due to gravity. Source term S(U)

is defined by: where S 0x and S 0y are the bed slopes, n is the Manning resistance coefficient, f a term that takes the Coriolis’s acceleration into account, ρ a the air density, ρ w the water density, W x , W y the wind velocities in the x and y directions and C D the wind shear coefficient. Q is the depth averaged pollutant source or sink. Analyzing the advection-diffusion equation in dimensionless form (starred variables) we obtain: where P e =U 0 L 0 /D 0 is the Pêclet number and U 0 , L 0 and D 0 are respectively the velocity, spatial and diffusion scales. A simple analysis of scales in the lagoon of Grado and Marano gives a Pêclet number P e ≈ 5000. This means that the advective transport prevails on the diffusive and therefore particular care must be taken over the choice of the numerical scheme to solve the equations in order to avoid an excessive and unrealistic numerical diffusion. Moreover, observing that a sudden immission of pollutant represents a real shock phenomenon, a scheme of integration which is not very numerically diffusive is necessary as well as a shock-capturing scheme. 3 NUMERICAL METHOD In accordance with the observation made,

which is the necessity for a numerically little diffusive and shock-capturing scheme of integration, a finite volume method (FVM) was chosen. One way to solve Equation 1 is to keep the time variable t continuous and consider the equation we obtain by integrating Equation 1 over a two-dimensional generic control volume (Fig. 1): where H c = [F c , G c] is the tensor of advective fluxes, H d = [F d , G d] the tensor of diffusive fluxes, n the outward unit vector normal to the boundary ∂Ω, dl a length element and H ·n dl the flux components normal to the boundary ∂Ω. <U> and <S> represent the values: averaged on the control volume Ω. x y n dl control volume H c ·n dl H d ·n dl Ω ∂Ω •

Figure 1. Generic control volume used to integrate

Equation 1. x

y y (l) x (l) H ck ·n k side k cell i intercell flux cell i+1 Δl k

Figure 2. i-th control volume and the fluxes associated to

its k-th side.

In the finite volume approach Equation 5 has to

be satisfied on each control volume that results from

discretising the physical space into a number of poly

hedral control volumes or computing cells; the accu

racy of the spatial discretisation depends on the

particular scheme with which the fluxes are evaluated.

Assuming quadrilateral finite volume Ω i , where the

subscript i identifies a generic cell (Fig. 2), Equation 5

can be discretised as:

where k identifies a generic side of the cell, Δl k its

length, and<H c > k and<H d > k are the average fluxes

across the intercell boundary Δl k : For simplicity in the following we omit the parentheses <>. To solve the semi-discrete Equation 7 we can use a standard

split-operator scheme in which the advective and diffusion-source steps are solved separately. To this purpose we write Equation 7 as: where: and: are called respectively advection operator and diffusion operator with source term. Equation 9 can be solved in time by means of standard ODE methods; here we use a splitting scheme that consists in solving (Yanenko 1971, Toro 1999) the two subsequent initial value problems at each time step: U n i being the solution at time step t and U n+1 i the target solution at time step t+Δt. U adv i is the solution of the first initial value problem (Eq. 12). It can be seen immediately that system 12 is hyperbolic while system 13 is diffusive and it has a source term. This means that while for the second system it is possible to choose from a relatively ample range of integration schemes, for the first a more careful evaluation is necessary. One way to solve system 12 is to solve the so-called local 'Riemann problem'. The most delicate aspect in the solution of this problem is the evaluation of the advective intercell flow H ck ·n k (Fig. 2) by an appropriate solver. In this paper we use the approximate Harten, Lax, van Leer (HLLC) solver modified by Toro (1999). 3.1 The HLLC solver The intercell fluxes H ck ·n k , as H dk ·n k , can be estimated by exploiting the rotational invariance (Toro 1999):

where:

is the vector of rotated conserved variables referred to

a local (x (l) , y (l)) Cartesian system (Fig. 2), T k is the

rotation matrix:

and T −1 k its inverse. Through Equation 14 the evalu

ation of the intercell fluxes is reduced to that of an

augmented one-dimensional problem and the tech

niques used for the evaluation of the flow in these

systems can be applied. The HLLC solver is one of

these techniques.

The HLLC method gives an approximate estimation

of the fluxes for solving the Riemann problem (Fig. 3):

across the intercell under consideration (side k of

Fig. 2).

Following the ‘method of characteristics’ proposed

by Stoker (1957), and subsequently widely dealt with

by Whitham (1974), the Riemann problem is solved by

referring to a characteristic diagram (x (l) , t) (Fig. 4).

The area (x (l) , t) is divided into four regions delim

ited by the straight lines representing wave speeds S m

(m= 1, 4) corresponding to eigenvalues of the hyper

bolic problem described by Equation (17).

In the regions 1 and 4 conserved variables (U (1) k

and U (4) k) and fluxes (F (1) k and F (4) k) are
constant and

Figure 3. The local Riemann problem solved by the HLLC

method and a MUSCL-Hancock TVD scheme. known. In the
regions 2 and 3 mean values of the conserved variables (U
(2) k and U (3) k) and fluxes (F (2) k and F (3) k) are
obtained integrating Equation 17 successively over the
control volumes [x (l) i , x (l) i+ 1]× [0,t], [S 1 t, S
∗ t]× [0,t] and [S ∗ t, S 2 t]× [0,t] (Toro, 1999).
Results for fluxes are: where F ck =H ck ·n k is the target
intercell flux and: The wave speed estimates S 1 and S 2
are performed according to elementary wave solutions of the
Riemann problem (i.e. rarefaction, shear or shock waves).
The wave speed S ∗ = S 3 = S 4 is estimated by the equation
proposed by Toro (1999): Assuming: the intercell flux F ck
estimated by Equation 18 is first-order accurate in space.
To solve the problem Figure 4. Structure used in the HLLC
method to solve the Riemann problem.

at second-order we use a MUSCL-Hancock TDV

scheme (Hirsch 1988, Toro 1999) in conjunction with

a ‘minmod’ limiter for slopes α i and α i+1 (Fig. 3).

The solution of system 13 (diffusive with source

term) was found by applying a standard finite differ
ence centered scheme which is second-order accurate.
Finally, the second-order time accuracy is obtained
using a split-operator technique that brings to the
scheme:

4 RESULTS OF SOME TESTS

A number of tests were carried out to check the model,
here we show the results of a couple of them: one
purely advective and one purely diffusive.

4.1 Advective test

In this test we analyze the pollutant concentration
transport in one-dimensional dam-break problems.
The domain, 50 m long (x-axis) and 10 m wide (y-axis),
is discretised by cells of dimensions 0.5× 0.5 m. The
Courant-Friedrichs-Lewy coefficient is C cfl = 0.9.The
initial conditions (t= 0 s) are given in Table 1.
In Figure 5 is shown the comparison between
numerical and analytical solutions of the pollutant
concentration transport at time t= 7 s.

4.2 Diffusive test

In this test we analyze the pollutant concentra
tion transport in a purely diffusive one-dimensional
problem.
The domain, 5 m long (x-axis) and 2 m wide (y
axis), is discretised by cells of dimensions 0.1×

0.1 m. The Courant-Friedrichs-Lewy coeffcient is

C cfl = 0.8. The initial condition is still water, the

boundary condition at x= 0 is set at a constant immis

sion of pollutant concentration C = 1. In this test we

assume a constant isotropic diffusion coefficient D=

0.25 m 2 /s.

In Figure 6 is shown a comparison between numer

ical and analytical solutions (Fisher et al. 1979) of the

pollutant concentration diffusion.

The lagoon covers an area of around 16,000 hectares, for a length of around 32 km and a mean width of 5 km. It is connected to the open sea through 6 natural mouths (Fig. 7). Recent investigations have been carried out for the dredging of the lagoon channels and they have underlined, among the various forms of pollution, a consistent presence of Mercury diffuse more or less throughout the whole Lagoon. Two hypotheses have been formulated about the origin of this pollution: the former ascribes the polluting 0 5 10 15 20 25 30 35 40 45 50 0 0.2 0.4 0.6 0.8 1 1.2 x (m) C (-) analytical solution numerical solution Figure 5. source to the mercury area of Idrija in Slovenian ter

ritory. This area, close to the Isonzo, nourishes the

river that on Italian territory flows into the Lagoon

along a channel called Isonzato. The latter hypothe

sis (Mattassi et al. 1991) ascribes the source to the

chemical industries, such as that of chlorine-soda for

the production of cellulose in Torviscosa. According

to Matassi such chemical industries, located along the

river Ausa, have introduced, between 1949 and 1970

around 20 kg/day of pollutant and between 1970 and

1984 around 7 kg/day. Since 1984, the adoption of

more efficient systems of recovery of mercury has

led to the substantial disappearance of such sources

of pollution.

The two hypotheses have been studied using the

implemented model.

5.1 Mesh

For the simulations a mesh of 31,041 quadrangular

elements was built with mean dimensions varying between 6 and 250 m (Fig. 8). The mesh was opportunely thickened in proximity to the lagoon channels. 5.2 Manning, diffusion and wind coefficients A uniform Manning resistance coefficient n = 0.020 m −1/3 s was assumed on the whole lagoon basin. This value was obtained by elaborating data from literature and from measurement taken on site, based on the reduction of the wave amplitude and the tidal delay recorded at some measuring points located inside the lagoon

(Fig. 9). As far as concerns the diffusion coefficients D xx and D yy , an isotropic condition was assumed due to the scarce importance of the diffusive process of dispersion in comparison to the advective. The conditions are characterized by a single diffusion coefficient D=D xx =D yy = 0.25 m 2 /s deducted from data from literature (Fisher 1979). The wind shear coefficient was given the value C D = 1.0 · 10 -3 , obtained from elaborating data found 0 1 2 3 4 5 6 7 8 9 x 10 4 19

in literature on the lagoon, which specified changes in the sea water level in correspondence with particular wind event. The value found of C D agrees with the values proposed by Hicks et al. (1974) in the case of closed basins with reduced water depths.

Finally, to estimate the mean wind velocity W , a statistic analysis was carried out on the data recorded by wind stations considered relevant to the lagoon of Grado and Marano. In Figures 10, 11 are shown the mean directional distribution obtained, this highlight the prevalence of the winds coming from the northeast (Bora) and from the southeast (Scirocco). From this

data was drawn out an average occurrence of the Bora 1 % 2 % 3 % 4 % 30 210 60 240 90270 120 300 150 330 180 0 NE SW EW SE NW S N Figure 11. Directional distribution (annual average) of the winds greater than 15 m/s blowing on the lagoon of Grado and Marano. characterized by a speed W = 10 m/s and direction of origin θ= 50 ∘ N. While the Bora blows directly on the free surface of the lagoon water, the Scirocco blowing on the whole Adriatic sea manifests itself with a set-up of the sea due to the wind that increases the tidal level. For this reason the effects of the Scirocco have been included in the amplitude of tidal oscillations. 5.3 Boundary and initial conditions Beach and wall boundary conditions were assumed everywhere except for the six lagoon mouths where tidal oscillations described subsequently were imposed. As characteristic tides, two oscillations were selected.The first with an amplitude equal to 0.5 m and the second 1 m both with periods of 12 hours. These values were deduced by analyses of the data recorded by the tide-gauges of Trieste and Grado keeping in mind the existing correlation between them.The above mentioned values are held representative of normal

oscillations of tides (0.5 m) or of medium to high tides (1.0 m). These tidal values are already inclusive of the set-up induced by the Scirocco. As initial conditions the values of velocity and level in the basin are those found after some tidal oscillations. 5.4 Influx of pollutant from the river Ausa The study was conducted for two different tidal amplitudes H with the same period T , in the absence and

(test AUS1).

Figure 13. Distribution of the pollutant from the mouth of the Ausa-Corno after 18 h of simulation. Tidal amplitude 1 m,

period 12 h, absence of the Bora. Increasing concentration passing from the white tonality to the black. in the presence of the Bora. The characteristics of the simulation are shown in Table 2. A value of C cfl = 0.7 was used for a duration of the simulation equal to 24 hours. Figure 12 shows the mean velocities obtained in some lagoon mouths with the simulation AUS1. These values like those of the other simulations, are coherent with the only available measures in literature, even if not very recent (Dorigo, 1965). Figure 13 shows the results after 18 hours of simulation in absence of wind (test AUS2) and Figure 14 shows those in the presence of the Bora (test AUS2A). In the absence of wind (Fig. 13) a portion of the total mass of pollutant introduced from the mouth of the Ausa-Corno remains as diluted pollutant inside the basin of Porto Buso and the remainder goes out to sea through the Porto Buso channel. Instead, in the presence of wind (Fig. 14) the level of concentration of pollutant remains rather high because the hydrodynamic regime induced by the wind prevents an immediate exit of the pollutant from the Lagoon. Furthermore, the mass of polluted water is pushed towards the west, involving areas such as Marano and Lignano, apparently immune from a phenomenon of this type. 5.5 Influx of pollutant from the river Isonzo In this simulation we assumed an immission of pollutant into the lagoon from the river Isonzo (along the Isonzato channel) equal to 10 kg for a duration of 2 hours; this amount is considered to be representative of the mercury coming from Slovenia.

Figure 14. Distribution of the pollutant from the mouth of the Ausa-Corno after 18 h of simulation. Tidal amplitude 1 m,

period 12 h, presence of the Bora (10 m/s). Increasing concentration going from the white tonality to the black.

Table 3. Characteristic conditions used for the simulation of

pollutant from the River Isonzo (through Isonzato channel).

Tide	Wind	Pollutant	H	T	W	θ	Quantity	Time
Test	(m)	(h)	(m/s)	(∘ N)			(Kg)	(h)
ISO1	0.5	12	0.0	–			10	2
ISO1A	0.5	12	10.0	50			10	2
ISO2	1.0	12	0.0	–			10	2
ISO2A	1.0	12	10.0	50			10	2

Also in this case, after fixing the quantity of introduced pollutant, the study was conducted for two different oscillations of tide (0.5 m and 1 m of amplitude) both in the absence and in the presence of the Bora (Tab. 3).Also in this application a value C cfl = 0.7 was used and the duration of the simulation was 24 hours.

In these circumstances, the results both in the presence or the absence of wind are almost the same due to the embankment of the road that connects Grado to Belvedere. In Figure 15 the results after 18 hours of simulation in the presence of the Bora are shown (test ISO2A).

As can be seen (Fig. 15) in this case, even if the total amount of pollutant introduced is equal to that of the previous simulations (20 kg), its concentration remains much higher.

Such a phenomenon can be ascribed to the presence of the Grado-Belvedere road embankment that prevents water exchange between the East (Basin of Primero) and the

West (Basin of Grado) part of the lagoon, with the only exception of two small channels (Figariola and Grado). The analysis of the hydrodynamic field also shows the scarce vitality of the basin of Primero, that has low velocity and water level oscillations if compared with the other basins. Returning to the dispersion of pollutant, this kind of hydrodynamic isolation of the Basin of Primero substantially limits the passage of pollutant from the Isonzato channel over the Grado-Belvedere road embankment. Most of the small amount of pollutant that passes beyond the road remains near the road itself while the rest leaves the lagoon through the mouth of Grado. 6 CONCLUSIONS AND FUTURE WORK A finite volume numerical model was developed for the study of the dispersion of a pollutant dissolved in shallow water. Many tests of verification showed its reliability and accuracy. Some hydrodynamic tests carried out on the lagoon of Grado and Marano confirmed these characteristics, showing coherence between numerical results and experimental data available in literature. Subsequently the model was applied to the study of the dispersion of pollutants dissolved in the lagoon of Grado and Marano. The results showed the influence that the Bora and the road embankment that connects the town of Grado and Belvedere have on the dynamics of such a phenomenon.

Figure 15. Distribution of the pollutant from the River Isonzo (through Isonzato channel) after 18 h of simulation. Tidal

amplitude 1 m, period 12 h, presence of the Bora (10 m/s). Increasing concentration going from the white tonality to the black.

This study showed that a pollutant, for instance

mercury, from the river Isonzo, could cross the road

embankment only in a small part, and most of it would

anyway laeve the lagoon through the mouth of Grado.

Thus, it is not very reasonable to ascribe the pollu

tion of the West side of the lagoon (lagoon of Marano)

to the Isonzo river. Moreover, a source of pollutant

from the river Ausa could easily propagate towards

Marano and Lignano, especially in the presence of the

Bora. This could justify the presence of mercury in the lagoon of Marano too, with concentrations similar to those present in the basin of Primero.

Improvements of the implemented model, espe cially for long periods of simulation, can be obtained using techniques of interpolation ENO and WENO (Jiang & Shu, 1996) that allow a more accurate solu tion of the local ‘Riemann problem’ (Petti & Bosa 2003).

Numerical simulation of transport processes in not uniform turbulent streams

I. Cotto & R. Revelli

Dipartimento di Idraulica, Trasporti ed Infrastrutture Civili, Politecnico di Torino

Corso Duca degli Abruzzi, Torino, Italy

ABSTRACT: The numerical simulation of the advection dispersion equation with non constant parameters is presented in order to simulate the behaviour of a pollutant in a natural stream with variable geometric and dynamic characteristics, i.e. with a non constant water depth, mean velocity and dispersion coefficient. A collocation interpolation method based on sinc function is used and the results are presented in the form of temporal and spatial moments. Both conservative and non conservative substances are accounted for, this latter with a decay reaction rate both linear and non linear. The results show in particular the behaviour of the centroid, variance and skewness depend on the velocity variation along the

river and decay reaction rate. It was also found that the influence of the water depth change is less important than the velocity variation.

1 INTRODUCTION

The presence of pollutants and hazardous substances in a natural stream is a problem of great interest both from the speculative and applicative points of view. It is in fact well known that this problem is important in the environmental economic debate and how a good comprehension and description of the phenomena are necessary to apply correct development and management politics.

Since the early fifties a great deal of work has been devoted to describing the behaviour of the substances in a turbulent stream and natural flow and one of the main theoretical results is the formulation of the advection-dispersion equation (e.g. Taylor 1953, 1954, Aris 1956, Fisher et al. 1979) with the description and formalization of the effect of phenomena such as turbulent diffusion and shear dispersion. This classical advection-dispersion equation however generally considers a uniform stream and if a non conservative substance is taken into consideration the decay reaction is of a linear type.

Under these assumptions the result of the mathematical problem for an instantaneous release is of a

Gaussian type form for the concentration (e.g. Fisher et al. 1979); an integral convolution, therefore, makes it possible to find the mathematical form of the con centration distribution for each form of the release.

On the contrary, it is not normally possible to find an analytical solution with a non uniform stream or non linear decay reaction. Starting from these fundamental results, many studies over the last decades have been dedicated to refining the Taylor model in order to better describe some features that are present in natural streams. This has principally been due to the fact that a great number of laboratory and field studies (dedicated to validating the analytical models or to fitting the appropriate parameters), recognised a bias between the theory and the data (for example, the problem known as “skewness persistence”, etc. . .). It is now clear that the presence of transfer mechanisms, of a physical, chemical or biological nature, between the main stream and the boundaries (river bank, bed, free surface), could give rise to discrepancies, in particular due to the occurance of long tails in the concentration distribution (e.g. Hays et al. 1966, Trackston & Schnelle 1970, Day et al. 1975, Valentine & Wood 1977, Benkala et al. 1980, Nordin & Troutman 1980, Kim et al. 1990, Czernuszenko & Rowinski 1995, Hart et al. 1995, Worman 1998, Schmid 2002). Even sorption-desorption phenomena due to the presence of suspended sediment (e.g. Ng & Yip 2002, Revelli & Ridolfi 2002, 2003) or the kinetics between the river and the neighbouring aquifers (e.g. Kim et al. 1990, Worman 2000) are able to modify the form of the concentration breakthrough. As in Taylor’s model, a quite general characteristic of the models, that are generated according to the previous considerations (i.e. transient storage equation, aggregated dead zone models, stochastic formulation

etc. . .), is to assume a uniform stream, or at least to describe the river as a sum of different reaches with constant characteristics.The possibilities of a variation in the parameters along the river (Zoppou & Knight

1997, Gupta & Cvetkovic 2000) are not often taken in consideration. This is principally due to the fact that in this case it is not generally possible to find an analyti cal solution to the problem and methods like moments analysis cannot be applied.

The present work intends to join in the debate with a numerical analysis of a non constant coefficient model. In particular, the advection-dispersion equa tion will be simulated starting from a stream with quantities such as water depth, mean velocity or disper sion coefficient which are variable along the stream. In addition the chemical, physical or biological transfer mechanisms with boundaries or suspended load will be neglected.

The possibilities of simulating the behaviour of a non conservative substance will also be taken into consideration. In particular both the linear and non linear decay rate will be considered in order to model the common chemodynamic nonlinearities (Schwarzenbach et al. 1993, Brezonik 1996, Schnoor 1996).

The paper is organized as follows: in the next sec tion the model is briefly mentioned, and the solution method is presented. The results of several simulations are given in the last sections and some conclusion are

drawn.

2 MATHEMATICAL PROBLEM

Let us consider a one dimensional, steady, not uniform turbulent channel flow with a mild slope i b . A reference system with the x-coordinate along the channel is introduced. The stream has a depth H (x) and a mean velocity U (x).

Without any lack of generality, we assume that the hydraulic geometry of the channel can be expressed as a power law function along the length of the stream (Leopold & Maddock 1953, Gupta & Cvetkovic 2000), so that

where a H , and a U are dimensional constants; b H and b U are dimensionless constants; and L is a reference length, which will be assumed to be equal to the length of the channel.

Let us also suppose that a chemical is dispersed in the stream and let us define C =C(x,t) as the averaged concentration of the chemical per volume of water. If we suppose that there is a local balance between the longitudinal advective transport and the cross-sectional turbulent diffusive transport in any point of the stream, and that the chemical is uniformly distributed along the vertical coordinate, we can write where K(x) is the dispersion coefficient; and R accounts for the decay reaction. In order to describe the dispersion phenomena we can write (Elder 1959), for sake of simplicity, where u ∗ (x)= (gi b H) 0.5 is the friction velocity and g is the gravity acceleration, therefore so that a K = 18.57i 1/2 b a 3/2 H and b K = 3/2 b H . Rearranging 1 gives where the prime means the derivative with respect to x. By substituting the Equations 2, 3 and 4 in the Equation 5,

the mathematical model is recovered. The mathematical statement of the problem related to Equation 5 can be obtained by linking the previous equations to suitable initial and boundary conditions. The boundary conditions are defined by while, as an initial condition, we require where ϕ(x) can be any function, e.g. a Dirac delta, in order to simulate an instantaneous release. 3 NUMERICAL METHOD The mathematical problem of the Equations 5, 6 and 7 is numerically integrated using an interpolationcollocation method based on sinc functions (Bellomo & Ridolfi 1995) that is particularly suitable for nonlinear models and to simulate wave phenomena (Revelli & Ridolfi 2004). Although the method has been presented in several papers let us here recall the main steps while reference can be made to the works by Bellomo & Ridolfi (1995) and Revelli & Ridolfi

(2004) for a detailed description and for an extensive

bibliographic review.

The method is a modification of the differential

quadrature method proposed by Bellman et al. (1972)

and Satofuka (1983). It consists of the transformation

of the Equation 5 into a system of ordinary differential

equation with a spatial discretisation of the variable

C(x, t) in a finite number of points and considering

the values of the variable itself in the spatial nodes as

new unknowns. Let us choose, in the spatial domain,

x ∈ [0, L] a number n of collocation equispaced points

with i= 0, . . . , n+ 1 and h=L/(n+ 1). We then col

locate an interpolating function S i (x) in each point so

that the solution of the Equation 5 can be approximated

with the summation

where u i (t)= u(t, x i). In this way each term of 9 is

given by the product of two functions: the first which

depends on space and the second which depends on

time.These latter functions u i (t) are the new unknowns

of the problem.

In this work we have choosen a sinc as the inter

polating function (for alternative possibilities see for

example Bonzani 1997)

with z i =π(x/h- i) and δ Kronecker's delta.

By placing the Equation 10 in the Equation 9 and

deriving with respect to x we obtain

where

with a ii = 0 and b ii =-1/3(π/h) 2 .

The substitution of the Equations 9-13 in the

Equation 5 transforms it into a system of ordinary

differential equation that can be solved, linked to

the proper boundary and initial conditions, with the

aid of classical iterative methods such as the Runge

Kutta, multi-step Adams-Multon or Adams-Bashforth

methods. 4 TEMPORAL AND SPATIAL MOMENTS The solution of Equations system 5-7 is analysed through the use of the temporal and spatial moments; some features of the solution of the constant coefficient model can in fact be given in terms of the Laplace transform of the solution itself and with the consideration that the moments can be calculated by expanding in Taylor series the Laplace transform itself (e.g. Aris 1956, Nordin & Troutman 1980, Czernuszenko & Rowinski 1995, Schmid 2002). Temporal (central) moments of the p-th order can be defined as and similarly the spatial (central) moment of the p-th order can be defined as where m p t and m p x are temporal and spatial noncentral moments of the p-th order respectively. It is important to note that in 14 and 15 we have replaced the usual superior limit +∞ which T and L which are the time length simulation and the channel length, respectively; this is important for the

subsequent discussion of the results. If we normalize the concentration with respect to m 0 we can find the links between 14 and 15 and the centroid. In this way we are able to find the centroid m, variance σ 2 , and skewness coefficient G: In the case of the constant coefficient model and ϕ(x) as a Dirac delta it is possible to find an analytical formulation for 16-18 (e.g. Nordin &Troutman 1980). In this case, for the spatial case, it is easily to obtain

while for the temporal case one obtains

5 SIMULATIONS AND RESULTS

Using the previously described numerical method,

the advection-dispersion equation with nonconstant

parameters is simulated. The set of parameters that

we kept constant for the whole series of simulations

are i b = 0.001, L= 33.6 km, T = 9 hr, a H = 1.27 m and

a U = 0.48 ms −1 which means a K = 0.84 m 2 s −1 . These

parameters are quite similar to the set proposed by

Gupta & Cvektovic (2000) and Revelli et al. (2004)

so useful comparison can be made. The parameters

that we changed are b H and b U which we varied from

0 to 0.6. The analytical solution corresponding to the

constant coefficient is given by b H = b U = 0.

The chosen parameters imply a variation of the

velocity from the initial value of 0.48 ms −1 (x= 0) to

0.73 ms −1 for the highest b U (x=L) and a water depth

variation in the river from the initial value of 1.27 m

(x= 0) to 2.22 m for the highest b H (x=L). Corre

spondingly the variation of dispersion coefficient lies

between 0.84 m 2 s −1 to 1.94 m 2 s −1 .

We changed the value of b H or b U in every sim

ulation keeping the others identically equal to zero:

in this way the influence of each single parameter it

easily recognizable.

Regarding the initial condition we always used the

same function i.e. a gaussian type form in order to

simulate a common source form.

We chose a spatial discretisation grid with n=300

while the system of ordinary differential equations was

integrated with the Adam predictor-corrector method

with an adaptative time step.

5.1 Conservative substances (R= 0)

Figure 1 shows the spatial centroid versus time for

different values of the parameter b U .The values were

normalized with respect to m x,0 , i.e. value given by

the Equation 19 of the constant parameter model. The

centroid increases regularly and at the end of the sim

ulation it can be greater than at the start by about 2 4 6 8 t(h) 1.05 1.1 1.15 m x m x,0 b U = 0.10 0.20 0.30 0.40 0.50 b U = 0.60 ƺƺƺƺƺƺƺƺ Figure 1. Spatial behaviour of the centroid for different values of b U (b H = 0). The values are normalized with respect to the constant parameter value m x,0 . 6 8 10 12 14 16 x(km) 0.9 0.95 1 m t m t,0 b U = 0.10 0.50 0.40 0.30 0.20 b U = 0.60 ƺƺƺƺƺƺƺƺ Figure 2. Temporal mean behaviour for different values of b U (b H = 0). The values are normalized with respect to the constant parameter value m t,0 . 15–20% for b U = 0.60. The same behaviour occurs if we consider the b H variation but the change is in the order of 0.1%. This is a characteristic that is almost constant over the whole range of simulations: there is a considerable influence of b U

and a practically nonexisting influence of b H . Figure 2 shows the behaviour of the temporal mean for different values of parameter b U . Even in this case, the influence of b H is unimportant (a few fractions of unity). The behaviour in this case is different from the previous example, because there is a diminishing value of the rate with respect to time. The difference, with respect to the constant value model, can be up to 10% and the centroid exhibits a practically linear growth even for non constant coefficient models. The spatial range in Figure 2 was chosen in order to calculate the temporal moment for the whole cloud; for this reason it results to be lesser than the total spatial considered domain [0, L]. Normally analytical solutions do not suffer from this limitation (see Equation 14) because an indefinite channel length and a simulation time that is greater than the time necessary 2 4 6 8 t(h)

of b U (b H = 0). The values are normalized with respect to the

constant parameter value σ 2 t,0 .

for the whole cloud to reach the prefixed section are

often assumed.

The influence on the variance is more marked.

Figures 3 and 4 show the spatial and temporal variance

respectively, for different values of b U . The behaviour

is similar to that of the corresponding centroids. As

expected, there is a general growth in the dimensions

of the clouds and this growth is practically linear for

the spatial variance while a deviation from linearity

is evident when considering the temporal variance. It

is important to note that the influence of b U is up to

60% for spatial case while for the temporal one we

find a difference up to 15% with respect to the con

stant value model. Even for b H variations, there is a

similar influence but it is less marked: about 5-6% for

both cases.

As far as the spatial skewness is concerned, the sim

ulation shows that a change in parameters does not

change the value of the form of the cloud: i.e. the

skewness remains practically equal to zero and the

concentration shows evidence of a Gaussian type form

during time evolution. 6 8 10 12 14 x(km) 0.02 0.03 0.04 0.05 G t 0.30 0.40 0.50 b U = 0.60 b U = 0 (anal. sol.) 0.20 0.10 Figure 5. Temporal skewness behaviour for different values of b U (b H = 0). However, the temporal skewness, for different values of b H or b U exhibits an always decreasing behaviour and tends to G t,0 which tends to zero as x→∞ as x -1/2 (Nordin & Troutman 1980) even though the influence of b H is very low as in previous cases. The skewness now ever always decreases and the

difference between the constant parameter model is of the order of +50% at the start of the considered spatial domain (Fig. 5). 5.2 Non conservative substances (R ≠ 0) The result of the evolution of a non conservative substances is presented as a second series of simulations. In particular, we suppose that a decay rate exists and the most general case is considered in which the decay is nonlinear. The reaction rate, R in the Equation 5 is therefore modelled according to the power law where λ is the decay rate constants – with units of measure Kg 1-r m 3r-3 s -1 – and r≥ 1 in order to model the common chemodynamic nonlinearities (Brezonik 1996, Schnoor 1996, Schwarzenbach 1993). It is possible to find the analytical formulation for the linear case (r= 1), for the constant parameter model, corresponding to the Equations 19 and 20. In particular for the temporal case we found (e.g. Schmid 1996) where α= (a 2 U + 4a K λ) 1/2 , and α→ a U as λ→ 0. x (km) b U = 0.40 b U = 0 6 8 10 12 14

Figure 8. Non conservative substances: temporal skew

ness behaviour for two different values of b U . r= 1
(dashed

line) and r= 2 (dotted line). The continuous line represents

conservative substances (no decay).

Figures 6-8 show the behaviour of the temporal

centroid, variance and skewness respectively for the

two cases corresponding to the constant values model

(b U = 0) and non uniform stream (b U = 0.40), both

for the case with conservative substance, i.e. no decay

reaction (r= 0), linear reaction (r= 1) and not linear
reaction (r= 2). The decay constant was always kept equal
to 2 · 10 -4 Kg 1-r m 3r-3 s -1 for each case, which means
a half-life time of approximately 1 hr for the linear
decay. The dashed line in all the figures represents the
case r= 1, the dotted line represents the case r= 2 and the
continuous line represents the conservative substances
behaviour. It can be noted that the trend of the curves is
the same as the trend of the centroid, variance and
skewness without the decay term. This is consistent, for
example, with the results found by Schmid (1995) for the
transient storage equation whit decay substances. In
particular it can be seen in Figures 7 and 8 that the
simulations with r= 2 are very similar to the case r= 0 (in
Figure 6 the two curves are practically coincident), while
r= 1 implies the same different value of variance and
skewness. This is due to the fact that high r means a low

disappearing mass (see Equation 22) so it is reasonable to find the same result as the conservative case due to the short observation time interval; in other words, if the decay order r is much greater than 1, the behaviour is like the conservative case so the results of the previous simulations can be retained. In general the centroid and the variance decrease for an increase in b U while the corresponding skewness is decreases. As far as the variance is concerned (Fig. 7) the simulation shows that if r= 1 the values are lower (1%) than the conservative case, and the opposite occurs for r= 2. The same appears for the skewness behaviour (Fig. 8). A first explanation for this unexpected result could be the complex interaction between the nonlinearities present in the coefficients of the model and in the decay term itself, but this requires further studies. In every case, when it exists, the curves exactly match the analytical solution given by 23. 6 CONCLUSIONS The numerical simulation of the advection-dispersion equation with non constant parameters is presented in this note. In particular, a collocation-interpolation method based on the use of a sinc function is used due to its great ability to deal with nonlinear models. The presented results include the case of conservative substances and non conservative substances with linear and non linear decay reactions. The results are presented in the form of temporal and spatial moments (i.e. centroid, variance and skewness) and, when possible, the comparison with analytical outcomes is also given. In particular, the results show that the behaviour of the centroid, variance and skewness depend on the velocity variation along the river and the decay reaction rate. In general, for a conservative substance, an increase in velocity along the river causes a decrease in the

temporal centroid displacement and variance, while

the skewness seems to increase. The same specific

considerations are valid for non conservative sub

stances with some additional considerations regarding

the influence of the non linear decay rate.

Estimation of longitudinal dispersion and storage zone parameters

P.M. Rowiń́ski, T. Dysarz & J.J. Napiórkowski

Institute of Geophysics, Polish Academy of Sciences, Warsaw, Poland

ABSTRACT: Numerical computations are presented for the longitudinal transport of passive, conservative

solutes in an actual river channel with the inclusion of its geometrical complexities. Only one-dimensional

conditions after a substance has become fully mixed across the depth and width of the river are concerned. In

such case a model describing the processes of advection, longitudinal dispersion, and also temporary storage

is suitable for the description of the spread of admixture. A special emphasis is put on the method of the

identification of model parameters which is based on a specially designed optimisation procedure using random

control search algorithm. The algorithm is one of the random global optimisation techniques and particularly

its realization by means of the CRS2 method. Two different situations are considered, namely a linear version

in which one can assume that the mean velocity does not vary along the channel course and when the model

parameters are constant and the nonlinear version implying channel nonuniformity (and variability of model

parameters along the channel). The results of tracer tests carried out in the selected reach of the Wkra river in

Central Poland have been used in the analyses. A model taking into account the changes of model parameters

along river channel proved to provide better results when compared to the experimental data but the parameter

identification in such case is computationally much more expensive.

1 INTRODUCTION

Various versions of the storage-zone models have

become increasingly popular for the calculation of

the longitudinal dispersion of a solute in a river

with irregular cross-sections (e.g. Czernuszenko &

Rowiński 1997; Czernuszenko et al. 1998; Manson

2000; Thackston & Schnelle 1970, etc.). On top of the mixing processes (advection and dispersion) this model is the reflection of the existence in the rivers of stagnant zones of water that are stationary rela tive to the faster moving waters near the center of the channel. It constitutes a kind of a compromise between data consuming two-dimensional models and the simpler one-dimensional approach. Mathemati cally similar approach may pertain to the exchange between the streaming water and the subsurface bed sediment, namely to hyporheic exchange causing the retardation of the solute transfer (e.g. Packman & Bencala 2000; Fernald et al. 2001; Jonsson 2003).

As is usually the case in physically based models the main difficulty is the estimate of the proper values of the parameters occurring in the model. All those parameters have relatively clear physical interpretation and as such should assume logical values. It should be noted that even in the much simpler case of the application of the Fickian type advection-dispersion equation, the evaluation of the dispersion coefficient constitutes an important problem since usually the information necessary for its estimate is rather scarce. The methods of its evaluation are disputable (Deng et al. 2002; Sukhodolov et al. 1998; Rowiński et al. 2003). It is then not very surprising that a number of methods, often leading to different results, are proposed in respect to the dead-zone types of models. Recently Seo & Cheong (2001) discussed different methods for the estimates of the

parameters of the storage zone model and they concluded that the parameters obtained by the methods of moments are in good agreement with the measured parameters, whereas the fit by the maximum likelihood method as well as the existing literature approaches are not. A number of other estimation methods have been elaborated in literature such as physically based empirical method of Pedersen (1977); fitting of the theoretical slope of the Laplace transformed solution for the concentration of the flow zone to the observed slope (Czernuszenko et al. 1998), moments matching procedure (Lees et al. 2000) or even visual determination of the set of parameters yielding the best fit to the concentration data (Bencala & Walters 1983). An obvious element is the relating the computed solute concentrations to some experimentally obtained curves. Estimation of the parameters has to obviously be proceeded by a proper formulation of the computational procedure. Computational schemes for the

simulation of the mass transport equations in cross

sectionally averaged form have been widely used for

many years. A wide variety of schemes have been

produced encompassing much of what is generally

available in computational fluid dynamics: finite dif

ference, finite volume and finite element methods for

spatial discretization and explicit and implicit time

stepping. Discussion of such methods in respect to the

advection-dispersion equations but with the inclusion

of temporarily storage zone is rather scarce in litera

ture (Runkel & Chapra 1993; Strauber 1995). In this

paper we are concerned with the 1D solute transport

equations, which are combined with the process of

the exchange of mass between the mainstream and the

existing in the flow areas that cause temporary storage

of the solute.

The overall aim of the paper is to establish a robust and efficient scheme for modelling of solute transport in natural watercourses and to demonstrate its prediction capability. To achieve this goal a relevant procedure for identification of model parameters is proposed. The results of computations will be compared with selected experimental results obtained by means of a dye tracer test in a lowland river. This study is just a first stab and the performance of the model is demonstrated against the measured data from one dye tracer field study in Central Poland. The emphasis is rather put on the elaborated mathematical approach.

2 MATHEMATICAL MODEL OF LONGITUDINAL TRANSPORT OF SOLUTES

We will concern only one-dimensional conditions after a substance has become fully mixed across the depth and width of a river. In such case a model describing the processes of advection, longitudinal dispersion, i.e. the spreading relative to the cross-sectional averaged velocity and also temporary storage is suitable for the description of the spread of conservative, passive pollutants. The transient storage process describes water moving from the flowing stream channel into stagnant areas in which waters are well-mixed but not transported downstream. The detailed description of the

transient storage model may be, for example, found

in (Czernuszenko and Rowin´ski 1997; Czernuszenko

et al. 1998) and here we will just present the relevant

partial differential equations.

Transport of the solutes in the main stream may be

described by:

where x – longitudinal direction, t-time, C(x, t) –

solute concentration, u(x) – cross-sectionally aver

aged velocity of water, D(x) – dispersion coefficient, A – cross-sectional area of the channel. It has been assumed that the hydraulic conditions in the channel are steady, i.e. parameters u, A, D do not change in time. C D (x, t) denotes the concentration of solute in the storage zone, parameters ε(x) and T (x) denote the ratio of the volume of the storage zones to volume of the main stream for unit length and the penetration time of tracer into the storage zones, respectively. In many practical situations we may additionally assume that these parameters do not change along the channel and then the above equation is reduced to the following form: where U , D, ε and T are constant parameters. The balance of mass in the storage zones is represented by: Equations 1 or 2 and 3 describe variations of the solute concentrations in both the main channel and the storage zones. The solution domain is the plane Oxt limited by inequalities 0≤ x≤L and t≥ 0, where L is the length of the modeled channel reach. The model equations are complemented by the following: – initial conditions: – and boundary conditions: where C p , C Dp are the initial distributions of solute concentration along the channel reach in both the main stream and the storage zones and C 0 describes the inflow of admixture at the initial cross-section. The effects of simple shift in time and dissipation in traditional Fickian-type advection – dispersion transport are well known. The source term that occurs in Equations 1 and 2 causes additional effects of pollutant decrease and accumulation (Figure 1). The intensity of the exchange of mass between storage zones and the main stream depends on the difference in concentrations. At the beginning the storage zones accumulate the pollutants which causes the decrease of the admixture concentration in the main stream. However, the

stored mass is given back to the channel when the concentration in the main stream is lower than in the storage zone. This process may even cause the shift in time of the peak of concentration temporal distribution (Figure 1).

C t x = 0 input: concentration of pollutants in inflow cross - section

C x = x 1 advection – dispersion transport

C t x = x 1 advection – dispersion transport plus the effect of storage zones

Figure 1. Schematic representation of advection, dispersion

and storage zones processes.

3 NUMERICAL SOLUTION

Equations 2 & 3 may be solved analytically only

by means of statistical moments (Czernuszenko &

Rowin´ski 1997) and therefore numerical methods are

highly demanded. A finite difference method has been

applied for the described case. The scheme is set up

with a rectangular horizontal mesh. Equally spaced

points along both the tand x-axes are chosen with grid

spacing t and x correspondingly, which makes the

channel divided into N computational cross-sections and M temporal levels. A convention is used for which the cross-section denoted by 1 corresponds to x= 0, and by N to x=L. The Cranck-Nicholson differencing scheme has been used for the representation of Equation 2-3 which reads: for cross-sections j= 2, 3, . . . , N – 1 and for j= 1, 2, . . . , N . Approximation of boundary conditions at each temporal level leads to: for j=N Equation 9 has been obtained from 6 with the assumption that In the case of the model in the form represented by Equations 1 and 3 the situation is much more complex and the application of the Cranck-Nicholson differencing scheme has not led to satisfying results due to the generation of large errors in the process of computations. It has been assumed that the

influence of three processes (advection, pure dispersion and transient storage) might best be computed separately as three stages in a three-stage difference scheme. Abbott and Minns (1998) suggest to think about such multi-staging as some processes are being “frozen” or “locked” while the other is implemented. The procedure as described in details below may be schematically presented as in Figure 2. In the first stage a pure advection process has been considered: In the second stage the results obtained from (11) are corrected by considering the dispersion process:

Last stage concerns the existence of the storage zones

by means of the following equations:

An upwind scheme has been used for approximation

of Equation 11

for j= 2, 3, . . . , N

The Cranck-Nicholson differencing scheme could be

applied for the dispersion equation which resulted in

the following:

for j= 1 advection dispersion storage zone TRANSPORT input output advection dispersion storage zones input output upwind scheme Crank - Nicholson scheme Runge – Kutta method advection output advection dispersion output

Figure 2. Schematic representation of the applied splitting technique. for j= 2, 3, . . . , N – 1 and for j=N

It is important to note that in the second stage the input

for computations is taken from the first process and

not from the actual preceding time level. Equations of

the last stage are solved by means of the fourth-order

Runge-Kutta method. Let’s denote:

which allows us to present the problem 13-14 as

ordinary differential equation that reads

A single step of this method may be represented as:

It is proposed that the described method of taking indi

vidual consistencies over to component differential

forms and adding these differential component forms

to obtain a resultant differential form which brings

correct results.

[m −1/3 s] 4 FIELD STUDY – DYE TRACER TEST IN THE WKRA RIVER The presented model has been verified based on the tracer test performed in the lowland river reach in Central Poland, namely the Wkra River. The flow rate as well as other hydraulic and topographic characteristics in respect to all the measuring cross-sections are shown in Tables 1a,

1b, 1c. The measurements were repeated three times in the same river reach. A variety of different irregularities along the river banks were observed.The creation of wakes behind the sand waves as well as the areas on the insides of bends with small radius of curvature most likely causing that the flow “overshoots” the bend could be expected and therefore one may assume the existence of different storage zones in the considered river reach. The method of instantaneous injection of the tracer was applied and it did not require the complex dosing facilities and allowed to obtain high initial concentrations of the tracer. The dye release consisted of 10 liters of alcoholic solution of a fluorescent red dye (Rhodamine). This dye was released at three points at the cross-section just downstream of the stage of fall which speeded up the cross-sectional mixing of the admixture. Concentrations were measured at five cross-sections as indicated in Table 1. First crosssection was established at a distance at which 1D conditions were supposed to be achieved. During the early stages of a test the dye was visible to the naked eye, which facilitated sample collections. The dye was detected by using the field fluorometer Turner Design with continuous flow cuvette system on the one hand and also water samples were collected at sampling points. Measuring data were stored on graphical

5 IDENTIFICATION OF PARAMETERS –

PROBLEM FORMULATION

Model calibration problem is formulated as optimiza

tion problem

minimize F(x) with respect to x∈D⊂R n

where F : R n →R is scalar objective function and D

is admissible domain with potential solutions x. Many

different methods were used to solve such kind of prob

lems, but no one of them may be recommended if we do

not know the features of the objective and constraints

in the given problem. The most important features are the convexity of function F(x) as well as the convexity of domain D. The form of constraints guarantees that the set of admissible solutions is compact and convex. However, the described problem is a practical and a very complex task. So, we have expected that the calibration criterion may not be convex. This preliminary assumption was confirmed by further numerical tests. In such case the global optimization techniques should be preferred. These methods have been developed and investigated for several decades and they have been treated as alternative algorithms for problems with many local optimal points. Originally they have constituted the combination of random global search, i.e. Monte Carlo method, and local accurate procedure. Another kind of methods has become very popular during last 30 years. They are based on natural selection and evolution of wild species such as genetic algorithms, evolutionary strategies or evolutionary programming. One of the first descriptions of genetic algorithms was given by Holland (1975). At the same 0.00 0.02 0.04 0.06 0.08 0.10 0.12 0 2000 4000 6000 8000 10000 12000 14000 time [s]

time non-evolutionary methods of global optimization

were developed, and among them the methods based

on natural and artificial physical and chemical pro

cesses. Simulated annealing (Kirkpatrick et al. 1983;

Dekkers & Aarts 1991) and particle trajectory method

(Griewank 1981) are well known examples in this area.

Current knowledge of optimization and classic meth

ods for convex function was the basis for developing

new global techniques, i.e. Price (1983), Ali & Storey

(1994).

In the present study the results obtained by means

of the dye tracer test in the Wkra River have been used

and the time-concentrations distributions C m (x k , t)

(k = 1, 2, . . .,) at a few selected cross-sections in the

main stream have been used for comparisons. As for

the boundary condition at the inflowing cross-section

the measurement results from the first cross-section

C m (x 1 , t) have been taken. The measurements at the

remaining cross-sections have been used for the deter

mination of parameters with the objective function

taken as:

where F is the criterion function, T H – the optimization

time horizon, K – number of measuring cross-sections. The wetted cross-section has been determined from the mass balance under steady stated conditions given by: where Q is the given discharge. Special constraints have been put on the sought parameters or functions: where X min , X max are the lower and upper bounds for X (x). The computations of the values of the objective function for the estimated (by the described method) parameters u, D, ε, T have been realized through the simulations of the transport of solutes and the comparisons of the concentration distributions C(x k , t). In case of the identification of parameters of the model 1–3 a linear approximation of the sought parameters has been assumed to lower the dimensionality of the problem. The longitudinal variations of u(x), D(x), ε(x), T (x) have been determined based on their values at the same cross-sections where the solute concentrations had been measured. 6 CONTROL RANDOM SEARCH METHOD The optimisation problem 26 was solved by means of the global random search procedure (Price 1987) namely the

following version of Controlled Random Search (CRS2) described in details by Dysarz & Napiórkowski (2002). The algorithm is one of the random global optimisation techniques. Its basis is well known simplex method used in non-linear optimisation. The set of points from n-dimensional space is processed in following iterations. In each step, new solution is generated by reflection of a simplex vertex. One of a few well known versions of the method was used, namely CRS2. The algorithm starts from the creation of the set of points, many more than n+ 1 points in n-dimensional space, selected randomly from the domain. The optimal quantity of set was taken as suggested by Price (1987), equal to 10(n+ 1). Let us denote the set as S. After evaluating the objective function for each of the points, the best x L (i.e. that of the minimal value of the performance index) and the worst x H (i.e., that of the maximal value of the performance index) points are determined and a simplex in n-space is formed with the best point x L and n points (x 2 , x 3 , . . ., x n+1) randomly chosen from S. Afterwards, the centroid x G of points x L , x 2 , . . ., x n is determined. The next trial point x Q is calculated as the reflection of x n+1 , that is x Q = 2x G - x n+1 (Niewiadomska-Szynkiewicz et al. 1996). Then, if the last derived point x Q is admissible

and “better” it replaces the worst point x H in the set

S. Otherwise, a new simplex is formed randomly and

so on.

If the stop criterion is not satisfied, the next iteration

is performed. This part of the algorithm was formed

The experiments showed that following condition may be taken as the stop criterion where F ave is the mean objective function value in the set, F(x L) the objective function value at the best point x L and ε is the expected accuracy determined empirically (Dysarz & Napiórkowski 2002). 7 NUMERICAL COMPUTATIONS VISA EXPERIMENTAL RESULTS The results of a tracer test carried out in the selected reach of the Wkra River have been used in the analyses. Three different experimental tests (the discharge

Q was 4.18, 3.97 and 4.32 m 3 /s) performed over a 6

kilometers river reach with 5 measuring cross sections

are taken into account. As an initial condition for com

putations a lack of dissolved solutes in the channel was

assumed:

The time horizon for simulations was taken as 4 h.

Time step is taken as t= 20 s and the spatial one

x= 20 m.

Admissible range for model parameters is given in Table 2. Since the differences in the values of the sought parameters are large, a normalization was necessary and it was performed by projecting of the admissible set on the unit cube in R n by means of expression:

Examples of simulations of the transport of solutes are shown in Figures 3 and 4. These figures show the measured and computed concentration distributions at five cross-sections.

Performance of both linear and nonlinear models is presented. Table 2 provides the mean values of the objective function as well as the values of standard deviation obtained by means of the expression:

where X i is the single sample from a series of N samples having the mean value X . It is readily seen that the agreement with the measuring data is much better in case when the variability of model parameters along river channel is taken into account, i.e. in case of Equations 1 and 3. Mean values of the criterion function varied in the range from 0.005 to 0.01 in this case while those values were ten times larger in case of Equations 2 and 3. The values of standard deviation in both cases did not exceed 5% of mean value. However, the increase in the accuracy of results has

been obtained at much larger computational cost of parameters' identification. Mean value of the num ber of runs was 131.4 in case of linear model and it was as large as 4377.6 for the nonlinear model. Table 3 and Figure 5 provide mean values and the standard deviations for each determined parameter for both presented models. The values of the storage zone parameters reflects the relatively simple geometry of the considered channel ofWkra river. Discussion of the performance of these parameters may be, for example,

Impact of riverine and CSO inputs on coastal water quality under

different environmental conditions

Iran

B. Lin & R.A. Falconer

Civil Engineering Department, Cardiff University, Cardiff, UK

ABSTRACT: Details are given of a hydro-environmental modelling study aimed at investigating the impact of

riverine and CSO inputs and several environmental parameters on the bacterial concentration on an EU bathing

water (BW) compliance point, located on the Fylde Coast, UK. The several environmental conditions studied

including: wind, river discharge, storm flow, and CSO release time in relation to tidal phases, were studied in this

project. A series of scenario runs were undertaken to predict BW bacterial concentrations for three continuous

riverine inputs, located at the upstream boundaries of the model, and three intermittent CSO inputs, located

along the rivers. For each scenario one environmental factor was considered and the inputs were designed to

operate separately. To investigate the absolute effect of each factor on the dispersion and distribution of the

pollution a zero decay rate was assumed. It was found that increasing river discharges would cause an increase

in the bacterial concentration at the BW point. It was also found that the release time of a CSO input would

affect considerably bacterial concentration at the considered BW point. Wind direction and storm flows were

also found to be important environmental factors that significantly affect pollution distribution in the receiving

waters.

1 INTRODUCTION

It is known that many water quality parameters such

as the salinity, pH and turbidity levels, solar radia
tion strength and sediment concentration may affect
the bacterial population in coastal waters (Thomann
and Muller, 1987; Chapra, 1997). Some other envi
ronmental parameters such as tidal conditions, river
discharge, wind speed and direction, and flow velocity
may also affect the distribution of bacterial concentra
tion (Kashefipour et al, 2000). Moreover, the releasing
time of bacterial input in relation to the tidal phases and
other environmental conditions (e.g. sunlight inten
sity) can also be a relatively important factor to the
bacterial displacements.

This paper presents a hydro-environmental mod
elling study of the Fylde Coast and Ribble Estuary,
aimed at quantifying the impact of various bacte
rial sources along the river network on the receiving
coastal waters under different environmental condi
tions. The effectiveness of such environmental condi
tions on the bacterial concentration distribution was
illustrated by evaluating the faecal coliform concen
tration at an EU designated bathing water point. 2
HYDRO-ENVIRONMENTAL MODEL Kashefipour et al (2002)
developed an integrated hydro-environmental mathematical
model, in which a one-dimensional (1D) model was
dynamically linked with a two-dimensional (2D) model
enabled the users to apply this single model for modelling
the river networks and coastal waters simultaneously. The
1D and 2D shallow water equations were numerically solved
and integrated to form the hydrodynamic module of the

integrated model. The 1D and 2D advective diffusion equations were solved and integrated to form the water quality module. This model was able to accurately predict the impact of the river inputs on the bathing water quality along the Fylde coast. More information regarding the calibration and validation of this single model for the Ribble Estuary and its tributaries can be found in Lin et al (2001) and Kashefipour et al (2002). In this study a series of scenario runs were designed to investigate the effect of wind, river discharge, CSO release time in relation to the tidal phases and flood flows on the bacterial concentration at a bathing water location.

3 MATERIALS AND METHODS

Faecal Coliforms (FC) are mostly used as an indicator of the bacterial population. In this study a zero decay rate was assumed for the FC and this was because the main focus of the study was to investigate the effect of the environmental conditions on the FC distribu tion. The results obtained from this study can also be extended to other bathing water quality indicators.

Ribble Estuary is located along the North West coast of England, UK. Figure 1 shows the Ribble Estuary and its tributaries, including: the Ribble, Darwen and Douglas rivers. Three continuous inputs were located near the upstream boundaries of the rivers, and three CSO inputs, namely the Upper Rib ble CSO, Lower Ribble CSO and Douglas Inter (see Figure 1) operate intermittently.The continuous inputs were assumed to operate for the whole simulation time with a discharge of 0.05 m 3 /s and FC concentration of 1.0e+ 08 cfu/100 ml.A discharge of 1.0 m 3 /s and a FC

concentration of 3.0e+ 07 cfu/100 ml were assumed for all of the CSO inputs and they operated only for three hours. The input sources were set to operate separately for each scenario run, to investigate the effect of each input on the FC concentration at the bathing water location. St Annes Pier, located at the north of the Ribble Estuary, was an EU designed bathing water point (see Figure 1) and was used in this study as a target location for testing different scenarios. Wind direction, river discharge and storm flow and the CSO release time were four variables tested in this study. To drive the model water elevations predicted for a neap tide were used as the downstream open boundary. Discharges at the upstream boundaries of the three rivers including: Ribble, Darwen and Douglas, were used as the upstream boundary conditions. Fresh water with zero bacterial concentration was assumed for the flow entering to the domain from the upstream and downstream boundaries of the model.

The scenarios tested were listed in Table 1. In this table SW means a wind from south towards north with an angle of 225 degrees to the north and NW was

Figure 1. Ribble Estuary and its tributaries. a wind from the north to the south with an angle of 315 degrees to the north. Rib, Dar and Dug are abbreviations of the Ribble, Darwen and Douglas rivers, respectively. In Table 1 LW, HW, LS and HS are used for low water, high water, low storm and

high storm flows respectively. A constant wind speed of 10 m/s was applied. The hydrographs of the low and high storms are shown in Figure 2. It can be seen from Table 1 that the results obtained from the scenarios S1 and S2 were used to evaluate the effect of wind direction on the bathing water quality, S1 and S3 for the CSO release time, S1 and S4 for river discharge, and S1 with S5 and S6 for evaluation of the effect of storm on the FC concentration at the bathing water point. Table 1. Specifications of the scenarios. It should be noted that the total simulation time for

all of the scenario runs was 200 hours, which was about

16 complete tidal cycles.

4 RESULTS AND DISCUSSION

4.1 The effect of wind direction

The effect of wind direction on the FC concentrations

at St Annes Pier has been shown in Figure 3. As can be

seen from this Figure that the south west wind SW225

caused higher FC concentration than that caused by

the northwest wind NW315. Since St Annes Pier is

located at the northern coastline of the estuary (see

Figure 1) these results were expected. The average FC

concentrations predicted at the bathing water location

due to the continuous and CSO inputs under the above

wind directions are summarised in Table 2. This Table

shows that for all inputs the FC concentrations for wind

direction of SW225 were more than 5 times higher than

Douglas inter CSO 16 5 the corresponding concentrations obtained for NW315 direction. It can also be seen from Figure 3 that for all inputs the minimum FC concentrations at the bathing water point occurred at the high waters and the maximum concentrations at low waters. The sinuous shape of the concentration variations in Figure 3 was due to the

tidal conditions. Since the decay rate was set to zero so for the continuous inputs the maximum FC concentration increases after each tidal cycle. Whereas, for the CSO inputs with only three hours operation it was expected that due to the dispersion process, the FC concentration increases initially, reaches a maximum value and then reduces. This trend occurred for the NW315 wind (see Figure 3). It seems that if the simulation time continues more than 200 hours the same trend may also occur for the SW225 wind. The FC concentrations obtained were generally higher for the inputs closer to the estuary outlet and also for rivers with higher flow velocities (for example Darwen in comparison with Douglas, not shown in this paper). 4.2 The effect of the CSO release time The results obtained for different CSO inputs (see Table 1, scenarios S1 and S3) are compared in Figure 4. In scenario S1 the CSOs discharges were started at the High Water (HW), whereas in scenario S3 the release time was HW plus six hours, or Low Water (LW). As can be seen from this figure different behaviours occurred due to the CSO inputs. For example, for the CSOs located along the Ribble River, including: Upper Ribble and Lower Ribble CSOs (see Figure 1) the FC concentrations at the BW point decreased for scenario S3 in comparison with scenario S1. On the contrary for the Douglas Inter CSO, which is located close to the Douglas boundary, the FC concentrations at the BW point increased when the input was operated at the low water. This phenomenon could be caused by the interaction of river discharge, flow velocity and tide conditions. The travel time for the transport of the pollutants from the Lower Ribble, Upper Ribble and Douglas Inter CSOs to the BW point for scenario S1 were about 14, 27, and 28 hours, respectively. The corresponding values for scenario S3 were 23, 23 and 33 hours respectively. This information shows that for scenario S3 the pollutant reached the BW point for the Lower and Upper Ribble CSOs at the starting of the flood-tide phase and this means that a stronger dispersion effect on the FC plumes. On the contrary for the Douglas Inter CSO the pollutant reached to the BW point at the middle of ebb-tide phase. It should be noticed that with the neap tide, the tidal limit did not reach to the Ribble and Douglas upstream boundaries and between the tidal limit and river boundaries free flow occurs. Figure 4. Comparison of the FC concentration for different

CSO inputs due to the CSO release time.

These results might be a useful guide to the envi

ronmental managers for optimising the release time of

the CSOs along the river networks.

4.3 The effect of river discharge

Upstream river discharge was another environmental

factor considered in this study for investigating the effect of such factor on the FC concentrations at the BW point for different continuous and CSO inputs located along the river networks. In this regard the results obtained for scenarios S1 and S4 were com pared and illustrated in Figure 5. As Table 1 shows the upstream river discharges for S4 scenario were about 5 times of the corresponding values for scenario S1. As can be seen from Figure 5 that for all of the continuous and CSO scenario runs the FC concentrations at the BW point will increase significantly when upstream river discharges increase. It seems that the river flow

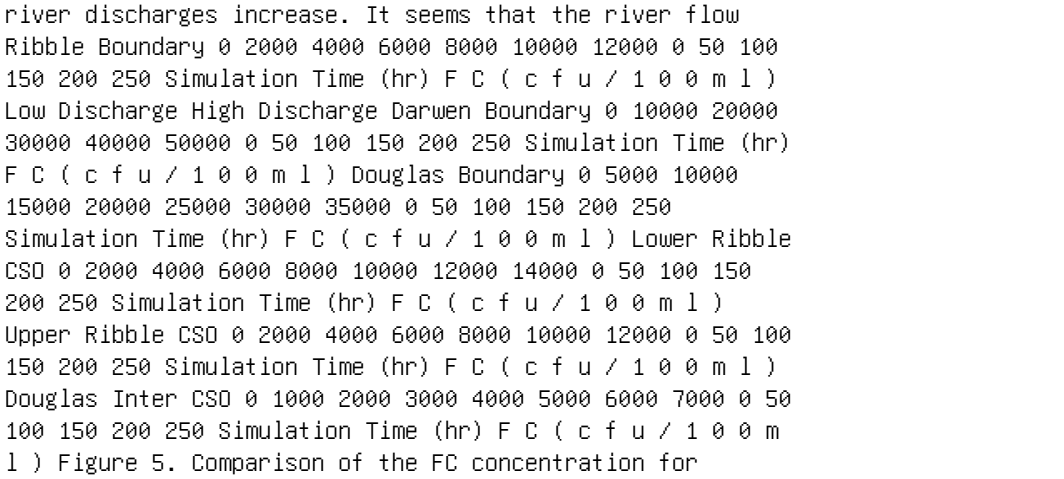

Figure 5. Comparison of the FC concentration for different continuous and CSO inputs due to the river discharge. velocity, which is generally affected by upstream flow discharge, could be an important factor affecting the pollution distribution. Higher discharge means higher velocity and as a result the dispersion of the pollutants along the river networks would reduce. For this scenario the travel times for the pollutants to reach the bathing water point were 13, 13 and 15 hours for the Lower and Upper Ribble and Douglas Inter CSOs, respectively. As it has been explained above that the duration of CSO inputs were only three hours and due to dispersion it was expected that the FC concentrations at the BW point take a maximum value and then reduce with time. This phenomenon has

happened for the scenario S4 during the simulation time and it could happen for other scenarios if longer duration of the simulation time was conducted. The average FC concentrations of the different continuous and CSO inputs for the scenarios S1 and S4 were computed and summarised in Table 3. With an increase of about 5 times in the upstream river discharge (from S1 to S4), the FC concentrations at the bathing water point increased by nearly 10 times. 4.4 The effect of storm Two storms, including: low storm with a small hydrograph and high storm with a big hydrograph, as shown in Figure 2, were considered to investigate the behaviour of the distribution of the bacterial population under different storm flows. The results obtained for scenarios S5 and S6 are shown in Figure 6, together with the corresponding results obtained for scenario S1. The FC concentrations at the BW point for all of the inputs were again increased with the increasing of storm flow. No significant difference was found

between the low storm (S5) and continuous discharge

(S1), and this was due to the small flow and short

duration of the storm. The average FC concentrations

at St Annes (BW) for all inputs were calculated and

summarised in Table 4.

According to Tables 3 and 4 it can be seen

that although the peak discharge of the high storm

hydrograph was nearly two times of the continuous discharge for scenario S4 the FC concentrations obtained for scenario S6 were less than the corresponding values for S4. This could be due to the short duration of the hydrograph. 5 CONCLUSIONS In this paper a hydro-environmental model has been used to investigate the effect of several environmental parameters on the bacterial concentration on an EU bathing water compliance point, located on the Fylde Coast, UK.The model was a dynamically integrated 1and 2-D model, developed by Kashefipour et al (2000). Three environmental parameters, including: wind direction, river discharge and storm, and one management factor, namely the CSO release time in relation to the tidal levels, were considered in this study. Three continuous discharges and three intermittent CSO inputs located along the river networks were used as the main sources of pollution. These inputs were assumed to operate separately. The main conclusions drawn from this study may be summarised as follows: • Wind direction is an important environmental parameter affecting the plume distribution. The bathing water sampling point studied in this project is located at the north of the estuary, thus it is more vulnerable to south-eastern wind. • The bacterial concentration at the bathing water point decreased considerably when the two Ribble CSO inputs were released at the flood-phase of a tidal cycle including low water. On the contrary, for the same release time the bacterial concentration increased when the Douglas Inter CSO was considered. This phenomenon could be due to the interaction between the flow velocities, pollutant travel time and tidal conditions. This phenomenon could be used utilised by local environmental managers to optimise the release time of the CSOs along the river networks. • River discharge is another important environmental parameter affecting the bacterial concentrations. Although the concentrations of a continuous input, or a CSO input, was kept the same for all of the scenario runs, the bacterial concentrations at the bathing water point increased significantly with the increase of river discharges. • The results for the two storm runs showed again that with an increase in the river discharge the bacterial concentrations at the bathing water points also increased. • Finally it has been concluded that the interaction between river and tidal flows, and interaction between these hydraulic parameters and environmental conditions were the main cause for the fluctuations of

bacterial concentration at the bathing water point.

River model calibration: a genetic algorithm with

evolutionary bottlenecking

J. Russell Manson

The Macaulay Institute, Aberdeen, Scotland

Steve G. Wallis

Heriot-Watt University, Edinburgh, Scotland

ABSTRACT: The advection-dispersion equation (ADE) has been used widely to model solute transport in

fluvial systems. In this model transport is characterized as having an advective (unidirectional) component rep

resented by the velocity, u, and a dispersion (bi-directional) component represented by the dispersion coefficient,

D. A significant body of work has been devoted to enhancing the ADE to include transient storage zones (or dead

zones). In these enhanced models two additional parameters (α, A s) are used to characterize the storage zone. So

these enhanced models have four characterizing parameters (u, D, α, A s). Both the standard and enhanced ADE

can be calibrated by fitting the model to experimentally derived solute concentration data. If some objective

function is defined, such as the sum of the square residuals between model and observations, then it can be min

imized by adjusting the model parameters. There are various algorithms available for doing this. In this research

a genetic algorithm (GA) approach was used for this task. This is the first time (to the authors' knowledge) that

a GA has been used for this particular application. Clearly, as in any optimization approach, a rapid method of

finding the objective function value is required. The objective function was defined in terms of the difference

between the "data" and "simulations". The simulations were generated by a numerical method of solution. Since

it is well known that numerical solutions to advection-diffusion equations are prone to various deficiencies (e.g.

numerical diffusion, grid-scale oscillations), it was important to use a tried and tested numerical method that

was known to be free of these problems. Therefore we adopted the semi-Lagrangian method, DISCUS. This

method includes an explicit, shape-preserving cubic interpolation update for advection and fully implicit tempo

ral treatments of dispersion and transient storage. Previous work has shown that DISCUS is accurate, robust and computationally efficient over a wide range of Courant and grid Peclet numbers. The semi-Lagrangian approach is also particularly attractive for optimisation problems because it caters well for the use of large time steps.

The GA based optimisation of the DISCUS model was applied to a test case of "data" generated with known characterizing parameter values, again using DISCUS. Thus the expectation was that the optimization would correctly identify these known values as the optimum solution. During initial experiments with the GA it was found that it was very good at finding the rough proximity of the global minimum but then it converged very slowly towards the true minimum. To overcome this difficulty, while retaining the GA framework, evolutionary bottlenecking was introduced to the GA. This involved successively and methodologically refining the parameter space and was found to greatly improve convergence.

1 INTRODUCTION

The advection-dispersion equation (ADE) has been used widely to model solute transport in fluvial sys tems. In this model transport is characterized as having an advective (unidirectional) component represented by the velocity, u, and a dispersion (bi-directional) component represented by the dispersion coefficient, D. Although widely used this model has several defi ciencies. One of these is the inability to capture long tails in observed tracer data caused by transient storage zones. Transient storage zones include recirculation areas, streambed irregularities and bed sediment interstices.

These zones are thought to be important for nutrient cycling and stream metabolism, [Kim et al, 1992; D'Angelo et al, 1993; Allan, 1995; DeAngelis et al, 1995; Valett et al, 1996; Marti et al, 1997; Morrice et al, 1997] and they have long been recognised as playing an important role in the transport of dissolved or suspended materials in rivers [Thackston

and Schnelle, 1970; Sabol and Nordin, 1978;Valentine

and Wood, 1979; Purnama, 1988; Denton, 1990]. The

storage zone's size (A_s) and the rate at which solute

mass is transferred to and from the zone (α) are thought

to be important characterizing parameters. So these

enhanced models have four characterizing parameters

(u, D, α, A_s).

Both the standard and enhanced ADE can be cali

brated by fitting the model to experimentally derived

solute concentration data. If some objective function

is defined, such as the sum of the square residuals

between model and observations, then it can be mini

mized by adjusting the model parameters. There are

various algorithms available for doing this. In this

research a genetic algorithm (GA) approach was used

for this task. This is the first time (to the authors'

knowledge) that a GA has been used for this particular

application. Clearly, as in any optimization approach,

a rapid method of finding the objective function value

is required. Herein the objective function was for

mulated using a numerical solution to the enhanced

ADE model. Indeed, the numerical model was used to create the “data” and the “simulations” on which the parameter optimization was based.

Since it is well known that numerical solutions to advection-diffusion equations are prone to vari ous deficiencies (e.g. numerical diffusion, grid-scale oscillations), it was important to use a tried and tested numerical method that was known to be free of these problems. Therefore we adopted the semi Lagrangian numerical method DISCUS (Domain of Influence Search for Convective Unconditional Sta bility). This method has been widely applied to fluvial scenarios, being highly suited to the non-uniformity of flow fields found therein. It is described in several earlier papers that demonstrate the successful applica tion of the method to: pure advection in uniform flow [Manson and Wallis, 1995; Manson and Wallis, 1997]; pure advection in non-uniform flow [Manson and Wallis, 1997]; advection-dispersion in uniform flow [Wallis et al, 1998] and advection-dispersion in non uniform flow [Manson and Wallis, 1999].

This method includes an explicit, shape-preserving cubic interpolation update for advection and fully implicit temporal treatments of dispersion and tran sient storage. Previous work has shown that DISCUS

is accurate, robust and computationally efficient over

a wide range of Courant and grid Peclet numbers. The

semi-Lagrangian approach is also particularly attrac

tive for optimisation problems because it caters well

for the use of large time steps.

During initial experiments with the GA it was

found that it was very good at finding the rough

proximity of the global minimum but then it con

verged very slowly towards the true minimum. To

overcome this difficulty, while retaining the GA frame

work, evolutionary bottlenecking was introduced to the GA. This involved successively and methodologically refining the parameter space and was found to improve convergence. 2 MODEL DESCRIPTION Only the enhanced model will be considered here, in which one-dimensional solute transport in steady, nonuniform flows in rivers with transient storage regions is described by the following mass conservation equations, where m(x,t) is the solute mass per unit length in the main channel (= cA), c(x,t) is the concentration of solute in the main channel, s(x,t) is the concentration of solute in the transient storage zone, Q(x) is the steady main channel river flow, A(x) is the steady main channel cross-sectional area, A s (x) is the steady transient storage cross-sectional area, D(x) is the longitudinal dispersion coefficient, α(x) is the solute exchange parameter between the main channel and the storage zones, x is the longitudinal spatial co-ordinate and t is time. The following boundary conditions are frequently used with these equations. At the upstream boundary, c(0,t)= c i (t), which specifies the solute mass entering the computational domain; at the downstream boundary a zero diffusive flux is assumed which implies that solute is advected out of the domain unhindered. Equations (1) and (2) were solved using a finite volume approach, evaluating the advection term explicitly in time and evaluating the dispersion and transient storage terms (fully) implicitly in time. The DISCUS method was used for equation (1). This employs a conservative semi-Lagrangian algorithm that combines a finite volume discretisation, the method of characteristics and a flux-based interpolation scheme. The

method is explained in detail elsewhere [Manson and Wallis, 1995; Wallis and Manson, 1997; Manson and Wallis, 1997; Wallis et al, 1998; Manson and Wallis, 1999; Manson and Wallis, 2000; Manson et al, 2001]. The backward implicit method used for the dispersion term and the transient storage terms is unconditionally stable and robust. It is deficient in the sense that it assumes that the exchange transport rates at the future time prevail over the entire time step: however, it does not suffer from the grid-scale oscillations of the formally more accurate Crank-Nicolson method. Tests

have indicated that for the range of parameters investi

gated here the method appears adequate [Manson et al,

2001].

When equations (1) and (2) are solved the solution

consists of estimates for c and s over some discretised

spatial and temporal domain, i.e. (c n i , s n i) for i= 1 to N

and n= 1 to T where N is the number of points in the

spatial domain andT is the number of points in the tem

poral domain. If this model is being fitted to observed

data that has been collected at M points in space and

time then a fitting parameter may be defined as,

so that an R value of 1 indicates a perfect fit. Note

that only the in stream concentration has been used

for the fitting. Concentrations in the transient storage

zone are more difficult to measure and so are rarely

documented.

3 PARAMETER ESTIMATION BY GENETIC ALGORITHM

3.1 Introduction

As defined in equation (3), R is used as the objec

tive function for the genetic algorithm, which seeks to choose the best combination of parameters in order to maximize R. The genetic algorithm employed is a modified version of secur GA by Carroll [Yang et al, 1998] and the reader is referred there for details. Briefly however, a population of individuals is defined. Each individual is characterised by four traits that in the current exercise are simply the fitting parameters (u, D, α, A s). One can think of this as analogous to say traits in humans such as eye colour, hair colour etc. So, for example, one individual could have large u, large D, low α and low A s . Another might have low u, high D, low α and high As. Now if such a popula tion is defined and then pairs of individuals from the population are allowed to reproduce, the offspring will have certain traits of both parents. For this next gener ation Darwinian selection is applied to allow survival of only the fittest individuals in the new population. Fitness is based on the value of R for the individual. After many generations the population is made up of only the fittest individuals.

Now when the algorithm was implemented, rather than using qualitative trait descriptors such as high and low, each trait was allocated a value from a pre-specified range of the corresponding parameter.

Clearly by choosing the number of values available

from the range, the precision of the final answer is

defined, since using a finer resolution (larger num

ber of values) enables a greater number of possible

parameter combinations to be explored. Figure 1. Contours of R over the parameter space (x, y) and important points for the bottlenecking algorithm. 3.2 Evolutionary bottlenecking In evolutionary terminology, “bottlenecking” is defined as a drastic reduction in population size. In the context of the genetic algorithm here we use it to rapidly restrict the parameter search space in a methodological fashion. This has the effect of speeding convergence to the global optimum and is highly effective when convergence is slow, i.e. when the objective function varies very slowly around the optimum point. For ease of explanation let us assume only two parameters (x and y) are involved. If the initial parameter space is defined by the limits: (x 0 min , x 0 max) and (y 0 min , y 0 max) , see Figure 1, then taking these as the limits of the search space we first use the conventional GA to find the best estimate of the optimum point, let us say this is (x 0 best , y 0 best) . Now we refine our search space to be centred at (x 0 best , y 0 best) and to extend from x i+1 min to x i+1 max in the x direction and from y i+1 min to y i+1 max in the y direction where, This algorithm can be generalized to n parameters as follows:

where β = max j ❙ ❙ j x i best − j x i max ❙ ❙ . The β factor has been

introduced to allow a search to move outwith the bot

tleneck whenever the “best” parameter combination

lies at the edge of the bottleneck region.

4 ALGORITHM TESTING

The algorithm was tested by generating some data

using the DISCUS model applied to a hypothetical

river reach. For this reach the river velocity (u) was

set to be 0.05 ms −1 , the dispersion coefficient (D)

was 0.1 m 2 s −1 , the exchange rate parameter (α) was 0.001 s −1 and the storage zone size (A s) was set as 0.05 m 2 . A tracer distribution was input to the hypothetical river at the upstream end of the reach and allowed to travel for about 2 hours downstream. The simulated concentration versus time curve at the downstream end of the reach was then used as the “data” for the fitting exercise. The genetic algorithm’s goal, therefore, was to find the best fit parameters as [0.05, 0.1, 0.001, 0.05].

To achieve this, a total of 64 possible values for each of the traits were specified from the following initial parameter ranges: (0.0< u< 0.1), (0.0<D< 0.02), (0.0<α< 0.002) and (0.0<A s < 0.1). The traditional genetic algorithm used a population size of 200 and was allowed to evolve for 50 generations, i.e. a random selection of 200 possible parameter combinations was used to generate 200 simulations of the data, using the DISCUS model. This required 10000 simulations and objective function evaluations. For the new (bottlenecking) genetic algorithm the population size was 100 and only 25 generations were used. Therefore only 2500 simulations and objective function evaluations were required. Five bottlenecks were used. The bottleneck fractions were: ζ u = 0.5, ζ D = 0.5, ζ α = 0.5

and ζ A s = 0.9.

So for the transient storage area the rate of parame

ter space reduction was restricted. Initial experiments

suggested that this prevented premature and erroneous

convergence. The results of both the traditional and

the bottlenecking genetic algorithms are presented

below in Table 1 and Figures 2 and 3. Table 1 shows

the final optimum parameters obtained by both algo

rithms. Note that the traditional GA used four times

as many objective function evaluations as the new

GA yet three of the four optimum parameters found

were still greatly in error, with the transient storage

parameters being the most difficult to correctly iden

tify. By increasing the number of generations better

estimates could be obtained but convergence was very

slow as a direct result of the shape of the optimiza

tion surface. The bottlenecking GA, however, which

“zooms in” on the optimum achieves a much greater

degree of accuracy in many fewer objective function

evaluations. Table 1. Final result of GA searches and %

Quasi-confidence regions for bottlenecking genetic algorithm at level R= 0.97. Figures 2 and 3 show the results of the searches in terms of “quasi-confidence” regions, i.e. a point was plotted in the parameter space wherever R was greater than some pre-defined accuracy level. Large regions

of widespread points then indicate a highly uncertain

parameter estimate.The figures show conditions for an

accuracy level of R= 0.97 and are particularly infor

mative.The traditional GA (Figure 2) shows very large

confidence regions for this test case.

Clearly a great degree of uncertainty surrounds

the estimates particularly the transient storage param

eters (α, A s). The smallest quasi-confidence region

spread is evident in the velocity parameter. The quasi

confidence region for the transient storage parameters

(α and A s) shows that we can only be confident that

the parameters lie within the total parameter space, i.e.

little information has been gained by the optimisation

process. The bottlenecking GA (Figure 3), however,

is much more useful. It manages to establish greater

confidence in at least u, D and α. However, at this level

(R= 0.97) it also has trouble establishing any confi

dence in A s , although it does manage to find a good estimate of the point of global maximum R.

5 CONCLUSIONS

This paper has presented a new approach for parame ter estimation in river models. The approach has been used here to estimate parameters in an advection dispersion transient storage model but the technique is not limited to this application. It can be applied in other areas of river modeling. For the application presented here the surfaces of the objective function are often very flat and convergence to the optimum can be very slow. The bottlenecking technique that we have introduced seems to have greatly enhanced the convergence. Clearly this is only one application and further testing of the approach is required. In particular it may be necessary to modify the algorithm to preserve genetic diversity so that interesting search regions are not prematurely excluded.

Gas-transfer coefficient in a smooth channel. A preliminary assessment of

dimensional analysis-based equation

Carlo Gualtieri & Guelfo Pulci Doria

Hydraulic and Environmental Engineering Department “Girolamo Ippolito”, University of Napoli “Federico II”,

Napoli (Italy)

ABSTRACT: Recent studies have confirmed that literature equations for the estimation of the reaeration rate

are not applicable to all stream hydrodynamic conditions. Since recent efforts have been addressed to develop a

comprehensive approach to gas-transfer using dimensional analysis to clearly identify the parameters involved in

the process, the present paper provides a preliminary quantitative assessment for this approach using 65 literature

laboratory data collected in smooth channels.

1 FOREWORD

The exchange of gases across the air–water interface is

important in regulating concentrations of various sub

stances of environmental and water quality concern,

such as oxygen, nitrogen, and volatile toxics (Thibo

deaux 1996; Chapra 1997). Oxygen transfer at free

surfaces has been widely studied since dissolved oxy

gen (DO) is a key water quality parameter and water quality standards and criteria for DO are provided by environmental regulation of many countries, such as USA, UK, Germany and Japan. Also in Italy, D.L. 152/1999 has, recently, established for streams and lakes a classification system which considers DO as a significant parameter (Ciaravino & Gualtieri 1999). The oxygen transferred from the atmosphere by means of natural reaeration replaces the amount consumed due to the oxidation of organic matter discharged into the water body.

The flux of dissolved oxygen at the air-water interface [ML −1 T −2] has been quantified according to (Chapra 1997):

where K L is the gas-transfer rate [LT −1], C sat is the equilibrium, or saturation, concentration of DO [ML −3] and C w is the DO concentration in the bulk water [ML −3]. Accordingly, oxygen is lost to the atmosphere when the upper waters are oversaturated (C sat <C w), and reaeration occurs when C sat >C w .

The accuracy of estimates of depends on the accu racies of the specifications of the gas-transfer coeffi cient, K L , and C sat and C w . Reaeration process is often parameterised using the volumetric reaeration coefficient K a [T −1], given, if h [L] is water mean depth, by (Chapra 1997): Since oxygen has low solubility and high vapor pressure, the exchange process is controlled

by the liquid side of the air–water interface (Chapra 1997). Recent studies have confirmed that available equations for the estimation of the reaeration rate are not applicable to all stream hydrodynamic conditions probably since some parameters involved in the process have been neglected in their formulation (Melching & Flores 1999; Gualtieri et al. 2002). Therefore, recent efforts have been addressed to develop a comprehensive approach to gas-transfer using dimensional analysis to clearly identify the parameters involved (Gualtieri et al. 2002; Gualtieri 2003). This approach has provided a relationship between the reaeration coefficient K L and some classical fluid mechanics index-numbers (Gualtieri et al. 2002). The present paper provides a preliminary quantitative assessment for that relationship using 65 literature laboratory data collected in smooth channels. 2 DIMENSIONAL ANALYSIS OF GAS-TRANSFER PROCESS In two previous papers a comprehensive approach to the gas transfer process at the air–water interface based

on dimensional analysis was proposed (Gualtieri et al.

2002; Gualtieri 2003).

Gas-transfer is mainly controlled by the turbulence

at both side of the air–water interface. Characterizing

turbulence influence on gas-transfer across air–water

interface has been proved to be difficult since this

influence depends on relative phase velocities, rough

ness of surfaces at the interface, frictional and adhesive

forces, surface tensions and several other parameters

(Weber & DiGiano 1996). Also, anisotropic turbu

lent conditions, with significant correlation between

the velocity fluctuations and the presence of a veloc

ity gradient and a shearing stress, further complicate

modeling effort (Moog & Jirka 1999). However, if

the gas-transfer is controlled by the liquid side, the

nature of turbulent eddies in the water can affect the parameters influencing the gas-transfer. Therefore, gas-transfer modeling approaches are different in shallow and rapidly flowing waters and in deep and standing waters because the nature of the forcing mechanism is different. In shallow streams, the surface turbulence is mainly due to the water velocity or, more precisely, to the interaction of the water flow with the bottom rugosity and depth variations. At the contrary, the surface of deeper environments is not affected by bottom features, and the shear stress exerted by the wind at the air-water interface is the main physical factor of turbulence (Chu & Jirka 1995). Also, in deep channels isotropic turbulent conditions, where the intensity of the velocity fluctuations in all three directions is very nearly the same, are more likely to exist (Thibodeaux 1997).The proposed analysis was addressed to turbulence generated by bottom shear stress, where the gas-transfer process is affected by the fluid and gas properties and by the hydrodynamics of the flow. A characteristic feature of turbulent flow is the presence of a wide range of eddy sizes, ranging to the flow domain to smaller sizes. If large eddies break down into multiple smaller eddies, they conserve their kinetic energy, which is efficiently transferred through

a cascade of eddy sizes (Pope 2000; Socolofsky &

Jirka 2002).

When the eddies become small enough, in the order

of Kolmogorov scale in size, viscosity takes over and

the energy is finally dissipated into heat. This con

version of energy can be quantified using the kinetic

turbulent energy dissipation rate ε [L 2 T −3]. In a homo

geneous turbulent flow, production and dissipation of

kinetic energy are balanced and ε must equal the total

turbulent kinetic energy of the flow, k. The rate ε is

proportional to the energy line slope J e as:

Therefore, J e should be included as key parame

ter in the dimensional analysis of gas-transfer process.

Notably, in steady uniform flow, the energy line slope J e is equal to the water surface slope J w and to the bed slope J b , whereas for steady non-uniform flow, they are generally different (Graf 1998). Consider now that it holds that R h ≈ h, where R h is the hydraulic radius. Also, assume that the gas-transfer process is controlled by the water side concentration boundary layer (CBL). Thus, the dimensional analysis could consider the following parameters: • natural constants and fluid properties such as the gravitational acceleration constant g [LT −2], the water kinematic viscosity ν [L 2 T −1], and the water surface tension T s [MT −2]; • gas exchanged properties, such as the molecular diffusion coefficient D m [L 2 T −1]; • flow properties, such as the mean depth h [L], the mean streamflow velocity v [LT −1], the energy line slope J e , the channel bed slope J b and the Manning's roughness coefficient n. First, the water surface tension,T s , was transformed into a kinematic parameter as τ s =T s /ρ [L 3 T −2], where ρ is the water density [ML −3]. Also, the coefficient n can be expressed as: where ε cw is the roughness coefficient of ColebrookWhite equation, that could be applied with good approximation also for streams and rivers. Thus, it holds: Assuming as fundamental quantities the water mean depth h, [L] and the molecular

diffusivity D m , [L 2 T −1], the dimensional analysis leads to where Sh, Sc, We, Re, and Fr are the classical Sherwood number, Schmidt number, Weber number, Reynolds number, and Froude number, respectively. Sh, Sc, and We are defined as: where U is water depth-averaged flow velocity [LT −1]. Finally, the relative roughness S is:

Equation (6) is the final form of the dimension

less gas-transfer rate in an open channel for liquid

controlled chemicals. This equation holds whatever is

the gas involved in the gas-transfer. Notably, classical

Darcy-Weisbach equation provides a relation between

Fr, Re, J e and S; thus, one of these parameters could be

expressed as a function of the remaining three of them

(Gualtieri et al. 2002). Also, in eq. (6) the temperature

influence is directly accounted for through the temper

ature dependent parameters, such as Sc and We. This

represents an advantage respect to the common appli

cation of a temperature corrective coefficient, such

as the classical θ of Van’t Hoff-Arrhenius equation

(Chapra 1997).

2.1 Comparison with large-eddy and small-eddy models

Classical literature large-eddies and small-eddies

models could be compared with the findings of the out

lined dimensional analysis. These models start from

surface renewal model, which states that rate of gas

transfer through the air–water interface depends on the

length of time that a certain water parcel coming from

the bulk water due to turbulent eddies is exposed to

the atmosphere. This time could range from zero to infinity. If r is the rate of surface renewal [T −1], the application of Fick's law leads to:

Therefore, r, which is a characteristic of the turbu lence, should be estimated. Two different approaches could be used depending on the considered size of turbulent motions renewing the CBL. If renewal pro cess is mainly affected by the largest, integral-scale eddies, the r is proportional to the intensity and to the scale of turbulence. Thus, vertical fluctuation veloc ity u ′ [LT −1] and Prandtl mixing length l [L] are used to define r (O'Connor & Dobbins 1958; Thibodeaux 1997).Also, they are usually related to the shear veloc ity u∗ [LT −1] and to the mean depth h, respectively, to consider that the renewal rate is r∝ u∗/h. This is the large-eddy model which states that (Moog & Jirka 1999):

where K L-ND is the dimensionless gas-transfer rate and Re∗ is the shear Reynolds number Re ∗ = (u ∗ 4 h)/ν. At the contrary, since the air–water interface tends to damp the eddies as they approach to it closer than their length scale, the contribution of small eddies, at the Kolmogorov scale, in renewing the CBL could be considered. Following this approach, that is called the small-eddy model, the renewal rate is r∝ (εν) 0.5 and the dimensionless gas-transfer rate is (Moog & Jirka 1999;

Socolofsky & Jirka 2002): Therefore, these two models could be generally represented as: where c 1 is a constant and n=-0.50 holds for the large-eddy model and n=-0.25 holds for the smalleddy model. Despite to their expressions, these models could be reduced to the proposed dimensional analysis. In fact, both equations (12) and (13) could be transformed into a form similar to (6). In particular, equations (12) and (13), after some arrangements, become: where, differently than in eq. (6), there are not the Weber number We, the channel bed slope J b and the relative roughness S. Thus, large-eddy and small-eddy models should be considered as a particular form of eq. (6) where the effect of the water surface tension, of the bed slope and of the roughness is not accounted for. 3 DATA ANALYSIS AND DISCUSSION The present paper provides a preliminary quantitative assessment of the eq. (6) using 65 laboratory data collected in smooth channels, i.e. S= 0. The considered data refer to different environmental and hydrodynamic conditions, though uniform flow conditions hold, i.e. J e = J b . First of all, the Froude number was discarded since it can be expressed using S, Re and J e . In fact, classical Darcy-Weisbach equation states; where λ is the friction factor, that in a turbulent flow is λ= λ(Re, S). Thus, eq. (17) yields: where Fr, S, Re and J e = J b are correlated. Equation (17) could be modified depending on certain; y = 38.977x 0.099 R 2 = 0.516 0

particularly, each one of the considered parameters could be, in turn, expressed as a function of the oth ers. For example the Froude number could be always expressed as:

Also, as a first approximation, since for the con sidered data the variation range of the Weber number is narrow, the influence of We was discarded. Thus, equation (1) yields:

where Sherwood number is affected by only Sc, Re and J b . Usually, correlations between Sh and Re are in the form (Incropera & DeWitt 1990):

where a, b, and c are constants which are derived from regression on experimental data. Often, c param eter is set c= 0.33, whereas the values of b exponent is reported on literature to be 0.87 (Probstein et al. 1972), 0.91 (Harriott & Hamilton 1965), 0.80 (Incr opera & De Witt 1990) and 0.89± 0.05 (Steinberger & Hondzo 1999).

The data used in the present study are all taken from literature. Particularly, the considered data are

those collected in laboratory flumes by Moog and

Jirka (Moog & Jirka 1999), by Ran (Ran et al. 2002;

Ran 2003), by Lau (Lau 1975), and by Thackston y = 0.042x 0.891 R 2 = 0.975 0 200 400 600 800 1000 0 20000 40000 60000 Re ynolds number Re S h e r w o o d n u m b e r S h Group n.2 Figure 2. Group n.3. and Krenkel (Thackston & Krenkel 1969), where well-controlled conditions hold. These four data sets refer to rectangular smoothchannels where the width ranged from 0.4 to 1.00 m. Notably, there is a significant separation in magnitude between the data by Moog-Jirka and the other three flume data sets since the first ones are generally higher (Moog & Jirka 1999). In the considered experiments the flow velocity ranged from 0.036 to 1.040 m/s, while water depth was from 0.011 to 0.145 m. The aspect ratio W/h avg , which has a significant influence on gas-transfer process (Gualtieri & Gualtieri, in press), ranged from 5.15 y = 0.007x 1.073 R 2 = 0.981 0 1000 2000 3000 4000 0 100000 200000 300000 Reynolds number Re

to 54.15. Interestingly W/h= 5 is the threshold value

for a “wide” open channel, where the effect of sec

ondary currents or “corner flows” could be neglected

(Nezu & Nakagawa 1993).

Finally, water temperature ranged from 11.3 to

25.7 ◦ C.Accordingly, Schmidt number was in the range

from 419.6 to 890.6, with an remarkable number of

data with Sc= 548, i.e. Lau data.

The analysis of the raw data has shown that they

could be divided in 8 groups according the value of

the channel bed slope J b and the Schmidt number Sc.

The main characteristics of each Groups are listed

in Table 1, where the number of data, the average bed y = 0.024x 0.897 R 2 = 0.950 0 100 200 300 400 500 0 10000 20000 30000 40000 5000 0 Reynolds number Re S h e r w o o d n u m b e r S h Group n.6 Figure 6. Group n.6. slope J b value, the average Sc value, and the average Re value are

presented. Bed slope J b-avg ranged from 0.00003 to 0.00350. Groups 4 refers to data with the same J b , which is equal to 0.01. Also, Groups 5 and 6 have similar value of slope J b-avg . while their Sc avg is different. Since the range of water temperature is quite narrow, the average Schmidt number Sc avg of the Groups ranged from 433 to 752. Moreover, Groups 1–5 have the same or very similar values of Sc avg and their overall average Schmidt number is Sc avg = 526. Finally, the values of Re avg exhibits an higher range, from 3977 to 227048. Groups 1–3 data belong to Lau set, whereas Group 4 is formed by Ran data. Groups 5 and 6 collect data collected by Lau and by Thackston and Krenkel, respectively. Finally, the higher data by Moog and Jirka are in Groups 7–8. These Groups present the highest Sc avg values, i.e. 704 and 752, respectively. In the present study a power relation between Sh and Re was proposed as: where μ 1 parameter depends from Sc and from the channel bed slope J b as: In the proposed model the dimensionless gas-transfer in quiescent water conditions is assumed to be zero. However, in stagnant water, i.e. Re= 0, gastransfer process occurs due to molecular diffusion (Thibodeaux 1997; Li Ran et al. 2002). Thus, a gastransfer rate for these conditions should be considered, but the available data does not allow to estimate this y = 1.610x0.654 R 2 = 0.970 0

rate. Moreover, since gas-transfer process in stagnant water is driven by molecular diffusion, this rate should be a temperature-dependent parameter.

The power relationship, i.e. eq. (21), between Sh and Re is presented for each Group in plots from Fig. 1 to Fig. 8, where R 2 parameter is also indicated.

Moreover, α parameter values are listed in Table 1.

These values are mostly close to literature values.

First of all, results demonstrate that eq. (21) pro vides a general good agreement with laboratory data and the proposed model is supported by the exper

imental data. Second, since it was assumed that α

parameter is independent from Sc, a common value for

α should be adopted. Thus, α values obtained from all

Groups were corrected using a weight criterion which

considers 3 parameters.

The first one is the number of data belonging to

each Group, the second one is ratio ΔRe/Re avg , i.e.

the ratio of the difference ΔRe between maximum

and minimum Reynolds number to Re avg value in each

Group, while the third one is 1/Re avg . As a result,

a value of α= 0.78 was estimated. This value was y = 6.453x
0.558 R 2 = 0.924 0 1000 2000 3000 4000 5000 6000 0 50000

m b e r S h Group n.8 Figure 8. Group n.8. Table 2.
Corrected values for μ 1 and α parameters. Group Data α μ 1
1 3 0.78 0.119 2 4 0.78 0.138 3 5 0.78 0.153 4 38 0.78
0.233 5 2 0.78 0.124 6 4 0.78 0.087 7 5 0.78 0.368 8 4 0.78
0.466 adopted as α in eq. (21) for all the Groups. Notably,
this value is consistent with those previously reported
from literature. As a result, corrected value for μ 1
values were obtained. They are listed in Table 2. The
analysis ofμ 1 data supports an interesting trend between μ
1 parameter, on one hand, and the bed slope J b and Schmidt
number, on the other hand (Fig. 9). In fact, Fig. 9 shows
that for Sc avg = 526 (the open circles)μ 1 parameter
significantly increases with increasing slopes J b . Also,
the data for Sc= 432 (the diamonds) presents for the same J
b lowerμ 1 than those for Sc avg = 526. Moreover, the same
trend could be observed in the data with higher Schmidt
number (the triangle and the cross), i.e. Sc= 704 and Sc=
752, where μ 1 parameter increases with increasing J b .
This results demonstrate that gas-transfer process is
enhanced by higher channel bed slope J b for the same value
of the Reynolds number. Thus, they confirmed that the bed
slope J b parameter should be included in gas-transfer
modeling framework. 0.000 0.100 0.200 0.300 0.400 0.500

μ 1 Sc=433 Sc=526 Sc=740

Figure 10. μ 1 parameter vs channel bed slope J b .

The two data with higher Sc were then regrouped

adopting an average Schmidt number, i.e. Sc avg = 740.

Linear regression of μ 1 parameter on bed slope J b

for both Sc avg = 526 and Sc avg = 740 is presented in

Fig. 10. The Group with Sc avg = 526 has 52 data,

whereas the Group with and Sc avg = 740 has 9 data.

Finally, only one data was available for Sc avg = 433.

Data with lower Sc avg exhibit an higher increase with

J b . Thus, the influence of Sc on μ 1 is supported and it

holds: 0.0 0.1 0.2 0.3 0.4 0.5 0.000 0.001 0.002 0.003 0.004 Channel bed slope J b S l o p e μ 1 Sc=433 Sc=526 Sc=740 Figure 11. Correctedμ 1 parameter vs channel bed slope J b . where μ 2 and μ 3 appear to be both affected by Sc. Fig. 10 shows that μ 3 is 12.52 and 35 for Sc avg = 526 and Sc avg = 740, respectively. These μ 2 values have been averaged using the number of data with Sc avg = 526 and Sc avg = 740, i.e. 52 and 9, respectively. A weighted averaged value ofμ 2 = 15.75 has been obtained. Results are

presented in Fig. 11. Notably, μ 3 parameter data support Sc influence. Therefore, eq. (21) yields: 4 CONCLUDING REMARKS Recent efforts have been addressed to develop a comprehensive approach to gas-transfer modeling. The present paper has provided a preliminary quantitative assessment for an approach based on dimensional analysis using 65 laboratory data collected in smooth channels. The present paper proposed a power relationship between the dimensionless gas-transfer rate and Reynolds number. The slope μ 1 of that relationship was found to be affected both by the channel bed slope J b and by the Schmidt number. A linear relationship between μ 1 and J b was derived for different Schmidt numbers. Its slope was finally averaged for all the data, providing a predictive equation which relates dimensionless gas-transfer rate with J b , Sc and Re. Further research should be focused to explore the influence on K L of surface tension and channel roughness developing a predictive equation including also We and S.

ABSTRACT: The recently introduced Italian laws (D.L. 152/99 and D.L. 258/00) have drawn attention to the

issues of conservation and recovery of the natural environment by defining general guidelines for the protection

of surface, ground and coastal waters. A methodological approach has been developed in order to assess the

vulnerability of surface waters and to define their environmental quality on the basis of an integrated analysis

of the river's ecosystem, which makes it possible for each river (or reach of river) to be attributed with an overall

index reflecting its environmental quality (river's environmental quality map). This procedure had been applied

to the pilot watershed of the Tusciano river (Southern Italy), by means of a monitoring network comprised of

8 experimental sections. The activities carried out have stressed the substantial validity of the methodology and

have made it possible to draw up a preliminary draft of the environmental quality map.

1 INTRODUCTION

The Italian law D.L. 152/99 defines the general frame

work for safeguarding surface, ground and coastal

waters by pursuing the objectives of preventing or con

trolling pollution, restoring water quality, protecting

waters used for special purposes, ensuring the sus

tainable use of available resources and preserving the

waters' natural ability to cleanse itself of impurities.

These objectives will be met through the use of a variety of instruments, including the targets of environmental quality and Protection Plans. However, before Protection Plans can be defined, the qualitative and quantitative status of water bodies needs to be determined and information has to be acquired regarding the physical, natural, social and economic characteristics of the basins in order to assess anthropic pressure and impact.

This varied set of investigative and planning activities constitutes a totally new approach to environmental policies regarding water resources in Italy.

2 METHODOLOGICAL APPROACH FOR SURFACE WATER ENVIRONMENTAL QUALITY ASSESSMENT

The first step in implementing Protection Plan calls for an environmental quality status to be attributed to the surface waters. Following the investigative surveys previously carried out in the area under the control of the Destra Sele Water Authority (Giugni et al. 2002), a methodological procedure was defined on the basis of assessments made regarding some indicators of the water quality and the Minimum Instream Flow. This allows a preliminary judgement to be made on the river's environmental quality so that suitable safeguards can be adopted and hence contribute to the planning activity regarding water usage. More specifically the procedure calls for: a) Physical, chemical and microbiological investigations aiming to assess the Level of Pollution from Macrodescriptors (LPM), which can be obtained by measuring the macrodescriptor parameters for the classification of surface waters (dissolved oxygen, BOD 5 , COD, ammonium-nitrogen NH 4 , nitrate- nitrogen NO 3 , total phosphorous, Escherichia coli). This will enable a preliminary quality assessment to be attributed to the river in question.The subsequent measurement of additional

parameters regarding organic and inorganic micropollutants (pesticides, organic solvents, aromatic polycyclical hydrocarbons, cadmium, chromium, mercury, nickel, lead, copper, etc.) will provide further information on the system's quality and vulnerability and on the extent of the transported load;

b) Biological Mapping of the river, aiming to assess the Extended Byothic Index (E.B.I.). Biological mapping allows a further assessment to be made, which is complementary to the physical, chemi cal and microbiological investigation, by assessing the overall effect of pollutants and various other external influences, even if only present sporad ically or in very small quantities (Ghetti 1995, 1997, Ruffo 1995, European Environment Agency 1999). Furthermore, the E.B.I. score corresponds to a preliminary quality class;

c) Classification of the River Ecological Status (RECS) achieved by comparing the quality class supplied by the macrodescriptors (LPM) with the result of the EBI, and attributing the reach in ques tion with the worse of the two values.Table 1 reports the quality classes envisaged by Italian law D.L. 152/99;

d) Determination of the definitive River Environmen tal Quality Status (REQS), by cross-referencing the ecological data with those regarding the pres ence of organic and inorganic chemical pollutants

according to the diagram reported in Table 2;

e) Definition of the River Functionality Index (RFI):

the RFI is derived from the RCE-I (Riparian Chan
nel Environmental Inventory). This method was
defined by R. C. Petersen (1992) who based it on
a 16-question checklist with 4 possible predeter
mined answers for each one. The main purpose
of the proposed model was to collect information
regarding the river's main ecological characteristics
in order to set up an inventory on the conditions
of Swedish rivers and riverbank vegetation. In this
framework, although the environmental assessment
can be inferred from the scores attributed to the indi
vidual characteristics, in actual fact, it was more of a
by-product than an explicit goal of the investigation.
Its many applications in Italy increasingly brought
to light the importance that this methodology could
assume not only in helping draw up an inventory
of environmental characteristics, but above all as
a model for assessing environmental quality. Con
sequently, the RCE-2 was proposed with a new
assessment checklist (Siligardi e Maiolini 1993).
When the new index was applied to cases all over
Italy, it was seen to be inadequately calibrated with
respect to the large number of possible river types,

thus fuelling the fear that the RCE was beginning to

encompass a heterogeneous family of indices hav

ing different contents and goals. Hence the need to

update the method so as to make it more general

and to allow it to define the goals more rigorously

by drawing up guidelines and precise instructions

for its users. The modifications made by a working

group coordinated by the Italian National Envi

ronmental Protection Agency (A.N.P.A.) were so

far-reaching that the index was attributed with a Table 1. River quality classes. Quality class Judgement Colour I Not polluted (or not considerably Blue alterated) environment II Environment that shows some Green pollution's consequences III Polluted environment Yellow IV Very polluted environment Orange V Greatly polluted environment Red Table 2. The RFI checklist comprises 14 questions (with 4 predetermined answers) organised in functional groups: • questions 1–4 concern the conditions of plant life along the riverbanks and in the surrounding area; • questions 5 and 6 refer to the relative size of the riverbed and the physical and morphological structure of the riverbanks; • questions 7–11 consider the structure of the riverbed; • questions 12–14 determine biological characteristics through structural analysis of the macrobenthonic and macrophytic community and the conformation of the substrate. The answers are specified for each bank of the river and are assigned numerical values in 4 ranges (minimum weight 1, maximum weight 30) which express the functional differences between the individual answers.The total score can assume a value between 14 and 300 and this is associated to a Functionality Level and a Functionality Assessment, as shown in Table 3 which also reports the conventional colours used in the mapping activity. Therefore, the proposed procedure includes not only the indicators

specifically envisaged in the national legislation (LPM, EBI, RECS, REQS) but also the River Functionality Index which, in the authors' opinion, constitutes a further important element for the characterisation of a

Table 3. RFI score. Funct.

river's environmental quality as it considers the river ecosystem overall, including its connections with the surrounding area. Finally, the above described investigations are integrated with the assessment of the Minimum Instream Flow (MIF), which aims to safeguard the physical characteristics of the river, the physical and chemical characteristics of the water and the typical biocenotic communities in natural environmental conditions, as pointed out in the recent Guidelines (a draft copy of which has been published by the Min istry for the Environment) in order to prepare for the

basin's hydrological balance (article 22, paragraph 4, of the law D.L. 152/99). In order to assess the MIF, reference has been made to the hydro-biological approach based on the search for environmental conditions suitable for the development of one or more representative species of the river's wildlife (biological indicator) using in situ measurement techniques, such as water depth and velocity and characteristics of the bottom substrate, to determine the above mentioned environmental conditions and hence define a habitat quality index as a function of the flow. In particular, reference is made to the Microhabitat Method (Bovee 1978, 1982, Marchetti et al. 1991, Manciola et al. 1994, Santoro 1994, Bovee et al. 1998, Manciola & Neri 2000), using the PHABSIM (Physical HABitat SIMulation system) software (Waddle 2001).

3 SURVEY ON THE ENVIRONMENTAL QUALITY OF THE TUSCIANO RIVER

The methodological procedure briefly illustrated above was applied to the Tusciano river (Campania, Southern Italy), which is under the control of the Destra Sele Water Authority. The waterway's main axis is about 37 km long and has a catchment area measuring approximately 260 km 2 . The main tributaries are the Vallone Isca della Serra, the Cornea, the Vallimonio, the Lama, the Rialto. For greater clarity, Figure 1 reports the catchment area and the hydrographic network of the

Figure 1. Catchment basin and hydrographic network of Tusciano river.

Tusciano river. In order to enable a reliable assessment of the environmental quality, the informations obtained in the previous surveys were used to set up a monitoring network comprising 8 sampling stations (indicated in Figure 2) located along the Tusciano (station n. 1, 2, 3, 5, 6 and 8), the Cornea (n. 4) and the Lama (n. 7). As far as the fish population of the Tusciano river is concerned, the lack of time available meant that it was not possible conduct a field campaign to determine the experimental curves for the fish life in the river and so reference has had to be made to suitability curves taken from the scientific literature. In particular, the knowledge of the river's main characteristic features suggested that, for the survey to be complete, reference should be made to both Salmonidae (SalmoTrutta Fario) and Cyprinidae (Chub), taking into account two developmental stages (adult and fry) for both species. The field surveys so far conducted have covered a time scale of six months. The results obtained – which should therefore be regarded as preliminary – are summarised in Table 4, which reports, for each sampled reach: • the order number; • the waterway in question;

• the watershed area;

• the results supplied by the physical, chemical

and microbiological macrodescriptor parameters in

terms of the overall score and the classification level

(LPM);

0.2-3.8 • the results inferred from biological mapping, in
terms of the Extended Byothic Index (EBI) and water quality
class; • the Ecological Status (RECS) - which always
coincides with the Environmental Status (REQS) - to be
attributed to the reach, with the corresponding assessment
and the reference colour in the environmental quality map;
• the results supplied by the RFI in terms of the
Functionality Assessment and the relative colour; • the
results obtained by applying the Microhabitats method, i.e.
the range of the optimal flow (Q opt) for the biological
indicators considered (salmo trutta fario and chub). The
survey and study showed that the River Environmental
Quality Status (REQS) was: • satisfactory in the mountain
reach of the Tusciano river (sampling sections 1 and 2),
attributed with a good assessment (green); • acceptable for
the foothill and valley sections of the Tusciano river
(sections 3, 5 and 6), attributed with a sufficient
assessment (yellow); • very bad (red) for the final reach
of the Tusciano river (section 8); • unsatisfactory for the
tributaries, with poor assessment (orange) for the Cornea
and very bad assessment (red) for the Lama. In conclusion,
the environmental quality status was insufficient for the
final reach of theTusciano river and for the tributaries
Cornea and Lama. It was then possible to draw up
theTusciano river environmental quality map, reported in
Figure 2, with the hydrographic

network marked in the colours corresponding to the

environmental quality assessment. However, it should

not be forgotten that the conclusions achieved on the

basis of the data collected so far should be integrated

by other in situ surveys so as to extend the field measurements to cover a time scale of at least one year.

Moreover, it must be pointed out that:

- with reference to the Level of Pollution from Macrodescriptors (LPM), in the surveys carried out there was an albeit small reduction in the macro descriptor values as the flow increased. Measure ments taken in periods characterised by low flow values – and hence by a lower dilution of pollutants – could therefore yield higher pollution levels;
- with reference to the Extended Byothic Index (EBI), the results are based on one or two measurements and not on a seasonal cycle (four measurements);
- the surveys carried out with reference to the River Functionality Index (RFI) reveal a slightly better sit uation for theTusciano river (sections 1, 2 and 8) and a much better one for the tributaries (in particular for the Lama). The “river ecosystem” overall, thus, appears to be characterised by better environmen tal status compared to that of the surface waters, in particular for the reaches with a worrying Environ mental Status (section 8,Tusciano, section 4, Cornea and section 7, Lama).

As far as the assessment of the Minimum Instream Flow is concerned, it must first of all be stressed that

application of the Microhabitat method yielded unsat
isfactory results for the fry of the biological indicators
considered, and so the data reported in Table 4 refer
to the adult species. The data obtained also made it
possible to assess the unit optimal flow rate values
q=Q opt /S (where Q opt and S indicate, respectively,
the optimal flow and the watershed area), summarised
in Table 5 for the Tusciano river.
Moreover, the unit optimal flow assumes extremely
high values for the tributaries, approximately 45–88
l/s · km 2 for the Cornea and 53–57 l/s · km 2 for the
Lama. In this connection it should be pointed out that
the Q ott values taken for the tributaries are higher
than the flows measured during the in situ surveys
and hence fall in the area of the simulation performed
by the PHABSIM software. There are, therefore, still
question marks concerning the advisability of deter
mining the optimal flow of waterways with small-sized
basins.
The minimum instream flow, which is obviously
much lower than the optimal flow, should on the other
hand be determined by assessing the consequences
on the biological indicators of a gradual reduction in
the Weighted Usable Area (WUA) corresponding to
the optimal flow WUA (Q opt). Calculations carried

out to this end, although tentative, have yielded the

Longitudinal dispersion in an extreme meander channel,

with changes in shape

J.B. Boxall

Lecturer, Department of Civil and Structural Engineering,

University of Sheffield, Sheffield, S1 3JD, UK

I. Guymer

Reader, Department of Civil and Structural Engineering,

University of Sheffield, Sheffield, S1 3JD, UK

ABSTRACT: Results are presented from a series of experiments conducted on a large-scale laboratory channel

with extreme meander planform geometry. The channel had an idealised ‘natural’ form, with longitudinally

variable cross-sectional shape, but constant cross-sectional area. Tracer studies were conducted to investigate

the effects of the channel configuration and different discharges on mixing and transport processes. From this

new data set, dispersion coefficients are calculated and compared to results for less extreme geometries. The

effects of non-dimensionalising are also explored.

1 INTRODUCTION

Understanding and predictive modelling of the fate of

soluble pollutants is essential for the efficient manage

ment of river environments. Pollutants may originate

from either slowly varying inputs, such as sewerage

treatment works, or more rapidly varying inputs, such

as accidental spills or intermittent discharges from

combined sewer overflows during storm conditions.

It is desirable to make predictions of both the travel

or retention times and the spreading or dispersion of

such pollutants, for applications such as environmen

tal impact assessment, protection of abstraction points

or aquifer recharge sites. Application of the European

Water Frame Water Directive requires quantification

of travel times and mixing processes for the estima

tion of water quality processes at a catchment scale. It

is desirable to understand, quantify and to be able to

predict the impact of channel form and discharge on

mixing processes.

2 BACKGROUND

Solute mixing has been an area of active research

since the work of Taylor (1953, 1954), who showed

that for pipe full flow, after an initial period, there

exists a balance between the effects of shear dispersion

(differential velocities) and turbulent diffusion. Reviews of fundamental theory, and application to open channel flows through laboratory and field studies can be found in Fischer et al (1979) and Rutherford (1994). Vertical mixing is often neglected in open channel flows because of the relatively short length scale. Transverse mixing is of particular interest below continuous sources, and has an inverse relationship to the processes of longitudinal mixing (Fischer 1969). Longitudinal mixing is associated with the temporal and spatial development of a slug of pollutant or tracer once it has become cross-sectionally well mixed, and is the focus of the study reported here. Previous studies have investigated the influence of many channel properties on longitudinal mixing. Jobson (1997) presented a compilation and regression analysis of field tracer studies in the USA. In particular looking at the relationship of empirical predictors for various channel properties, such as slope, dimensionless drainage area, relative discharge and local discharge. Rutherford (1994) prefaces his compilation of longitudinal mixing field study data performed on sinusoidal and meandering channels by noting the difficulties of accurately reporting values for hydraulic parameters for field studies. A similar compilation is presented by Fukuoka and Sayre (1973). The conclusion from these compilations is that a wide range of mixing coefficients are obtained from natural

channels, and that the non-dimensionalising under

taken was not sufficient to account for all the processes present.

Two parameters, which might be expected to have a major influence on mixing processes, are planform curvature and changes in cross-sectional shape. These two parameters will have a dramatic impact on shear dispersion, which Smith (1992) defines as the domi nant longitudinal mixing process by at least two orders of magnitude.

Rozovskii (1957) performed fundamental research into the hydraulics of flow in curved channels, deriv ing simple predictive expressions and providing field and laboratory validation and verification. Based on this, Fischer (1969) derived an expression to predict longitudinal dispersion coefficients under fully devel oped secondary flow conditions. The expression was proved for an infinitely long bend in the laboratory, but was shown to have limited validity for natural channel data. The expression includes an inverse relationship between transverse and longitudinal mixing. Hence, increased transverse shear effects, due to secondary currents induced by planform curvature (Boxall and Guymer 2003) reduce the rate of longitudinal mixing.

Fukuoka and Sayre (1973) and Guymer (1998) present results for laboratory studies into longitudi

nal mixing undertaken in sinusoidal and meandering channels. These studies again show a range of standard and non-dimensionalised longitudinal mixing coefficients. Guymer (1998) also studied the effects of various discharges, suggesting that the observed change in non-dimensionalised mixing coefficient with discharge was due to changes in degree of longitudinal variability of cross-sectional shape (trapping or dead zone effects) of the idealised natural channel form studied. The influence of dead or trapping zones in straight channels with boundary dead zones was explored by Valentine and Wood (1977).

The data reported in this paper was collected on the same experimental facility utilised by Guymer (1998), using a similar idealised 'natural', variable cross-sectional profile with a more extreme meander geometry.

3 ANALYSIS METHODS

Expressions based on Fick's law of diffusion can be theoretically derived to explain the mixing processes occurring in natural channels, provided several assumptions are met: sufficient time has elapsed since injection for equilibrium to establish between diffusion and dispersion, turbulence is statistically independent of time, and the flow cross-section is independent of

time and distance. These assumptions are not met in

most natural channel situations, however application

of mathematical solutions has been shown to provide good representation of measured data, Fischer (1979) and Rutherford (1994). The one dimensional analytical solution to a Fickian dispersion model may be written as: where c A is area mean concentration, M mass of pollutant or tracer,A area of flow, u A area mean longitudinal velocity, x longitudinal distance, t time and D the longitudinal dispersion coefficient. Prior knowledge or prediction of D and t are required to make use of such expressions in a predictive manner. Taylor (1954) showed that in specific situations the variance of a tracer cloud increases linearly with time, hence D can be defined from the change in spatial variance. Fischer (1966) used a frozen cloud approximation to determine the longitudinal dispersion coefficient through the change in temporal variance: where σ 2 t is the temporal variance in the longitudinal direction, and 1 and 2 upstream and downstream sites. Velocity, u A maybe evaluated from: where t i is the time of passage of the centroid of the tracer cloud, given by: and the temporal variance from: This is often referred to as the method of moments. In most experiments concentrations are monitored using Eulerian measurement techniques, hence temporal variances are most readily obtained. Expression 2 maybe evaluated by calculating the gradient of change in variance with distance along a study reach, from a sequential of measurement sites. This assumes that the mixing processes are constant over the reach.This assumption can be validated by the quality of the straight line fit obtained, this approach was employed by Guymer (1998). Alternatively the

dispersion coefficient can be evaluated between each

pairing of tracer measurement sites, and the consis

tency of mixing processes over a reach evaluated by

calculating the mean and standard deviation of the val

ues obtained. This method will be employed in this

paper.

Identifying the start and end of the tracer plumes is

essential for the above calculations. Variance in par

ticular is highly sensitive to this, since although the concentration maybe low at the plume extremes, the distance from the centroid will be relatively large and this term is squared in the calculation of variance. In the work reported here the plume edges are defined as a sequence of 30 data points with a concentration of less than 0.1% of the peak.

3.1 Guymer 1998

Guymer (1998) reports data obtained from the Flood Channel Facility at HR Wallingford in the UK. Two channel were studied one with trapezoidal cross section and the other an idealised natural channels form. Both channels were based on 60 ∘ meander plan form geometry and were cast in concrete.The idealised natural channel form had a variable cross-sectional shape with longitudinal distance, but a constant cross sectional area.This data set was available in its raw data format and has been reanalyzed using the method out lined above. The original and recalculated dispersion coefficients for this data set are presented in table 1. From table 1 it can be seen that the different meth ods of identifying the start and end of the data and of averaging the dispersion coefficient for each dis charge has resulted in a slight decrease in the values obtained. The variation within the repeat injections at

each discharge are indicated by the error bars in fig

ure 1. Figure 1 also shows the variation of dispersion

coefficient with discharge, showing a possible trend to

increase with discharge, although this is small relative

to the scatter in the data.

For predictive purposes it is desirable to attempt

to normalise the longitudinal mixing coefficient, such

that a single dimensionless predictive value, trend or

relationship may be obtained. Previous attempts have

Table 1. Dispersion coefficient values for 60 ◦ meander

channel from Guymer (1998) and from re-analysis. Discharge
D (1998) D (new)

Natural 10.5 0.0755 0.0663 utilised bed shear velocity (u∗) as a measure of flow resistance generating turbulence. The depth of flow has been adopted as a measure of the maximum length scale of turbulence, or perhaps more applicably to natural or varying channels the hydraulic radius should be used, as a measure of the maximum length scale of turbulence structures and/or as a measure of channel shape. Non-dimensionalising was reported in a tabular form by Guymer (1998), and can also be seen plotted as a function of discharge in figure 2. Guymer (1998) provides single averaged nondimensionalised values of longitudinal dispersion coefficient for the ‘natural’ and trapezoidal

channel shapes studied. However from figure 2 it appears that there maybe a more complex relationship with discharge for the natural channel. Dispersion, or differential shear, is thought to dominate mixing. As discharge increases in a straight uniform channel the transverse variation of longitudinal velocity will become more developed, increasing shear effects. Therefore longitudinal mixing might be expected to increase with increasing discharge. 0 0.04 0.08 0.12 0.16 0 10 20 30 40 50 Discharge, Q (l/s) D i s p e r s i o n c o e f f i c i e n t , D (m 2 / s) Natural Trapezoidal Figure 1. Variation of non-dimensionalised longitudinal dispersion coefficient for 60 ∘ natural and trapezoidal channel data, reanalyzed from Guymer (1998).

Guymer (1998) suggests that as discharge and depth

decreases the ‘tapping’ effects of the ‘plateaus’ on the

inside of the bends increases, which could explain

the overall increase in non-dimensionalised mixing

coefficient with decreasing discharge seen in figure 2.

4 EXPERIMENTAL SETUP

Data is reported from studies undertaken at the Flood

Channel Facility at HR Wallingford in the UK. The

channel was of the same type of idealised ‘natural’,

longitudinally variable cross-sectional shape as used

for study reported by Guymer (1998). This configu

ration was based on a 110 ∘ meander planform. The

channel was cast in concrete. The planform geometry

can be seen in figure 3 and a representation of ‘natural’

cross-sectional shape in figure 4. More details of these

planforms and cross-sectional forms can be found in Sellin and Greenhill (1992) and Knight et al (1992). Tracer studies were undertaken at a variety of dis charges, from bank full (~25 l/s) down to a minimum cover on the plateau around the inside of each bed of 10 mm (~12 l/s). Uniform flow conditions were set and monitored using a series of depth gauges. Short duration pulses of Rhodamine WT dye were intro duced as a line source across the bed at the channel inlet through a small diameter pipe with 0.5 mm holes at 5 mm centres. This was done to promote cross sectional mixing, reducing the distance to well-mixed conditions. FiveTurner Design Series 10 Fluorometers in continuous pump though mode were employed to obtain simultaneous measurements of the temporal variation of the solute cloud at different longitudinal locations, as indicated in figure 3.A further instrument was located upstream of the injection point to monitor the background buildup associated with re-circulating facilities. These instruments where all logged directly to a PC. 6 repeat injections were made at each flow rate.

Example concentration time plot from 110 ∘ channel at bank full flow conditions.

5.2 Analysed data

Figure 7 shows the trend for the mean travel times and

velocities calculated from the centroid of the tracer

clouds at each flow rate. The plot also includes error

bars indicating mean plus and minus the standard devi

ation for the repeat injections.As expected mean travel

time decreases and velocity increases with increasing

discharge.

Figure 8 shows the results of calculation for longitu

dinal dispersion coefficient from the measured tracer

data. Again the plot shows mean values, and error bars

for mean plus and minus standard deviation of the

repeat injections at each flow rate.

Comparing figure 8 with figure 1 suggests that the

longitudinal mixing coefficient for the 110 ∘ ‘natural’

channel is of a comparable magnitude to that found for the 60 ◦ ‘natural’ channel, although slightly lower. The longitudinal dispersion coefficients found for the 60 ◦ ‘natural’ channel data set showed a tentative trend, increasing with discharge. Figure 8 suggests that the trend for the 110 ◦ is a constant value, or slight reduc tion with discharge. However, the error bars for each data set indicate that the spread in the data is greater than any of these trends. This spread is associated with the sensitivity of the variance calculation to the definition of the start and end of the measured traces.

Figure 7. Travel time and velocity for 110 ∘ meander channel. The longitudinal dispersion coefficients found for the 110 ∘ degree channel have been non-dimensionalised by the hydraulic radius and the bed shear velocity evaluated from u∗= (gRS 0) 0.5 . The value obtained compares well with the reach average value of the sectional average shear stress presented by Knight et al (1992), and recreated in figure 9. This detailed data is only available for bank full flow conditions. Figure 9 highlights the low longitudinal variation in boundary shear stress, with only a slight peak partway into each bend. Table 2 presents channel properties and average non-dimensionalised longitudinal mixing coefficients as reported by Guymer (1998) with the addition of values for the 110 ∘ natural channel form results presented here. As reported by Guymer (1998) the values for the sinuous channels of constant cross-sectional shape are in good agreement, with a slightly greater value obtained for the trapezoidal channel, due to the greater shear dispersion effects associated with such a cross-section. Both the ‘natural’ channels with constant cross-sectional area, but longitudinally variable cross-sectional shape, show an

Figure 10. Non-dimensionalised dispersion coefficients for 110 ◦ meander channel.

non-dimensionalised longitudinal mixing coefficient, with a greater increase associated with the 60 ◦ less extreme meander geometry.

The variation of the non-dimensionalised longitudinal mixing coefficient with discharge for the 110 ◦ meander geometry is shown in figure 10. As with the 60 ◦ channel it can be seen that the non dimensionalised longitudinal dispersion coefficient is not constant with discharge. Unlike the 60 ◦ data the trend for the 110 ◦ data appears to be inversely proportional to discharge.

The trends with discharge of the non dimensionalised longitudinal dispersion coefficients resulting from both the 60 ◦ and 110 ◦ idealised natural channel forms are shown in figure 11. From this it can be seen that for both channel planforms the non-dimensionalised longitudinal mixing coefficient shows a similar decrease.

6 DISCUSSION

For both the 60 ◦ and the 110 ◦ channel planform data

sets reviewed and reported respectively in this paper,

it has been shown that as discharge increases the lon

gitudinal dispersion coefficient non-dimensionalised 30 50 70 90 110 10 15 20 25 3 0 Discharge, Q (l/s) N o n d i m e n s i o n a l i s e d l o n g i t u d i n a l m i x i n g c o e f f i c i e n t , D / R u ∗ ( ) 110˚ 60˚ Figure 11. Non-dimensionalised dispersion coefficients for 60 ◦ and 110 ◦ meander channels. by hydraulic radius and bed shear velocity, tends to decrease. This suggests that processes other than those accounted for by the non-dimensionalising factors are at work. Differential shear is thought to dominate longitudinal mixing. Hence as discharge increases in a straight uniform channel, and the velocity profile becomes more developed, the effects of shear dispersion should increase. Therefore longitudinal mixing might be expected to increase with increasing discharge. According to Rozovskii (1957), the strength of full developed secondary circulation is directly proportional to the mean longitudinal velocity. This taken with the inverse relationship between longitudinal and transverse mixing, highlighted by the expression of Fischer (1969) suggests that as discharge increases in a channel with planform curvature the effects of increasing longitudinal velocity shear will be counteracted by increasing secondary flows. However this trend will be further complicated by the buildup, decay and reversals of secondary circulations associated with meandering channels. It is suggested that as discharge increases the idealised natural channel shape used for these studies becomes more uniform, hence the trapping effects of the plateau around the bend apexes becomes less, decreasing longitudinal mixing. It is suggested that it is this last trend that dominates the data presented here. 7 CONCLUSIONS New longitudinal dispersion coefficient values are presented from experiments conducted on a channel with extreme meander geometry and an idealised ‘natural’ cross-sectional shape. Comparisons of these values with ones from a channel with less extreme geometry, but the same idealised natural cross-sectional form, show close agreement. Non-dimensionalised longitudinal mixing coefficients from two meandering channels with idealised natural channel forms are shown to be greater than

values resulting from straight rectangular and trape

zoidal channels. However it has been found that

increasing sinuosity does not correlate with increased

longitudinal mixing.

Attempts to normalise longitudinal mixing coeffi

cients resulting from the meandering natural channels

at different discharges, using bed shear velocity and

hydraulic radius, have been shown to be insufficient

to produce a single predictive value. However, a trend

with discharge is elucidated for these channels.

Evaluation of longitudinal dispersion coefficients for over-bank flow

Steve G. Wallis

Heriot-Watt University, Edinburgh, Scotland

J. Russell Manson

The Macaulay Institute, Aberdeen, Scotland

ABSTRACT: The majority of approaches for predicting pollutant transport in rivers rely on being able to

estimate dispersion coefficients. This paper makes predictions of dispersion coefficients for in-bank and over

bank conditions in a two-stage channel, the latter

predictions being a new contribution to the field. The work

combines a simplified method for predicting the transverse structure of open channel flows with an established

technique for evaluating longitudinal dispersion coefficients. The method was applied to an existing hypothetical

benchmark channel. For the in-bank case, the dispersion coefficient was very small (less than 3 m 2 /s) and

increased approximately linearly with flow rate. For the over-bank case, the dispersion coefficient was several

orders of magnitude larger and decreased non-linearly with flow rate. The predictions for both flow conditions

are consistent with experimentally derived trends reported in the literature, and they provide the first theoretical

support for the observations in the over-bank case. The cause of the very large dispersion coefficients in the

over-bank case is a strong transverse velocity shear created by areas of low velocity water on the flood plains.

The over-bank results have significant implications for users of mathematical models of pollutant transport.

1 INTRODUCTION

Mathematical models are routinely used to predict the

fate and transport of pollutants that are accidentally

released into rivers. Although several models have

been developed for simulating such pollution incidents

(Beltaos, 1982, Bencala & Walters, 1983, Wallis et al,

1989, Jobson, 1997, Worman, 2000), the majority are

based on the one-dimensional advection-dispersion

equation (Fischer, 1967).

The use of this approach requires modellers to esti

mate dispersion coefficients in rivers. Whereas there is a large body of work devoted to predicting dispersion coefficients in natural and man-made channels for in-bank flows, e.g. McQuiver & Keefer (1974), Jain (1976), Liu (1977), Fischer et al (1979), Rutherford (1994), Seo & Cheong (1998), Deng et al (2002), Wallis & Manson (in prep.), no corresponding work has been undertaken for over-bank flows. The primary aim of this paper is to address this gap in knowledge by making predictions about longitudinal mixing under these conditions that occur when rivers are in flood, with flow taking place in both the main channel and also in the adjacent flood plains. The hydraulics of such flows has been studied extensively in recent years (Keller & Rodi, 1988, Shiono & Knight, 1991, Ackers, 1993, Naot et al, 1993, Lambert & Sellin, 1996, Sofialids & Prionos, 1999, Ervine et al, 2000) primarily because so-called two-stage channels have increasingly been incorporated in the design of flood relief schemes as a means of providing sufficient flow conveyance and/or storage. However, the transport of pollutants that enter these channels during flood conditions has not been extensively studied. The specific objectives of the paper are to describe a method for predicting dispersion coefficients in channels, to apply the method to in-bank and over-bank flows in a two-stage channel and to discuss the implications of some of the predictions that are made for over-bank flows. 2 THEORETICAL BACKGROUND The advection-dispersion equation (ADE) for a conservative solute is given below: where C is the cross-sectional average solute concentration, U is the cross-sectional average longitudinal flow velocity, D is the longitudinal dispersion coefficient, x is the longitudinal space co-ordinate and t

is time.

In this, longitudinal dispersion is modelled using a diffusion term in which the rate of streamwise spreading of a solute cloud is governed by the magnitude of the dispersion coefficient. As a result of the one dimensional formulation of the ADE the nature of the dispersion coefficient is rather complex because it arises from the interaction of two physical processes, namely differential longitudinal advection and cross-sectional mixing. The former encapsulates the transverse and vertical gradients of the longitudinal velocity that drive the streamwise spreading while the latter continually re-distributes solute within the plane of the cross-section and tempers the streamwise spreading. Both turbulent diffusion and secondary currents contribute to the cross-sectional mixing. The way in which the dispersion coefficient depends on differential longitudinal advection and cross-sectional mixing is described by the following equation:

where A is the cross-sectional area of flow, U ′ is the local deviation of the longitudinal velocity from the cross-sectional average longitudinal velocity, f is a function that describes the cross-sectional distribution of the transverse and vertical mixing coefficients,

y is the transverse space co-ordinate and z is the vertical space co-ordinate. Given information on the magnitudes and the distributions of the longitudinal velocity and the mixing coefficients in a cross-section, Equation 2 can be used to evaluate D.

Since the work of Fischer (1967), which was based on the earlier work of Taylor (1954), it has generally been accepted that transverse differential longitudinal advection and transverse mixing dominate the gen eration of longitudinal dispersion in rivers because they are usually much wider than they are deep. The evaluation of D from Equation 2 is then simplified because only the transverse distributions of depth averaged longitudinal velocity and depth-averaged transverse mixing coefficient are required. Neverthe less, the practical application of this method is far from simple, requiring the evaluation of the following triple integral (Fischer, 1967, Fischer et al, 1979, French, 1986):

where W= channel top width (i.e. width at the water surface), h= h(y) is the local flow depth, $u' = u'(y)$ is the local deviation of the depth-averaged longitudinal velocity from the cross-sectional average longitudinal velocity, $\varepsilon_y = \varepsilon_y(y)$ is the local depth-averaged transverse mixing coefficient and the other symbols are as previously defined. Alternative approaches for evaluating dispersion coefficients include the method of moments, Fischer's routing method and the use of empirical equations

(Fischer et al, 1979, Rutherford, 1994, Wallis & Manson, in prep.). In the context of the current paper, however, the use of Equation 3 is the most appropriate method because much of the information that would be required to use the other methods is not available for over-bank flows. To use Equation 3 for any given channel crosssectional shape, we require information on the transverse velocity profile and the transverse distribution of the transverse mixing. A theoretical method for achieving this is described below. 3 THEORETICAL ANALYSIS OF FLOW STRUCTURE The two-dimensional depth-averaged shallow water equations may be simplified for the case of fully developed steady flow in a river of general cross-section. In the simplest case, the steady depth-averaged longitudinal momentum conservation equation can be written as (Shiono & Knight, 1991): in which ρ is the fluid density, g is the gravitational acceleration, S o is the channel bed slope, h= h(y) is the local depth, τ b = τ b (y) is the local longitudinal bed shear stress, θ is the transverse slope of the bed and τ yx = τ yx (y) is the local depth-averaged shear stress in the x-direction on the plane perpendicular to the ydirection. Equation 4 applies at all transverse locations and describes a local balance between the component of fluid weight down the channel slope and the resisting longitudinal shear stresses on horizontal and vertical planes (caused by bed roughness and transverse turbulent momentum exchange, respectively). Here, the effect of transverse secondary flows has been ignored. Also note that for a transversely horizontal domain, in which h is constant, θ= 0. Using a quadratic friction law the local longitudinal bed shear stress can be re-written in terms of Manning's resistance coefficient, n, giving: where u= u(y) is the local depth-averaged longitudinal velocity and the hydraulic radius has been replaced with the local depth.

Using the Boussinesq eddy-viscosity concept, the

longitudinal shear stress caused by transverse turbu

lent momentum exchange can be represented in terms

of the transverse gradient of local depth-averaged

velocity, as follows:

where ε yx is an eddy-viscosity, which in the simplest

case can be written as:

in which λ is a dimensionless eddy viscosity and u*=

u * (y) is the local shear velocity. In the absence of secondary flows it is often assumed that the turbu lent mixing of momentum is similar to the turbulent mixing of solutes, i.e. the eddy viscosity, ε yx , is equal to the transverse mixing coefficient, ε y . Combining Equations 4-7 gives:

in whichα is a binary constant. Ifα is set to 0 then a lat erally varying velocity profile based only on the local application of Manning's equation results. However, when α is set to 1, the role of the transverse momen tum exchange is included. In this paper we simplify the problem by considering the case whenα= 0, since this is sufficient for our purposes here. The more complex case is considered in Manson & Wallis (in prep.).

Having established equations for predicting u ′ (Equation 8 with α set to zero) and ε y (Equation 7), Equation 3 can be solved for D using numerical inte gration, following the method described in French (1986).

4 APPLICATION TO CASE STUDY

The two-stage channel used here for investigation was based on the hypothetical benchmark channel introduced by Ackers (1993). The channel is shown in Figure 1 and the channel parameters took the following values: B 1 = 15 m; B 2 = 1.5 m; B 3 = 20 m;

B 4 = 1.5 m; D 1 = 1.5 m; D 2 = 1.5 m. Manning's n

was taken to be 0.03 for both main channel and flood

plains. The bed slope, S o , was set to 0.003 and the

non-dimensional eddy viscosity, λ was assigned the

value 0.16 – a typical value for straight channels

(Rutherford, 1994). The local shear velocity was eval

uated by applying Equation 5 locally, assuming that

locally τ b = ρu 2 * .

Calculations were carried out for main channel flow

depths between 0 and 3 m in 0.15 m increments, thus

covering both in-bank and over-bank scenarios. B 1 B 2 B 3 B 4 D 2 D 1 Figure 1. Cross-section of benchmark channel. Since D was derived from numerical integration, it was essential to study the influence of the transverse discretisation,δy, on the calculated values. Hence, for each flow depth several evaluations were undertaken with δy being successively refined until the results became independent of δy. Only when the results had converged were they deemed to be acceptable. In this application, it was important to capture the shear layers at a sufficiently fine resolution. 5 RESULTS AND DISCUSSION The results are shown in the form of dispersion coefficient plotted against flow rate in Figures 2 and 3 for in-bank and over-bank flows, respectively. For inbank flows, the dispersion coefficient increases with increasing flow rate and is very small, being in the range 0–3 m 2 /s for flows between 0 and 50 m 3 /s. The trend is weakly non-linear, but is well approximated by a linear relationship. The magnitude of the dispersion coefficients is supported by the predicted transverse velocity profiles that consist of a wide uniform velocity region with very narrow shear zones at the channel sides. Since dispersion is promoted by gradients in transverse velocity, the very narrow shear zones are only capable of inducing minimal dispersion. As the flow depth increases, the shear zones become wider resulting in a larger dispersion coefficient. For over-bank flows the results are significantly different. Not only is the size of the dispersion coefficient different, but so is the variation with flow rate. The dispersion coefficients are

now in the range 38000- 500 m 2 /s for flows between 70 and 330 m 3 /s, respectively - several orders of magnitude larger than for the in-bank case. The coefficients decrease rapidly in the flow range 70-100 m 3 /s and then more slowly at higher flows. Clearly, the dispersion is being dominated by the role of the strong shear that develops as the flow begins to occupy the flood plains. This shear is easily recognised in the example transverse velocity profile shown in Figure 4, which shows that for this case the velocity in the main channel is about three times larger than the velocity on the floodplains. Although the influence of the velocity shear decreases as the flood plain flow depth increases, because the velocity becomes more uniform across

the channel, it retains its dominant role throughout the

flow range considered.

Observation of the convergence of the result of the

numerical integration as the transverse step size was

decreased showed that very small steps were required,

particularly when the shear layer was very narrow.

Typically, W/Δy needed to be of the order of 1000 to achieve satisfactory convergence using a uniform discretisation. Clearly, this very small step size was dictated by the requirement of accurately resolving the shear layer. The different behaviour of the dispersion coefficient between in-bank and over-bank flows is an important result. Interestingly, these theoretical results

are supported by experimental evidence in Rutherford (1994). Firstly, for the in-bank case Rutherford's Figures 4.7 & 4.6 indicate that dispersion coefficients increase with increasing flow rate. The former is directly comparable to the case studied here because it considers conditions at different flow rates in the same reach, for four rivers. In contrast, the latter shows conditions from a very wide range of reaches from about sixty rivers worldwide. For the over-bank case Rutherford's Figure 5.14 shows dispersion coefficients decreasing with increasing flow rates in four reaches of a single river. Rutherford's explanation is resonant of the conditions in the case studied here, namely that bank side areas of shallow flow create strong transverse velocity shear at low flows, but as the flow increases the velocity in the shallows increases causing a reduction in the transverse shear and a concomitant reduction in the dispersion coefficient. Finally, workers using the ADE to simulate solute transport in open channels should take note that existing methods for predicting dispersion coefficients cannot be used for the over-bank case. For example, many of the published empirical equations and the relationships available within software packages such as MIKE11 (Anon, 1992) and ISIS (Anon, 1998) do not necessarily cater for either, or both, of the magnitude of the coefficients or the nature of its flow dependence, predicted here. 6 CONCLUSIONS A method has been proposed for predicting dispersion coefficients in a two-stage channel based on a theoretical approach that requires a prediction of the transverse distribution of the longitudinal velocity field. This was achieved using a local application of the Manning resistance equation, although reference was made to an improved method that includes the effect of transverse turbulent momentum exchange (Manson & Wallis, in prep.). Numerical integration of Fischer's flow structure equation then yielded the dispersion coefficient. Results were obtained for the two-stage channel studied by Ackers (1993) under both in-bank and overbank conditions. The latter results are believed to be the first predictions of dispersion coefficients in such flows. By their very nature, the results are limited to straight channels with negligible secondary flows. The transverse mixing was modelled using a constant dimensionless mixing coefficient of 0.16 and a truly local representation of depth and shear velocity.

For the in-bank case, the dispersion coefficient was

very small (being in the range 0-3 m 2 /s for flows

between 0 and 50 m 3 /s) and increased approximately

linearly with flow rate. For the over-bank case, the dis
persion coefficient was very large (being in the range
38000–500 m 2 /s for flows between 70 and 330 m 3 /s)
and decreased non-linearly with flow rate. The pre
dictions for both flow conditions are consistent with
trends reported in Rutherford (1994).

Evaluation of transverse dispersion coefficient under transient concentration condition

I.W. Seo

Prof., Dept. of Civil Eng., Seoul National Univ., Seoul, Korea

K.O. Baek & S.J. Jeong

Grad. Student, Dept. of Civil Eng., Seoul National Univ., Seoul, Korea

ABSTRACT: Laboratory experiments were conducted to investigate characteristics of both the velocity field and the concentration field in the meandering channel having a rectangular cross-section. The S-curved channel has been built considering river morphology and previous experimental studies. The micro-ADV was used to

measure the three-dimensional velocity field. The electrode conductivity meter was used to obtain the tracer

concentration. The tracer was instantaneously injected into a flow as a vertical line source. Result of the flow

experiments shows that the maximum velocity of the primary flow occurs near the inner bank in a bend taking

the shortest course along the channel. For the secondary flow, complex flow pattern appears compared to

experimental results in a single-bend channel. Throughout the two-dimensional tracer tests, the meaningful

concentration versus time versus lateral distance data could be obtained. Using the tracer data, the transverse

dispersion coefficient was evaluated by the change of moment method. In addition, the 2-D routing procedure

was developed in order to obtain more accurate transverse dispersion coefficient.

1 INTRODUCTION

Dispersion is the spreading out of particles along

a stream or channel due to velocity differences. In

a mathematical model, the dispersion term occurs

as transforming the three-dimensional advection

diffusion equation into the two-dimensional advection

dispersion equation by integration with respect to a

depth. Knowledge of the dispersion characteristics of

streams and rivers is essential to the understanding and

managing of water pollution problems. Furthermore,

the transverse dispersion is more important in water

quality management than either vertical or longitudi

nal mixing, especially, when dealing with the discharge

of wastes from point sources or the mixing of tributary inflows. Because of importance to understanding of the pollutant transport in natural streams, many researches including laboratory and field works, and analytical and numerical calculations have been performed on the transverse dispersion. Up to date, many of those researches have concentrated on the mixing in straight, prismatic channels. However, natural streams are rarely straight and prismatic for any considerable distance. The effects induced by non-uniformity and meandering should not be negligible. When a two-dimensional analysis of the tracer mixing is performed in meandering streams, it is the essential task to determine the transverse dispersion coefficient. There are several methods to determine the transverse dispersion coefficient in case of knowing the concentration versus time data. The change of moment method proposed by Sayre and Chang (1968) has been frequently used. This approach can be obtained by taking the integration with respect to the transverse direction of the steady state conservation equation for two-dimensional flow in a rectangular channel with uniform velocity distribution and no longitudinal dispersion. Holley et al. (1972) suggested the generalized change of moment to overcome disadvantages of the change of moment method. This method can consider transverse velocities, irregular depth, and so on. However, those methods can only be applied to the steady concentration condition, and errors may occur according to inaccurate variance of the concentration curves. In many cases, it would be preferable to perform an instantaneous injection rather than a continuous test. Some of the advantages of the instantaneous injection test are that the amount of tracer needed to perform an instantaneous test is much less than that is required for a continuous test, and an instantaneous test can provide the information on the longitudinal and time spread characteristics as well as the information on the transverse mixing.

In this study, in order to evaluate the transverse dis
persion coefficient under the transient concentration
condition, the two-dimensional routing procedure was
developed. The laboratory tracer tests were conducted
in the meandering channel having a rectangular cross
section to observe behavior of the tracer cloud and to
obtain the concentration-time data.

2 THEORETICAL BACKGROUND

In most rivers, the aspect ratio is large and the tracer
becomes well mixed vertically before well mixed
transversely. The vertical mixing is only important
close to the tracer source. In the mid-field, the ver
tical concentration gradients can be neglected, and
our attention can be focused on transverse and longi
tudinal changes of the depth-averaged concentration.
The full three-dimensional advection-diffusion equa
tion can be averaged over the depth to yield the
two-dimensional equation. Assuming a non-buoyant
tracer being transported in an unsaturated incompress
ible flow, the two-dimensional advection-diffusion
equation in the Cartesian coordinates is

where C = depth-averaged concentration; t= time;
x, y=Cartesian coordinates systems; u, v= depth
averaged longitudinal and transverse velocities;
h= depth; and D L , D T = longitudinal and transverse

dispersion coefficients respectively.

2.1 Transformation transient condition into steady condition

Evaluation of the transverse dispersion coefficient

has been associated with continuous injection tests,

i.e. tracer is injected into a stream at a constant rate

so that a steady-state distribution of concentration is

established some time after the commencement of

injection. A literature review revealed that the most

existing methods are only applicable to steady-state

experiments. Extensions to unsteady situations are the

oretically possible but they would introduce enormous

complexities in the calculation. However, Beltaos

(1975) presented a procedure for applying the existing

methods to the results of instantaneous tests without

increasing the computational efforts or decreasing the

accuracy of computations. He introduced the concept

of a dosage as Integrating Equation (1) with respect to time, Equation (1) becomes Equation (3) shows that the quantity θ of a slug test behaves exactly in the same manner as the concentration C of a corresponding continuous test. According to the suggestion of Beltaos (1975), the transient test can be converted into continuous test so that the moment method can be applied to the transient test. 2.2 Routing procedure In this study, the new method for evaluating the transverse dispersion coefficient is developed without any conversion procedure. The new method was based on the routing procedure proposed by Fischer (1968). He proposed the one-dimensional routing procedure to calculate the longitudinal dispersion coefficient. In the routing procedure, the dispersion coefficient is calculated by matching a downstream observation of passage of a tracer cloud to the prediction based on an upstream observation. The equation of the onedimensional routing

procedure can be derived from the solution of the one-dimensional dispersion equation which is where K = longitudinal dispersion coefficient which accounts for the effects on the cross-sectional averaged tracer concentration of variations of velocity across the channel cross-section. When it is considered that the solution corresponding to a mass M instantaneously released at time t= 0 at the point x= § , the solution is Suppose that the initial conditions were C(x, 0)= f (x), then the concentration at point x and time t resulting from the slug centered at § and of width d§ and height f (§) is Therefore, the total contribution is the superposition integral as follows

In order to route a distribution of the downstream

concentration from an upstream concentration, Equa

tion (7) can be rewritten as

where C(§ , t 1)= observed concentration as a func

tion of distance at time t 1 ; and C(x, t 2)= predicted

concentration as a function of distance at time t 2 . Equa

tion (8) requires knowledge of the instantaneous tracer

concentration versus distance profile (spatial concen

tration profile), such as might be determined by an

aerial photography. However, it is common to know

the tracer concentration as a function of time (temporal

concentration profile) at a fixed sampling site down

stream. Under the frozen cloud assumption (Fischer,

1968; Rutherford, 1994) which is that no dispersion

takes place during passage of tracer cloud past the

measuring station, the routing equation of a spatial

concentration can be converted into those of a temporal

concentration.

where C(x 1 , τ)= observed concentration as a func

tion of time at an upstream site; C(x 2 , t)= predicted

concentration as a function of time at a downstream

site; t 1 , t 2 =mean times of passage at upstream and

downstream sites respectively; and τ = a dummy time

variable of integration. Through the Equation (9), the

concentration profile at a downstream can be cal

culated, and then by fitting between the calculated

concentration and the observed concentration, the

longitudinal dispersion coefficient can be obtained.

Based on the one-dimensional routing procedure,

the two-dimensional routing procedure is developed in

this study. The conceptual diagram of an application

of the two dimensional routing procedure at a stream

is shown in Figure 1.

The equation of the two-dimensional routing pro

cedure can be derived from the solution of the

two-dimensional dispersion equation which is Figure 1. Conceptual diagram of the 2-D routing procedure. When it is considered that the solution corresponding to a mass M instantaneously released at time t= 0 at the points x= ξ and y=ψ , the solution is Through Equation (11), the spatial two-dimensional routing equation can be expressed as where C(ξ ,ψ , t 1)= observed concentration as a function of longitudinal distance and transverse distance at time t 1 ; and C(x, y, t 2)= predicted concentration as a function of longitudinal distance and transverse distance at time t 2 . Under the frozen cloud assumption, Equation (12) can be converted into the temporal two-dimensional routing equation which is where C(x 1 ,ψ , τ)= observed concentration as a function of time and lateral distance at an upstream site; and C(x 2 , y, t)= predicted concentration as a function of time and lateral distance at

a downstream site. Using the Equation (13), the concentration profile at a downstream can be calculated, and then by matching between the calculated concentration and the observed Table 1. concentration, not only the transverse dispersion coef

ficient but also the longitudinal dispersion coefficient

can be obtained.

The merits of the two-dimensional routing proce

dure are: (1) dispersion coefficients can be obtained

under the transient concentration condition without

any conversion procedure; (2) not only the transverse

dispersion coefficient but also the longitudinal dis

persion coefficient can be obtained simultaneously,

whereas only the transverse dispersion coefficient can

be obtained through the moment method; and (3) the

transverse dispersion coefficient can be obtained in

more detail according to the longitudinal positions. 3 EXPERIMENTS 3.1 Experimental setup The S-curved laboratory channel was constructed to investigate meander pattern of natural streams.Among the various hydraulic factors of the meandering channel, channel width (W), radius of curvature (R C), arc angle (θ), wavelength (λ), and sinuosity were considered. The properties of meander pattern of the S-curved channel used in this study are shown in Table 1. The S-curved laboratory channel which has a rectangular cross-section is 15 m long, 1 m wide, and

0.6 m deep. It consists of circular arcs connected by

straight sections as shown in Figure 2. The radius of curvature is 2.4 m, the wavelength is 9.7 m, and the arc angle is 120 ∘ . The channel was equipped with instrument carriages, which rested on rails mounted on the flume. One carriage is equipped with an auto traversing system for the velocity measuring sensor throughout the depth and breadth of the flow field. An electromagnetic flowmeter was installed to con tinuously measure the discharge of the flow passing through the channel. A point gauge was used to measure the flow depth. A side-looking micro-ADV, developed by SonTek, was used to measure the three dimensional distributions of velocity and turbulence. The micro-ADV operates on a pulse-to-pulse coherent Doppler shift to provide a three-component velocity at a rate of 50 Hz. The concentration measurements were made with the electrode conductivity meter, which was developed by KENEK.The probe of electrode conduc tivity meter is very small like φ4 mm, and there is little influence to the flow. The electrode conductivity meter can obtain concentration data at a rate of 10 Hz, the measuring range is 0~ 30,000 ppm, and the linearity is ±1.5%.

Six electrode conductivity probes were arranged at each transection by the hand-operated traversing

system, and the concentration distributions are mea
sured simultaneously at three transactions. The probe
calibration for a response to a concentration was per
formed by a series of standard salt solutions whose
range were from 0 ppm to 10,000 ppm. The concentra
tion signals were fed into the data acquisition system,
which converted the sampled signals to digital volt
ages. The amplifier unit was adjusted to give zero
output in the flume water. A calibration curve of out
put voltage versus concentration was constructed by
immersing the probe in each of the standards and
recording the voltage output. The tracer was a salt
solution, and a red dye ($KMnO_4$) was added to aid
in visualizing the diffusing cloud. The density of the
tracer solution was adjusted to that of the flume water
by addition of the methanol. The tracer was instan
taneously injected into the flow as a full-depth vertical
line source using the instantaneous injector. The injec
tor consisted of the fixing plate and φ9.0 cm cylinder.
By lifting the cylinder from the fixing plate, the tracer
can be introduced into the water.

3.2 Experimental conditions

In the S-curved channel, seven cases of tests on mea
surements of velocity field were conducted according
to flow conditions. The flow experimental conditions

are tabulated in Table 2. Measurements of velocity field were conducted at eleven transections whose location was marked at Figure 2. The interval of measuring points at each transection is transversely 7 cm, Table 2. Flow conditions. Case H (cm) V (cm/s) Q (l/s) W/H Fr 070 7 28.6 20 14.3 0.34 101 10 30.0 30 10.0 0.30 151 15 20.0 30 6.7 0.16 152 15 40.0 60 6.7 0.33 211 21 14.3 30 4.8 0.10 212 21 28.6 60 4.8 0.20 213 21 42.9 90 4.8 0.30 Figure 3. Depth-averaged primary velocity vectors (Case 101). and vertically 3~5 cm. Thus, the number of measuring points at each section varies from 30 to 90, depending on the water depth. The concentration experiments were conducted in the all flow conditions. The tracer was instantaneously injected into the flow as a full-depth vertical line source at the centerline, left bank, and right bank of the channels. The injection point was marked at Figure 2. The initial concentration of the tracer was 100,000 mg/l (ppm). The interval of concentration measuring points at each transection is 14 cm transversely. 4 EXPERIMENTAL RESULTS 4.1 Velocity field One of the purposes of laboratory experiments is to investigate flow patterns in the S-curved channel. In order to observe a primary flow pattern, depth-averaged primary velocity vectors are plotted in Figure 3 for the representative cases. The transverse distribution of the primary velocity skews toward the inner bank at bends and is almost symmetric at the crossovers. The noticeable phenomenon is that the maximum velocity occurs taking the shortest course along the channel, irrespective of flow conditions. In natural streams, however, it has been known that the maximum velocity occurred along the thalweg line which appeared near the outer bank. The reason of this discrepancy in the flow pattern is that experiments were conducted on the rectangular cross-section channel, whereas, the cross-sectional shape of the natural stream is usually triangular, and skewed to the outer

bank.

4.2 Concentration field

Throughout the tracer test in the S-curved channel, the concentration versus time data could be obtained at six transverse positions in nine transections.The three dimensional concentration fields, which consisted of concentration, time, and transverse distance from a left bank to a right bank, are drawn for centerline injection of Case 101 in Figure 4.

In order to visualize the behavior of the tracer cloud, the spatial contours of the concentration are plotted through the concentration-time curve using the inter polation technique in Figure 5~7.As shown in Figure 5

through the first bend so that high concentration was

detected near the right bank along the whole chan

nel. Also, the length of the tracer cloud is longer than

others. Not only the transverse mixing but also the

longitudinal mixing may increase by the effects of the meander in the case of the right bank injection.

5 ANALYSIS

In this study, the routing procedure and the moment method were applied to evaluate the dispersion coefficients in the S-curved channel. Using the two dimensional routing equation (Equation 13), both the longitudinal dispersion coefficient and the transverse dispersion coefficient can be evaluated simultaneously. In order to fit the predicted concentration to the measured concentration, the Gauss-Newton method, which is one of the nonlinear multiple regression techniques, was used. The representative case of applying the two-dimensional routing procedure is depicted in Figure 8. As shown in this figure, the calculated concentration distributions are generally in good agreement with the measured concentration distributions though peak points are somewhat underestimated.

Observed dispersion coefficients calculated by both the moment method and the two-dimensional routing procedure for all cases are tabulated in Table 3.

The representative transverse dispersion coefficient was chosen among the several values of the dispersion

Table 3. Comparison of the observed dispersion coefficients. M-M 2-D routing procedure Inject. Flow cond. cond. D T /HU * D T /HU * D L /HU * Up-down Center 070 0.51 0.29 15.1 D2-U4 101 0.45 0.70 15.6 D1-U4 151 0.33 0.46 10.9 D2-U3 211 0.18 0.19 5.9 D1-U3 Left 070 0.69 0.34 5.2 D1-U3 101 0.58 0.63

5.7 D2-U2 151 0.46 0.43 3.4 D1-U2 211 0.19 0.34 3.1 D2-U4 Right 070 0.43 0.70 32.5 D4-U1 101 0.45 0.56 37.6 D1-U4 151 0.42 0.35 21.0 D1-U3 211 0.17 0.10 38.8 D3-U3 coefficients obtained by the routing procedure for each case. The dispersion coefficient had less RMS error and was computed through long distance between upstream and downstream. For the dimensionless transverse dispersion coefficient (D y /HU *), results by the moment method and the routing procedure show little differences. Also, it is found that the dimensionless transverse dispersion coefficient is independent of the injection conditions. However, the dimensionless longitudinal dispersion coefficient varies according to the injection conditions. Especially, results on the right bank injection are larger than others. This is due to the separation of the tracer cloud as shown in Figure 7. 6 CONCLUSIONS The two-dimensional routing procedure which was based on Fischer (1968) was developed to evaluate the transverse dispersion coefficient under the transient concentration condition. Also, the laboratory tracer tests were conducted in the meandering channel having a rectangular cross-section in order to obtain the concentration-time data. Result of the flow experiments shows that the maximum velocity of the primary flow occurs near the inner bank in a bend taking the shortest course along the channel. Throughout the two-dimensional tracer tests, it reveals that behavior of the tracer cloud was quite different according to the injection conditions. Using the acquired concentration data, the transverse dispersion coefficients were evaluated via the new developed routing procedure. The evaluated transverse dispersion coefficients by the routing method were in good agreement with those by the moment method.

River meandering restoration – case study and laboratory experiments

R. Banasiak, R. Verhoeven, L. De Vos & S. Verfaille

Hydraulics Laboratory, Ghent University, Belgium

ABSTRACT: In the frame of a pilot project a multidisciplinary study concerning the evaluation of the feasibility

and sustainability of river re-naturalisation has been conducted. Special emphasis was put on the hydraulic aspects

of the restoration of a natural meandering river course degraded by engineering works in the past. Firstly, an outline

is given of several predictions for the river meander pattern. Most formulas however, are of empirical nature,

which makes them less suitable for case studies with specific local conditions. Secondly, a case study, performed

in order of the environmental department of the Flemish government, is highlighted. Thirdly, a laboratory

investigation, performed in a flume set-up, is described. During several tests the development of the meander patterns was recorded using discharge, slope of the river bed and initial channel bed configuration as variable parameters. The influence of artificial interventions, such as deflectors, to promote meander development, has been tested as well.

1 INTRODUCTION

Meandering is a basic feature of natural rivers. In the past many natural watercourses have been trained to meet different economical needs.These training works often neglected ecological aspects in such a way that the transformed rivers were straightened and thus lost their ecological value. Moreover, even the original aim of anti-flood protection has failed since the river straightening and flood plain cutoffs led to a decrease in river storage capacity and faster propagation of flood waters and higher flood peaks. In Flanders this has caused frequent flooding in both rural and urban areas, in particular in the downstream parts of water courses. The results became clear: wet or water filled cellars, more frequent agriculture losses and streets under water.

To meet these problems the Flemish Administration for Environmental, Nature and Landplanning (AMINAL) has recently conducted a pilot project aiming at the evaluation of the feasibility and sustainability of

river restoration. In particular the restoration of mean

dering river courses is considered.A preliminary study

indicated several sites, which are suitable for meander

ing, taking into account a variety of different aspects.

This article mainly investigates several aspects of the

hydraulic changes that occur in rivers subjected to

meander restoration.

The overall idea behind any restoration is to create

a stable channel. In order to avoid potential problems,

it is important to understand the changes that a river

will experience when different control or regulation schemes are applied. The prediction of these changes is an important aspect of every restoration project. A brief description of a physical model study, performed in the Hydraulics Laboratory, Ghent University, is included. This model study was performed to gain more information on the mechanism of meander development. The influence of obstacles on the meander development is a specific part of this study. 2 PREDICTORS ON RIVER MEANDERING The meandering forms that are created even across a range of spatial scales and environmental boundary conditions display often startling regularities. The sinuous shape of the meandering planform has led scientists to look after the factors responsible for shaping river meanders. So far, several theories have been proposed and many, in majority, empirical formulas based on some sets of data have been derived. In many empirical formulas the discharge is regarded as the dominant independent variable to which the dependent variables, such as width, depth, velocity and meander wave length, adjust. Dependant variables are usually expressed as power functions of bankfull discharge, and the meander parameters are related to the channel width, e.g. (Leopold & Wolman, 1964):

where B= bankfull channel width (m); λ=meander

wave length (m), a=meander amplitude (m), r c =

maximum meander radius (m), and C B and α=

constants.

The physical explanation for the selection of the bankfull discharge as bed forming parameter is that with smaller discharges less sediment transport occurs, which hardly affects the river bed transformation. For discharges larger than bankfull the water masses are conveyed over the flood plains with as a consequence presumable lower bed forming activity. The empirical relations obviously do not include many other impor tant factors such as bed and bank material, sediment load, slope, etc. Therefore, the empirical coefficients are usually specific site dependent.

Chitale (1970) investigated meandering patterns of more than 40 rivers in India. Using field data consist ing of depths and widths for bankfull discharge, slope and bed material size, single and multiple correlations were performed resulting in the following equations for shape and relative size of meanders:

in which S * = slope in feet per 10,000 ft length of the channel, d 50 =mean bed material diameter, D= average depth of channel, B= surface width of channel, M=meander length. The percentage errors of estimation using this equations were 18.69 and 58.05 respectively. Accuracy did not improve much by increasing the number of variables in Eq. 5 against

other single correlation. Significant scatter between the observed and estimated values for the equations were supposed due to omission of the definition of the nature of bank material, sediment concentration, sediment gradation and the inevitable limitation of data. In addition, as both depth and width vary along a meandering channel from bend sections to transi tion sections, the ratios of d 50 /D and B/D vary along the channel. Furthermore, the bankfull discharges often had to be estimated, resulting in significant uncertainties.

Stability theories have been applied to delineate the origin of meanders. Analysis by Ikeda et al. (1981) and Parker et al. (1983) using a dynamic equation for lon gitudinal velocity and a kinematic equation for bank erosion have provided the mechanistic founding of the meander path. An expression for the wavelength was Figure 1. Plan geometry of river meanders (Chang, 1984b). derived as: where D= flow depth, f= friction coefficient from Darcy-Weisbach formula. The meander curvature and other geometric features for rivers were analysed by Chang (Chang, 1984a, Chang, 1984b). Chang uses an energy approach combined with relations for flow continuity, sediment load, resistance to flow, bank stability and transverse circulation in channel bends to obtain a mathematical formulation for the equilibrium river state. The analysis establishes the maximum equilibrium curvature, stated as the radius-of-curvature to channel-width ratio, which has an average value of 3; it shows only minor variation within the meandering range: From the regular meander path model Chang obtained a graphical relationship for the plan geometry of river meanders as shown in Figure 1. 3 MEANDERING RIVERS – CASE STUDY 3.1 Historic and present

river courses In this section five selected rivers in Flanders showing a typical lowland character, are considered. These rivers are the Kleine Nete, Grote Nete, Marke, Warmbeek and Kemmelbeek. The first data of implemented modifications date from the 19th century. The rivers were subjected to training works, over which the first data found are dated from 19th century. In that time attempts to control frequent flooding and to meet the rising demands for agriculture led to significant changes in the structural quality of most watercourses and reservoirs in the region. Later on,

Figure 2. The Kleine Nete river course changes in time

(van Wallons, 2002).

the training works were continued, in particular in the

60and 70-ties of last century. Most of these rivers

were channelised and straightlined to their the present

far-to-nature state.

As an example, Figure 2 shows the river course

changes throughout the time for the river Kleine Nete.

For this evaluation more recent and old maps, dating

from the eighteenth century, were used.

From this Figure, it is clear that the Kleine Nete

indeed was a meandering river. Comparable results

were obtained for the 4 other rivers. A large amount

of wave lengths has been calculated for each river,

in order to determine the predominant wave length,

together with other meander characteristics. The old

maps show the natural state of the river and thus are

valuable sources for determining an equilibrium river

pattern. They can serve as a reference for the restora

tion project. However, some problems were encoun

tered while trying to assess the meander patterns.

It is assumed that the oldest maps by Ferraris

(1771-1778) aren't reliable for the determination of

the meander characteristics, as significant deviations

in the river trajectory were found compared to the later

elaborations. Presumably, the topographical methods

of that time were not accurate enough. Therefore the

first evaluation goes back to the years 1846-1854, to

the military maps by Vandermaelen.

Furthermore, due to the irregularity of the river

course, instead of immediately determining the mean

der wavelength, it was mostly calculated as twice the

distance between two inflection points, as this was

easier to determine.

Finally, the sinuosity of the rivers was determined

as the ratio between the actual length of the river over

a section to the distance between the begin and the end

of the sections (Fig. 3). This was done in a careful way,

as it appeared that the section length differs from map

to map depending upon the map scale and the number

of details included.

3.2 Geometry and hydraulic parameters

Parallel with morphologic studies a large amount of

geometrical and hydraulic data has been gathered Figure 3.
The Grote Nete river - determination of the sinuosity.

during field measurements. Representative parameters for the selected sections of the rivers were derived from a large set of cross sections. Friction coefficients were established based on discharge and water surface measurements. The river bed material was collected in several points along the rivers and analysed to determine the grain size distribution. The formation of the banks consists mostly of fine graded sand, locally with significant silt-clay content. The main hydraulic parameters of the studied rivers are collated in Table 1. 3.3 Predicted meander size The set of morphologic and hydraulic data is used to determine the meander patterns according to the above presented formulas. Then they are compared with the meander patterns read from historic sources. The results of these calculations and the average values from map reading are summarised in Table 2. One can see that significant differences for meander parameters are obtained by different methods, which needs some comments. The results derived by the Chitale formula are realistic concerning the prediction of the sinuosity of the rivers. On the other hand, the sizes of meanders are significantly overestimated; the predicted amplitudes are 3-4 times larger than those found in the maps. The determination of the meanders using Chang's graphical method was somewhat problematic. The studied rivers feature relatively small width-depth ratios, as a result of which the values B/D fall in the right-bottom part of the graph were accurate reading is difficult.This results further in very high values for the sinuosity, especially for the Warmbeek and the Grote Nete river, where M/λ is higher than 5. Chang believes that smaller width-depth ratios associated with cohesive properties of channel forming material promote the development of very sinuous channels. The corresponding values for meander wave length are relatively good. However, when using the sinuosity from the maps, the λ/D ratio from the graph would be around 100-120, which is much more than the actual values for the studied rivers.

Similarly, overestimated values for meander length

are obtained with the relationship suggested by

Ikeda & Parker.

The ‘best’ results are obtained using formulas by

Leopold & Wolman. These simple formulas, based

on bankfull channel width only, produce the meander

amplitude, length, curvature radius that comes reason

able close to the natural development of the studied

rivers.

The differences in results are not surprising, as in

the reported studies the scatter of the measured mean

der patterns, to which the formulas were fitted, was

also significant. An explanation for the geometrical

variations, despite those already mentioned in pre

vious paragraph, is the heterogeneity that exists in natural rivers. The heterogeneity, which includes factors such as vegetation, cohesive sediment content, variation of sediment size, fallen trees, rocks, etc., may inhibit the development of a self-formed meander geometry. That is why more sophisticated formulas, that use some selected factors can produce misleading results.

From this one can conclude that the choice and use of any formula must be done carefully and at best proceeded by verification to the local conditions using reference meander patterns. It is evident that the understanding of the meander development is still far from satisfactory. 4 LABORATORY STUDY Because of the incompetence of the existing formulas, a physical model study was launched to gain more information on the mechanism of meander development. Hereafter, several laboratory tests are discussed. Considering the complexity of the simulated process, the test should be regarded as a preliminary stage of the ongoing study. 4.1 Test conditions The laboratory experiments were conducted in a test flume that is 15 m long and 2.6 m wide and is enclosed in a circulating water system. The flume was filled with a mixture of sand and caolinite clay. The characteristic diameters of the sand are d 10 = 0.17 mm d 50 = 0.23 mm d 90 = 0.315 mm. The cohesive fraction was added in order to increase the stability of the channel banks. Its content in the sediment mixture was 3%. The sediment was leveled to obtain a flat plain with an average thickness of 15 cm.The longitudinal slope was situated between 0.7 mm/m and 7 mm/m. In the centre of the flume a straight trapezoidal channel was formed. The channel has a depth of 6 or 8 cm, a 15 cm bottom width and a bank slope of 1:1. The initial geometric parameters were chosen in respect to the Warmbeek river, one of the studied meandering rivers.

Figure 4. Testing set-up.

The morphologic changes that occurred during the tests were recorded on a video camera. The horizontal and vertical geometry was measured with a laser interferometer. The interferometer was mounted on a carriage that could shift over the flume. No sediment was added in the current test.

4.2 Test performances

Test 1

In the first test a slope S= 0.00067 was applied. The straight channel had a depth of 8 cm and a width of 31 cm. The bankfull discharge was initially 5.7 l/s but was during the test reduced to 2.75 l/s (1 cm below the banks) because water started to flow over the banks in the downstream section. Since after 30 hours no meander patterns were observed to develop, the discharge was increased again to about 3.7 l/s. After another 50 hours of test run no meander patterns were developed.

Test 2

The slope was the same as in Test 1. The channel depth was smaller, 6 cm and had an initiating bend (with $\lambda/2$ 2.6 m and a= 0.35 m). Also in this test no meander formation was obtained, see Figure 5.

From these initial conditions, it could be concluded that the flow had not enough potential to transport the

sand along the bed and to erode the banks.

Test 3

In this configuration the slope was significantly in

creased to S= 0.007. The channel had a depth of

8 cm and an initiating bend with λ/2= 2.6 m and

a= 0.3 m. The discharge was set to 3.33 l/s. At 17

hours, the bed topography was measured for the first

time. The total duration of the test was 86 hours. Dur

ing this test, significant sediment transport and bank

erosion was observed. The obtained transformation is

shown in Figures 6 and 7 respectively representing an

intermediate and the final meander pattern. Figure 5. Channel after the end of Test 2. Figure 6. Test 3: Channel development after 20 hours. Figure 7. Test 3: Channel development after 86 hours. Although the channel becomes wide and shallow, a deeper sinuous talweg and an extended downstream wave migration can be easily recognized. In Figure 8, the recorded cross-sections through the top of

a sinuous wave are shown.The asymmetrical character of this section is remarkable.

At 17 h, the meanders had a wavelength of 2.63, 2.63 and 2.81 m, and an amplitude of about 0.6 m, which was nearly constant along the channel. After 86 h the meanders evolved to 3.41, 4.0 and 4.09 m in length and the amplitude varied from 0.6 to 1.5 m, increasing along the channel. Smaller meanders in the upstream channel section were due to the lack of sediment sup ply at the entrance, which caused erosion of the bed, consequent flatter slope and loss of capacity to erode the banks.

Test 4

InTest 4 the initial conditions were the same as inTest 3 except for the initiating bend; the channel was straight over the entire length. The discharge of 3.33 l/s was maintained constant throughout 29 hours of testing.

The resulting channel configuration is shown in Fig ure 9. The talweg extends in the downstream direction with a sinuous shape and increasing depth. The width of the meandering channel belt increases linearly from 0.31 m to 1.45 m. The meander length varied from 1.2 to 4.03 m, and the sinuosity reached a value of 1.27.

Test 5

In this and in the following test it was intended to

check the influence of an obstacle in the straight chan

nel on the initiation of meander formation. The use of

such obstacles, known as deflectors, is a recommended

measure to recreate meandering patterns in degraded Figure 10. Final channel development in (a) Test 4, (b) Test 5 (units in cm; circle indicates the position of the obstacle). straight rivers, FISRWG (1998). In this test a single permeable obstacle was placed in the right bank of the channel, at 7.2 m from its beginning.The other channel characteristics remained the same as in Test 4. During the test it appeared that the deflector had little impact on the development of the meander pattern. Only at the very beginning of the test the deflector influenced the erosion of the opposite bank. Later on, local turbulence caused erosion of the bank around the obstacle, which led to a deflector cut off from the bank it was built in. The deflector lost its significance quite soon and in the end it was just an unnecessary obstacle in the channel. After 23 hours, the meandering talweg reached a length varying from 2 to 3.2 m and an amplitude up to 1.1 m. The sinuosity reached a value of 1.2 in the most downstream section. Figure 10 represents the final channel state for the last two tests, which had the same initial configuration except for the deflector, used in Test 5. The larger size of the meandering talweg in Test 4, in comparison with Test 5, is due to the longer duration of the test. Remarkable in Test 4 is the deviation of the sinuous meander pattern. The meander transverses appear to be convex, facing downstream. This is comparable with natural rivers, which usually develop intrinsically asymmetric meanders too (Sun & Parker, 2000). Test 6 This time, the impact of three thin wall defectors built in the right bank and oriented in different ways towards the channel axis, as shown in Figure 11, were examined. The deflectors, in particular the two upstream ones, reflect the stream towards the opposite bank causing its almost immediate erosion. Thereby, the speed and magnitude of meander growth was considerably higher than in previous tests. The perpendicular orientation

upstream

Figure 11. Deflectors orientation.

Figure 12. Channel development in Test 6 (units in cm).

of the deflector resulted mainly in local scoring and had a smaller effect on the formation of a meander. In the course of test, it appeared again that the remaining deflectors form an undesired obstacle to further meander development. While the amplitude and length of the meanders increased, the meander also shifted downstream. The deflectors were the cause of the resulting meander pattern, which consists of 1 meander between two successive deflectors, see Figure 12. The discontinuity in the talweg between deflector 2 and 3, was also caused by the presence of the deflectors. This is because the deflectors maintained the position of the first top, that was formed behind each deflector.

4.3 Discussion

In the performed tests, the caving banks are the source of the transported material within the meandering channel. The rate of bank erosion appears to be important, not only for determining the meandering state, but also for the determination of depth and width of the cross-sections. Easily eroding banks result in wide and shallow sections. The increased slope or discharge causes rising velocities, through which the bank erosion grows and the channel widens and shoals.

In these experiments, the resulting channel pattern

appears to be more like a sinuous talweg than a truly meandering channel. Although a curved channel did develop from an initially straight channel, the sinu osity was rather low. The shoaling of the channel is due to the easily erodible banks, whereas the stream is ‘overloaded’, having a to steep slope.A next step in the testing should include the use of another type of bed material and the variation of the slope. Slowly eroding banks are supposed to result in deeper and narrower channel cross-sections. As it was already noted, rivers with a small width/depth ratio promote the develop ment of very sinuous channels. Various combinations Figure 13. Bottom slope of the channel after Test 4. of fluvial materials have been recently tested with the aim of reproducing meandering rivers in the lab. The preliminary results show that e.g. a mix of diatomaceous earth and kaolinite clay is able to produce a meandering channel with a sinuosity of almost 2.0 (Smith, 1998). The initial cross-section of the channel had no significant influence on the meander development. The tests confirm that when an erodible material is used, a river will shape its cross-sections in accordance with its flow, slope and bank materials, irrespective to its initial cross-sections. A river deepens or shoals until it reaches an equilibrium configuration, for which the rate of sediment supplied to the cross-section from the adjacent banks is balanced by the rate of transport towards the downstream sections. The tendency to attain this equilibrium can be illustrated by the elevation of the channel, recorded in Test 4 (Fig. 13). In the upper section, the channel deepens and the slope flattens until the flow no longer has the power to erode the banks. When erodible material is used, the channel shoals, and the slope steepens until the transport capacity of the channel equals the rate of bank erosion. The development of a meandering talweg is also a result of the dissipation of excessive energy. The higher the valley slope is, the higher the rate of meandering will be. The prerequisite is to have stable, not easily erodible banks.

The most remarkable result is that the use of deflectors as an artificial measure to initiate meandering is not a suitable solution for recovery of meandering watercourses. The deflectors need to be removed after the meander has started to develop, otherwise it will disturb the ongoing development of river course. Instead of constructing and removing such deflectors, a deflector which is eliminated by the meander process itself, is a simple and recommendable solution for restoration projects. Test 3 and Test 5 demonstrate that an initiating bend or a permeable deflector does not influence the meander pattern but only the speed of its development.

5 CONCLUSIONS

A comparison between calculated meander geometry and the geometry deducted from old maps of naturally meandering rivers has been performed. This comparison shows that it is hard to find reliable formulas that approach the meander characteristics. The quality of the prediction seems to depend rather on the set of data to which the formulas were fitted, then on the amount of variables in the formulas. Simple relations obtained by Leopold & Wolman (1964) reveal meander patterns close to those found in the considered sites.

The physical experiments provide a better insight in some practical aspects concerning the performance of laboratory tests. They give an idea of the feasibility of artificial interventions to promote the meander restoration in degraded straight rivers. The next testing program will include the change of the sediment strength configuration to reach a higher sinuosity in the small laboratory flume.

Small river re-naturalization and cultural heritage

G. Müller

Department of Civil Engineering, The Queen’s University of Belfast, Belfast, UK

P. Fröhle

University of Rostock, Civil Engineering Dept.

ABSTRACT: Until the advent of modern power sources such as steam and combustion engines, the small

rivers in Middle Europe played a central part in the economy as suppliers of mechanical power, water and means

of transport. As a result, virtually all small rivers host a variety of remains of previous industrial activities such as

weirs, mill races, ponds etc. which were built in the era ranging from the Middle Ages to the beginning of the 20th

Century. Today, these remains are often not even recognized as such any more by hydraulic engineers, planners

and the general public. The canalization of many rivers during the 1960s and 70s destroyed many remnants of the

pre-steam age industries along the small rivers. As a result of the increasing ecological awareness, the concept

of re-naturalization was developed in the 1980s. The current ‘ideal’ aim of re-naturalization, of re-creating a

‘natural’ river, does not take the historical context of our rivers into account, so that re-naturalization as well as

the ‘hard’engineering solutions can both result in the irretrievable loss of the cultural heritage. A current research

project conducted by the authors tries to raise awareness of the historical context and to develop concepts of how

to integrate the remains of the industrial past into the changing demands on our small rivers whilst contributing

to the overall quality of the environment.

1 INTRODUCTION

Before the advent of steam power, the small rivers

played a vital part in the economy of the Central

European countries as well as in North-America.

Rivers supplied mechanical power for industry, irri

gation water for agriculture, drinking water for the

population, water for defense systems and they were

used as transport ways for bulk goods. In order for

the rivers to fulfill all these duties, and to ensure that

the course of the river remains stable, man made very

significant changes to the small rivers ever since the

Middle Ages. These changes include the construction

of weirs, fortification of banks, change of river course,

addition of diversion or transport canals, creation of

lakes for water storage, and many other items. With

the development of first steam power and then elec

tricity and the internal combustion engine, the use of

the small rivers by man declined until it reached a point

where they are hardly used at all. Following the decline of usage, and the increasing demand for rural and urban space, many small rivers were forced into straight beds, concrete channels or even underground, changing the river from an ecosystem into a lifeless drain. This happened in particular during the 1960s and 70s. With the development of an increasing consciousness for our environment, other ecologically acceptable solutions for the small rivers were sought for. The solutions principally include the re-naturalization or return of the river to its natural state, using traditional construction methods and natural materials. The river would therefore be allowed to develop its own dynamics and ecosystem. Re-naturalization is today seen by many scientists, engineers and landscape architects and subsequently the public as the most desirable development strategy for rivers. Many hydraulic engineers are not fully aware of the extent of the former use of the small rivers, or of the purposes they were used for. Quite often the

redevelopment of a river – be it a ‘hard’ engineer

ing solution or a ‘soft’ re-naturalization – therefore

destroys the remnants of forgotten industrial activities

not by intention but by lack of knowledge and aware

ness. These remnants however constitute a significant

part of our cultural heritage and indeed of the devel

opment of engineering, which are subsequently and

irretrievably lost.

The authors of this article, engineers and an archae

ologist, are currently conducting a research project

where the character and the importance of this her

itage is investigated with the aim to raise awareness of

the situation and to develop integrated solutions.

2 CULTURAL HERITAGE AND CULTIVIZED LANDSCAPE

2.1 Introduction

When engineers in Germany talk about ‘Kulturland schaft’ (cultivated landscape), they invariably mean the landscape shaped by man’s current activity like agriculture, construction, infrastructure and so on. Archaeologists however have a rather different defini tion of this term. For them, ‘Kulturlandschaft’ means the landscape which was shaped by man for hundreds and thousands of years, and which – for today’s inhab itants often invisibly – contains significant parts of our cultural heritage. Very often the remains of this field of agricultural and industrial activities are overlooked simply for lack of knowledge about our pre-steam era industrial past both on the side of engineers and the general public. In addition, the question arises as to how far an ecosystem which developed within a man-made environment for up to eight centuries can not be considered as natural. Modern textbooks on river hydraulics and river re-naturalization often completely omit the historical context, e.g. Patt et al. (1998). Only very recently has the term ‘Kulturland schaft’ been introduced into the engineering field, Hintermeier (2003). Today, the extent to which the

small rivers were formerly used, and the importance this usage had to society, is hardly known even to specialists working in this field such as hydraulic engi neers. Therefore the remains of the former usage are often not even recognized as such.

A small comparison may illustrate the importance of rivers as power source and means of transport in times before steam or combustion engines existed: a typical water wheel of 10 kW provided more, cheaper and more reliable power than 30 to 40 horses or one hundred men; a horse drawing a boat on a canal could shift 40–50 times the weight it could move on a road. Water courses were therefore of prime importance. In the following, some of the principle uses of small rivers and their features will be presented in order to illustrate the way and the extent to which rivers were changed. Figure 1. Typical mill installation (WWA Aschaffenburg, 1889). 2.2 Cultural heritage 1: power production The water wheel is one of man's oldest hydraulic machines; water wheels were already described by the Roman architect Vitruvius (in 'De Re Libri Architecturi X'). A water wheel installation required a head difference in the river, which was usually provided for by a weir. The wheel installation itself was located at a mill race (today it would be called a 'diversion canal'). Apart from wind mills, water wheels were the only mechanical prime movers before the advent of steam engines and drove flour mills, textile and mechanical machinery, powder and mineral mills, water pumps for drinking water supplies etc., Reynolds (1983). It is estimated that in 1850 there were 25–30,000 water wheels in operation in England, 6,400 in Ireland and around 40,000 in Germany. Even as late as 1925, there were still 33,500 water wheels in operation in Germany with individual capacities of 1–75 kW and an overall capacity of

approximately 200 MW. This technology eventually disappeared in the 1950s and is today already virtually forgotten. Figure 1 shows a typical mill installation (River Aschaff/Bavaria 1889) with a weir, inflow detail, mill race, mill building with water wheel and outflow. Water wheels are today regarded as an outdated technology belonging to the romantic ages. Some recent research has however shown that water wheels had been developed into very efficient energy converters. Figure 2 shows some typical water wheels and the measured efficiency curves which indicate the surprisingly high efficiencies of 75-85%. More technical information about water wheels can be found in Müller & Kauppert (2002, 2003). 2.3 Cultural heritage 2: 17th century fortifications Traditionally, city fortifications are envisaged by most people as walls with towers, possibly with a water filled ditch in front of the wall. This type of fortification was in use until, at the end of the 15th

Figure 2. Typical water wheels for head differences of

1.0-5.0 m, Müller & Kauppert (2003). century, modern cannons were introduced which simply shot stone walls apart in a very short time. As a result, fortification design changed dramatically during the 16th century and a system of earthen ramparts, bastions, outworks and major hydraulic elements, some of which are still visible today, evolved. The City of Braunschweig in Northern Germany is one of the few German cities where even the river course was changed in order to create a wet ditch for the artillery fortification, and where this altered course is still in existence. Today, not even the name of the river branches (‘Umflutgraben’, flood diversion canal) recalls their original purpose. Figure 3 shows two maps of the City from 1650 and from today. In Figure 3a the original course of the River Oker through the city centre is still visible. The river channel running through the city center was maintained, probably for transport purposes, and weirs and mill races were built in order to power mills inside of the

city in case of a siege. These canals are also visible, as is the very narrow wet ditch of the mediaeval fortifications (thick dark line). In Figure 3b, most of these items have disappeared and only small sections of the medieval ditch and the wet trench of the 17th Century fortification still exist. 2.4 Cultural heritage 3: transport and irrigation The use of rivers for transport did not only mean navigation, but also e.g. the floating of timber. Often, special float canals were built alongside the river to provide sufficient depth and width of water for floats; as can be seen in Figure 4 for the River Aschaff. Apart from transport, in particular very small water courses were often used for irrigation purposes.The run of such small water courses was therefore frequently changed from its typical location at the lowest point of a valley to a zig-zag course running from the low point to the edge of the valley further downstream. This new and higher course enabled parts of the valley to be irrigated from above, and reduced the river's gradient and dynamics. In addition, ponds were created for purposes such as storage of logs, provision of water to float logs downstream, fish farming, provision of additional water for mills during daytime etc. In many instances rivers were made navigable by building weirs and possibly side canals; this aspect is also very interesting both from the point of view of cultural heritage and the re-use today for leisure boating. This topic is however beyond the scope of this article. 3 RENATURALIZATION AND EXISTING WATER COURSES 3.1 Re-naturalization One characteristic of historic (i.e. before the 1900s) alterations of river courses was that usually only those

Figure 3. The City of Braunschweig, Northern Germany, in

1650 and today.

small sections were changed where a change was

absolutely required, such as the addition of a mill

race. The development of hydraulics as an engineer

ing discipline led to a situation where small rivers

were perceived by engineers purely as channels for Figure 4. Floating logs (Aschaff, ca. 1920, Spessartprojekt). rainand groundwater. During the 1960s and 70s many small rivers were subsequently straightened over long stretches, often using concrete linings, in order to minimize the land required by the river (e.g. to maximize farmland or inner city land usage) or to protect roads and railway lines. This straightening generated a number of very undesirable side effects, such as a deepening of the river bed and the unfavorable superposition of flood waves caused by their accelerated propagation. The rivers running in concrete channels could not support eco-systems or even trees any more, and degenerated into lifeless drains. Following the increasing ecological awareness of the public, engineers tried to develop a concept for an ecologically and hydraulically acceptable alteration of water courses. The re-naturalization of rivers is a concept which is today regarded by biologists, ecologists, landscape planers, by the public and by many engineers as the most desirable development. The main goal of renaturalization is to bring the river as close to its original or ‘natural’ state as possible by removing artificial obstacles such as weirs, by changing of canalized sections, by provision of fish passes, of space for flood plains etc., e.g. Patt et al. (1998). In addition, renaturalization tries to create a water-land interface to create a living space for aquatic and an access area for land based animals and to increase flood retention areas, although the latter aim is difficult to achieve due to the high demands for space. For these purposes, ‘soft’ construction techniques using natural material like willow branches, wood and rock were developed. ‘One of the primary aims of the national and international effort for the protection of rivers is the creation or re-creation of a free passage; …therefore weirs and barrages can be regarded as a significant anthropogen disturbance of the ecosystem’, Schrenk (2003). The German recommendations for the management of small rivers which are currently being developed give a ‘potentially natural state of the water course’ as the development aim. The ‘potentially natural state’ is

Figure 5. River Elsava.

defined as an ideal conceptual state of future devel

opment of the water course which is undisturbed by

man. Although this ideal is defined, current practice is

to bring water courses ‘close to a natural state’ rather

than creating a truly natural state. The latter concept is very difficult to achieve due to a variety of reasons such as land interests, the proximity of infrastructure installations such as roads, railways, gas, water, sewage and electricity lines etc. which must not be interfered with, recreational use and other reasons.

A review of the interference of man with the rivers since the 1960s however shows that ‘hard’engineering solutions and current re-naturalization concepts have one peculiar aspect in common: the historical con text is completely omitted, and the implementation of either concept implies the destruction of all historical artefacts along the river.

In the following, three examples will be given in order to illustrate the complexity of the problem of defining what constitutes the natural state of a small river, and which effects the various man-made alter ations had or have and to define what constitutes a desirable development.

3.2 Existing water courses 1: River Elsava

The River Elsava (NW Bavaria) is a typical small European river with a length of approximately 15 km, a drained area of 142 km 2 and an average flow rate of 1.23 m 3 /s. This river has been used by man since the middle ages for power production and irrigation and a

large number of man-made features still exist along the river. A water mill at the old monastery of Himmelthal (Elsava) was first mentioned in 1232, water rights for the extraction of water for irrigation purposes were recorded in 1435 (Elsava). It can therefore safely be assumed that weirs and side channels have existed for 600–750 years. Figure 5 shows a stretch of around 3000 m of the river Elsava in North-West Bavaria

Figure 6. Aerial photography of the confluence of the River Aschaff with the River Main, with alterations from 1917 to 2001.

Figure 7. River Aschaff, changes of the estuary section.

importance of the river and thus the reasons for today's situation (including the loss of many aspects of the heritage).

From 2001 to 2002, an upstream section of the River Aschaff was re-naturalized, giving it a meandering plan view with ragged banks and shallow water zones which provide an suitable environment for aquatic animals. The course of the River had to be fixed in order to avoid interference with a newly built motorway and a vari ety of other infrastructure installations. Figure 8 shows today's course of the river with plan views of the two

mills which existed before the re-naturalization with

mill races, side channels and weirs. Again it can be seen that all remnants of the previous use of the river have disappeared in favor of a naturally-looking river. The River Aschaff demonstrates visibly the effect of the alterations of the last 40 years which were implemented following the prevailing river development philosophy but disregarding the historical context. 3.4 Existing water courses 3: the Wallensteingraben The Wallensteingraben in North-Eastern Germany today looks like a natural water course, draining Lake Schwerin towards Wismar and the Baltic Sea. In reality, it constitutes the remains of a small canal

Figure 8. Re-naturalized section of the Aschaff with former

mills (WWA Aschaffenburg, 1889).

built at the end of the 16th century to further Wis

mar’s salt trade. The canal was finished in 1580, with

a total length of 15.5 km and a height difference of

37.60 m which was overcome with 12 locks. Due to

political developments, mainly caused by the 30 Years

War (1618–1638) and the fact that Wismar became

Swedish, depriving the city of its hinterland, the trade

and with it the requirement for the canal practically

disappeared. Subsequently the canal fell into disrepair.

It still acted as a drainage for the lake, and powered

water mills. In Figure 9, the course of the Wallenstein

graben between Lake Schwerin (bottom) and the City

of Wismar is shown. Today’s remains of the artificial

waterway (Goldammer, 1997) are indicated by circles,

the locations of old mill races along the natural river

(Hohensee, 1989) by water wheel symbols. Some rem

nants of the channel are still visible, though much of the canal was destroyed during railroad construction. Figure 10a shows a part of the summit reach excavated up to 10 m deep. In parts, the earthworks of the locks can still be identified, as well as stones and bricks orig inally used for the sluices can be found which were re-used later in other buildings, Goldammer (1997).

A small natural stream which drains the hinterland of Wismar and provided fresh water, fish and water power for the local population and eventually became part of the canal.

Along this small river and theWallensteingraben, 14 water mills were situated which produced mechanical energy from hydro power. Some of the mills can be traced back to the 1250s. At the beginning of the 20th century, the operation of the mills ended at all mill races.

Turbines were installed at some of the historic mill sites to produce electric energy, but only two turbines still utilize this renewable energy resource. Over the centuries a, new biological and morphodynamic equilibrium has established itself in such man-used Figure 9. The Wallensteingraben: Map, (BUGA, 2000). and -made ‘river’ reaches. The development strategies, where weirs and mill races are removed, often mean that the historical remains of early hydraulic and cultural engineering activities are destroyed. Figure 10 illustrates the state of the old canal as it can be seen today. Currently the

Wallensteingraben is used for flood control and to stabilize the water level in Lake Schwerin. The average discharge at the northern outflow of the lake is about 0.8 m 3 /s. Dating back to the times of the former GDR, parts of the river are designated Nature Preservation Areas. Concerning the channel, plans are currently emerging to again connect Lake Schwerin to the Baltic Sea, thus, to reactivate or rather rebuild the canal along a new, slightly changed course not for the transport of salt, but for

a. The 10 m deep cut of the Wallensteingraben through a hill

leisure boating and recreation to further the economic development of the region once more (Buga, 2000).

4 DISCUSSION

4.1 General

A study of some small rivers in Central Europe indicated that these water courses have been altered by man for many centuries for varying purposes ranging from power production over transport to fortification. One additional aspect of the changes often was the reduction of the gradient and therefore the dynamics of the river. The geometry and functionality of our small rivers can therefore not be understood without their historical context.The ecosystems which evolved around the rivers are subsequently adjusted to an ‘artificial’ situation, but have sometimes been established for a very long time. Although the ideal aim of a ‘natural river’ is under discussion, it appears that in today’s

world the constraints imposed by infrastructure and

settlement are too severe to allow for a river to develop

its own natural state again.

4.2 The Canadian River Heritage System

The removal of all historical artefacts which usually is

a consequence of re-naturalization deprives our soci

ety of a part of its cultural heritage and therefore of a part of its identity. In Canada, this has been realized some time ago and the Canadian Government has designated a number of river sections as ‘Heritage Rivers’, which are protected river sections of (amongst others) special ecological, geological, archeological, historical or recreational interest.The aim is to systematically create and maintain a Canadian River Heritage so that Canada’s nature, history and society is reflected in the river system without which the development of the country had been impossible. Within the Canadian River Heritage System (CHRS) these sections are administrated and managed, Nagel & Goldhammer (1997). This system by now comprises nearly 6000 km of rivers, amongst them a long stretch of the Grand River. CHRS incorporates a large variety of nearly 100 organizations ranging from Universities to representatives of the indigeneous people (Six Nations Council), cities, government authorities, newspapers etc. which all have an interest in their river. It appears that the idea of the ‘cultivized landscape’, as a system not just with hydraulic and environmental aspects but also with a historical context which is worth preserving has been taken to a practical conclusion by CRHS and may serve as a model for further developments in other countries. 4.3 Re-naturalization and cultural heritage Re-naturalization is today considered to provide a natural environment for the development of an ecosystem as well as an area for recreation. The inclusion of the cultural heritage in the management of small rivers today would imply that the river would have to retain some usage apart from recreation. The development of rational strategies of usage of the available power and water which are compatible with the historical usage could present a new area of activity. Some progress in the field of power production has been made recently, where it could be shown that water wheels are not the out-of-date inefficient machines they are usually considered to be. A detailed literature review revealed

that water wheels can be regarded as very efficient and ecologically acceptable energy converters for low head hydro power conversion, Müller & Kauppert (2003). This means that even our small rivers can – as renewable energy sources – contribute to the overall aim of carbon-dioxide reduction. 4.4 Outlook The authors are convinced that the re-naturalization in particular of canalized sections of small rivers is of great benefit to our environment.The re-naturalization of rivers which are still in a state where the old usage is recognizable (see section 3.2) would however destroy the cultural heritage. With the inclusion of the historical context, and the preservation and purposeful re-use of the resource river as e.g. a renewable energy source,

it becomes possible to preserve our cultural heritage

as well as to develop a functioning eco-system (influ

enced by man of course to some degree) around our

small rivers. In a re-naturalization (or river restora

tion) project therefore the ‘added value for nature’ of

the restored river and the ‘historical value’ of the river

(and a possible further use by man within the context

given by history) should be weighed against each other

in order to obtain an acceptable solution. An exist

ing water mill e.g. could be protected and, preferably,

be operated again and integrated into an overall solu

tion. A very small old canal which can never be used

again however, may currently only provide a poor nat

ural environment and should therefore be ‘restored’

or rather upgraded to create a functioning and eco

logically diverse solution with the emphasis on the

ecosystem rather than the historical value. In conclu

sion it can be said that the ‘cultivized landscape’ as

perceived by engineers should be expanded to include another dimension, namely time.

5 CONCLUSIONS

From the Middle Ages onwards the small rivers in Central Europe were re-built and used by man for a variety of purposes. Before the 20th Century, the small rivers formed a vital part of the economy. The remains of these activities are still in existence, but often not even recognized as such for lack of knowledge and awareness. Examples for such remains are:

a. Weirs and mill races belonging to old mills which constituted the nuclei of modern industrial developments.

b. Wet ditches which formed parts of the cities' defensive system.

c. Irrigation canals, storage ponds, canals for floating logs.

In addition, some old artificial waterways built for transport are today considered as being natural. Past and current re-development strategies for small rivers (canalization and re-naturalization) very often neglect the historical context and therefore result in the loss of historical artifacts and a diminution of our cultural heritage. An integrated solution for the devel opment of small rivers which includes and weighs

ecological as well as cultural aspects, and possibly

incorporates a re-use of the historical installations such

as micro hydropower, should therefore be sought. The

scope of an engineering evaluation of our environment

or, Kulturlandschaft' should be expanded to include

Stability of reinforced block ramp

S. Pagliara & P. Chiavaccini

Department of Civil Engineering, University of Pisa, Italy

ABSTRACT: Block ramps are structures able to produce high dissipation energy, ensuring a stable stream bed

and are usually used in naturalistic stream restoration projects as alternative method for grade control. A way to

increase ramp stability consists in covering the base ramp blocks with boulders. In this work the results of tests

performed in a flume located in the Hydraulic Laboratory of the Civil Engineering Department of the University

of Pisa are presented. The ramp was founded on a geotextile where two or three layers of the base material were

placed. The rocks were angular and crashed with an almost uniform granulometric curve. The stability tests

were conducted evaluating the failure discharge as a function of base diameter, boulders concentration and their

planimetric arrangment.

1 INTRODUCTION

Block ramps are structures able to produce high dis

sipation energy, ensuring a stable stream bed and are

usually used in naturalistic stream restoration projects

as alternative method for grade control because they

succeed in putting together hydraulics and ecologi
cal exigencies. In fact, they modify the longitudinal
profile of the river and, at the same time, guarantee cor
rect biological exchanges between the downstream and
upstream reaches. From the hydraulic point of view
experimental researches (Pagliara et al., 2000, 2002)
have pointed out that block ramps act as an excel
lent energy dissipator, giving place to strong energy
losses. From the environmental point of view block
ramps do not act as barriers, as the hydrodynamic
conditions on the ramp can be generally compatible
with the characteristics of dynamism of the stream
fauna. The functionality of the ramp can be ensured
only if the structure for the design discharge is sta
ble that means that the shear stresses are not able to
move the bed material. Some relations express the link
among the diameter of the base rock, the unit dis
charge and the slope of the ramp to ensure the stability
(Whittaker & Jaeggi, 1996, Robinson et al., 1998).
Armanini & Scotton (1995) evaluated the stability in
term of Shields parameter. The critical part for the
ramp stability is the downstream one, in which the
shear stresses are greater and the ramp failure is gener
ally sudden; in this part the movement of few elements
brings to the total failure of the structure (Pagliara &

Chiavaccini, 2003). The present study better investi

gates the hydraulic conditions which characterize the

different failure types of the ramp and the effects on the stability of boulders placed over the ramp. The use of boulders gives different advantages: they can increase the energy dissipation caused by the ramp acting as macroroughness elements and can facilitate stream fishes passage across the ramp, as their presence create on the ramp an alternance of swifter and slower flow zones more favorable to the biologic exchanges (Pagliara & Pozzolini, 2003). 2 MATERIALS AND METHOD The experimental flume was 0.5 m wide by 9 m long. Ramp height was 0.25 m. The ramp was based on a geotextile where two or three layers of the base material were placed. A sill at the downstream end of the ramp prevented the skidding of the ramp ensuring a stable toe during tests. The rocks were angular and crashed with an almost uniform granulometric curve. The tests were conducted on ramps of different slopes s (1:4, 1:8 and 1:12) covered with rocks having medium diameter of 0.011, 0.022 and 0.032 mm (Figure 1), where boulders in different concentration (up to 40%) were placed. Boulders projected from the base ramp for half diameter. A schematic drawing describing the experimental apparatus is presented in Figure 2. The concentration R of the boulders was measured by the following relation (Armanini & Scotton, 1995): where S b is the surface of the boulders and S tot is the total surface of the ramp. The diameter of the boulders

were three times bigger than the base material. Boul
ders projected from the base material of about half
diameter.

The tests were conducted increasing the flow until
the reaching of the discharge that provokes the ramp
instability. Flow rates were measured with an hydrom
eter placed upstream of the ramp.

3 FAILURE MECHANISMS

Tests pointed out that the failure of the ramp is
characterized by 4 steps:

- the initial movement of the base material, in which
the rocks begin to vibrate;
- the entrainment of some isolated elements.
- the local failure in which a group of elements leave
their position simultaneously, producing a circular
or semicircular scour hole; in some case (for the
highest boulder concentrations) the initial move
ment can happen for the boulders instead of the
base material;
- the global failure of the ramp (Figure 3) in which
different local failures happens: the ramp presents
longitudinal holes and the layers of the base material
are completed removed, especially in the down
stream part of the ramp.

In this paper the third step has been considered the

significant step in order to define the ramp failure.This

choice is due to the fact that the condition of local fail

ure modifies the geometry of the ramp, its hydraulic Figure 3. Ramp before and after global failure. behavior and its functionality. For prototypes this situation means that is necessary to repair the structure itself with burden of costs. In the base condition, without the use of stabilizing systems the local failure happens in the downstream part of the ramp. In order to verify the validity of the experimental model, the values of failure discharge measured for the base condition were compared with the values calculated using the block ramp stability formula of Whittaker and Jaeggi (1996): where q is the unit critical discharge (m 2 /s), ρ s is rock density (N/m 3), ρ w is water density (N/m 3), α is the slope of the ramp and d 65 is the nominal diameter of the material for which 65% of the sample is finer by weight (m). The results (Figure 4) point out that there is a good correspondence between calculated and measured values with differences generally minor than 20%. 0

Figure 5. Boulders placed over the ramp (upstream view).

4 THE USE OF BOULDERS TO INCREASE

STABILITY

Tests conducted on the base material have shown that the failure of the ramp is sudden and the weakest part of the ramp is the downstream half. To increase the stability of the ramp, the use of boulders disposed with different concentration has been investigated (Figure 5).

The stability tests were conducted evaluating the failure discharge as a function of boulders concentration and of their position. Boulders placed in rows, random and in arch forms were examined (Figure 6) in order to evaluate what is the best choice for the design of these structures. For each condition at least 3 failure tests (for a total of 108 tests) were performed, increasing incrementally the flow until the identified failure mechanism was reached.

The presence of the boulders improves the stability conditions. The effect depends not only on the concentration but also on the planimetric arrangment used. In particular arc forms appear less stable than other forms (Figure 7 and Figure 8) because water flow is

concentrated to the center of the flume, while there ARC DISPOSITION ROWS DISPOSITION RANDOM DISPOSITION FLOW DIRECTION Figure 6. Disposition of the boulders (plan view). are no evident differences between the random and the rows disposition (Figure 9 and Figure 10). Besides in the arc form, the weakest part of the ramp are the boulders themselves, because the scour hole formed downstream provokes their instability. Rows and random disposition are

different only for the way in which failure is reached. The rows of boulders create a series of little hydraulic jumps downstream each row where the initial movements verify, while for random disposition the flow is uniformly disturbed and the initial movement happens randomly. In Figure 11 the effect of local failure for random arrangement is shown. As evident a little scour hole is formed and consequently boulders has moved downstream.

Local failure for boulders in random disposition. 0 0.5 1 1.5 2 2.5 0 10 20 30 40 R% q / q 0 Rows and random disposition Eq. (3) Eq. (3) S=1.3 S=1.3 Figure 12. Increase of stability as a function of boulder concentration and

fitting curve. However, the effect of the disposition (rows or random), referring to the values of failure discharges, appears negligible in according with the results obtained for other kinds of stability system such as micropiles (Pagliara & Chiavaccini, 2003).

The increase of stability for random and rows dispo

sition reach values up to 180–190% for concentration

of 30–35%. Results show that the slope of the ramp and

the dimension of the base material has a little influence

on stability (Figure 12).

A new relationship for block ramp stability covered

with boulders can be derived. This equation links the

increase of stability (the ratio of failure discharge of

the ramp with boulders q and the failure discharge of

the ramp with only the base material q 0) to the boulders

concentration, expressed by means of the parameter R.

The best fitting is obtained with the following

equation:

where:

a = 0.008

b = 0.36

This curve presents a correlation coefficient

r= 0.76.

The parameters a and b are defined for a ratio of the

boulder diameter and the diameter of the base material

equal to 3. Therefore Eq. (3) cannot be used for other

ratios.

A safety coefficient S = 1.3 is recommended for

practical uses.

When R= 100% the ramp is all covered with boul

ders and its behavior is the same of a ramp where the

base material is bigger. In this case stability can be

determined using expression (2) in which d 65 for the

ramp all covered with boulders is expressed by d 65B

while for the ramp in base condition it is expressed by

d 65f . The test were conducted for d 65B = 3d 65f , thus for

R= 100%

The Eq. (3) for a value of R= 100% gives

q/q 0 = 5.11

5 CONCLUSIONS

The present study analyses the mechanisms of fail

ure of different block ramps. The effect on stability

of boulders placed over the ramp is accounted. Fail

ure of the ramp happens in four different steps: initial

movement, initial leaving, local failure and global fail

Three dimensional hydrodynamics of pool-riffle sequences for urban stream restoration

J.F. Rodríguez

School of Engineering, University of Newcastle, Australia

M.H. García, F.M. López & C.M. García

V.T. Chow Hydrosystems Laboratory, University of Illinois at Urbana-Champaign, USA

ABSTRACT: A set of laboratory experiments was carried out to investigate the 3D flow structure of pools and riffles in constricted streams. The experiments included four different bed configurations: flat bed (FB), centered pool-riffles (CPR), alternate pool-riffles (APR) and alternate pool-riffles with vegetation (APRV). The CPR configuration was included since centered pools minimize the possibility of scour near the banks, and are thus particularly suitable for urban settings where bank erosion is unacceptable.

1 INTRODUCTION

The present research was motivated by a concrete prob lem: the restoration of a channelized, low-gradient, urban stream using in-channel structures of the pool riffle type (Rodríguez et al., 2000). In-channel solu tions are preferred in restoration projects on urban settings due to the limitations in planform alignment imposed by the existing infrastructure. If carefully designed, pools and riffles can enhance the aquatic habitat and achieve the restoration goals. Designing artificial pools and riffles is not easy, since knowledge of their 3D hydrodynamic behavior is limited. Most of the analysis to date has been 1 or 2D, and mostly qualitative, despite the fact that 3D flow patterns are fundamental in the development and maintenance of pools and riffles. Past restoration practices have tried to reproduce features of natural pool-riffles based on observations, with limited success.

A set of laboratory experiments was carried out to

investigate the 3D flow structure of pools and riffles.

The experiments included four different bed config

urations: flat bed (FB), centered pool-riffles (CPR),

alternate pool-riffles (APR) and alternate pool-riffles

with vegetation (APRV). The CPR configuration was

included since centered pools minimize the possibility

of scour near the banks, and are thus particularly suit

able for cases in which bank erosion is unacceptable.

The sequence FB-CPR-APR-APRV not only repre

sents an increase in hydrodynamic complexity; it can

also be seen as different steps in the restoration pro

cess of a degraded stream.The FB series represents the behavior of the channelized stream with no geomorphological diversity, the CPR experiment describes a naturalization alternative with man-made in channel structures, the APR set gives insight into the hydrodynamics of in channel structures that are more likely to be found in a natural stream, and finally theAPRV configuration includes the effect of vegetation. Each series included low (run 1) and high (run 2) flow conditions. 2 METHODS 3D velocity measurements were collected using an Acoustic Doppler Velocimeter in a laboratory flume (0.0025 slope) where the four bed configurations were successively set up (Figures 1 and 2). The flume was 12.5 m long, 0.9 m wide and 0.6 m high, with 1-cm diameter crushed stone on the bed to provide a fixed, hydraulically rough surface. The simulated vegetation of the VAPR test was flexible (plastic aquarium plants) and was placed in a hypothetical seasonal flooding zone (Figure 2).The data was collected at five test zone A/D board ADV mobile gauge upstream gauge downstream gauge weir S=0.0025 Figure 1. Experimental setup.

cross sections: upstream and downstream riffles and

pool entrance, center and exit. At each cross section,

measurements were spaced 5 cm and 1 cm in the trans

verse and vertical directions, respectively. Wall shear

stresses were computed using a bed-normal law of the

wall. Experimental conditions are shown in Table 1.

3 RESULTS

3.1 Low flow

The FB1 test (Figure 3) shows three cores of high

streamwise velocity that are evenly spaced. These

high velocity zones are about 10% faster than the

surrounding flow and are associated with regions of

downwelling and high wall shear stress. Secondary

circulation is characterized by the presence of six cir

cular cells. All these features are typical of secondary currents produced by turbulence anisotropy at the flow boundaries (Nezu and Nakagawa, 1993). In the CPR1 experiment, convergence and divergence patterns affect the streamwise as well as the transverse velocity distributions. The streamwise velocity presents two cores of high velocity at the riffles (Figure 4) as a result of transverse flow divergence. Transverse flow convergence consolidates the cores towards the center of the channel at the pool center. The high velocity cores are associated with flow downwelling, and the resulting recirculation pattern is surface divergent on the riffles and surface convergent on the pools, as usually observed in natural pool-riffle sequences. The wall shear stress distribution shows a concentration towards the centerline of the pool center with a maximum at the pool entrance. TheAPR1 test (Figure 5) shows the effect of thalweg curvature generating centrifugal forces. Transverse velocity components are now clearly superimposed to convergence at the pool entrance.This effect is felt only moderately by the streamwise velocity, which has two high velocity cores that remain throughout the pool. The cores are associated with four major cells. At the riffle centerline the cells are surface divergent and at the deepest part of the pool they are surface convergent, as occurs in natural pool-riffle sequences. Shear stresses are higher at the pool entrance. At the pool center cross section shear stresses are higher in the shallower side. The effect of vegetation in slowing down the flow and raising water levels is observed in the APRV1 test (Figure 6). The streamwise velocity is always concentrated on the vegetation-free central zone, with little 1.3 b) 0.1 0.2 0.3 0.4 0.5 0.6 0.7 0.8 0.9 y (m) τ / < t > <τ>=2.02 N/m 2 1.2 1.1 0.9 0.8 0.7 0 1

effect of thalweg curvature. Two central circulation

cells are defined by downwelling on the centerline

(associated with the high-velocity core) and upwelling

at the borders of the vegetation zone. Shear stresses are

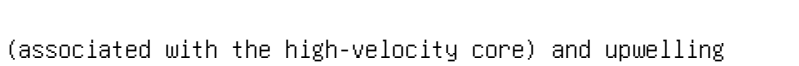
concentrated along the centerline.

3.2 High flow

The FB2 test (Figure 7) shows a structure similar to that

of FB1, but with two cores of high velocity only. This

is because the secondary circulation cells scale with flow depth, and only four cells can fit in the whole channel width. Wall shear stresses are greater under the high velocity cores. As with the FB1 test, the pattern is characteristic of secondary circulation due to turbulence anisotropy at the flow boundaries. The similarity between the CPR2 (Figure 8) and the APR2 (Figure 9) tests is remarkable. Velocities are slightly higher in theAPR2 experiment, which also has a shallower depth.Three high velocity cores are present throughout the structure, corresponding to six cells. The agreement with the wall shear stress is also very water surface water surface 0 0.1 0.2 0.3 0.4 0.5 0.6 0.7 0.8 0 0.1 0.2 0.3 0.4 0.5 0.6 0.7 0.8 Y (m) Y (m) 0 0.05 0.1 0.2 0.15 0 0.05 0.1 0.2 0.15 pool entrance pool center Z (m) Z (m) b) a) 0.5 0 5 6 7 8 9 x y <<τ>>=2.4 N/m 2



good. The cells scale approximately with the depth of the riffles and stretch down to occupy the whole cross section at the pool. Besides this stretching, the shape of the geometry does not seem to affect the sec ondary circulation patterns. Compared to the FB2 test, the CPR2 andAPR2 tests present two more circulation cells. This difference is due to the fact that cells scale with the flow depth at the riffles, which are consider ably shallower than the depth of the FB2 test. In fact, the flow patterns of the pool-riffle experiments corre spond better with the FB1 test, which has a depth of the order of the riffle depth.

The APRV2 experiment (Figure 10) has a differ ent pattern, which is similar to the APRV1 test. The vegetation directs the flow towards the center, with only one velocity core and two well defined cells. However, there is some indication of the presence of two incipient high velocity cores at the sides. Wall shear stresses are concentrated on the centerline, with a slight increase towards the shallower side of the pool.

4 ANALYSIS AND DISCUSSION

4.1 Topographic effects

The previous section has shown important differ ences between the high and low flow behavior of the pool-riffle configurations without vegetation (series CPR and APR). For low flow, the geometry of the bed plays an

important role in determining the three dimensional hydrodynamics. This is more obvious in the CPR1 case than in the APR1 case, probably due to differences in discharge. The CPR1 case has the lower discharge, and geometric effects are expected to be more effective under this condition. The bed geometry produces lateral divergence and acceleration on the riffles and lateral convergence and deceleration on the pool. In the APR1 case it also produces lateral shoaling at the pool entrance and exit. The combination of lateral divergence and acceleration generates the splitting of the maximum velocities into two cores at the riffles. These cores induce an undulating pattern on the bed shear stresses, which results in secondary circulation. As the flow enters the pool, lateral convergence displaces the velocity cores towards the deepest part of the pool, generating a different secondary flow pattern (this effect is less evident in the APR1 case). The velocity cores are associated with surface convergent secondary circulation and downwelling, so they produce surface convergence/near bed divergence in the pool deepest part and surface divergence/near bed convergence at the riffle centerline. The pattern described is in total agreement with the ideas of Thompson 0 0.05 0.1 0.15 pool entrance Z (m) 0 0.1 0.2 0.3 0.4 0.5 0.6 0.7 0.8 Y (m) 0 0.1 0.2 0.3 0.4 0.5 0.6 0.7 0.8 Y (m) 0 0.05 0.1 0.15 pool center Z (m) <<τ>>=2.4 N/m 2 b) a) 0.5 0 5 6 7 8 9 x y water surface water surface

Figure 10.

(1986) based on field observations and is related to

Prandtl’s first kind secondary currents.

The high flow situation shows no apparent effects

of the pool-riffle geometry. The flow behaves essen

tially like in a uniform flow situation, with turbulence

anisotropy in the bed and channel walls generating sec

ondary circulation and associated high-velocity cores.

The walls are important in constricting the flow, pro

ducing a narrow channel effect. The riffle controls the

secondary circulation patterns and the position of the

high velocity cores, since the cells scale with the riffle depth. At the pool, the cells stretch vertically to cover the whole cross section. Downwelling or upwelling can occur in the pool and riffle centerlines depending on the width/depth relation. The description resembles a uniform flow situation and is associated with sec ondary currents of Prandtl's second kind (Nezu and Nakagawa, 1993).

The difference in low and high flow behavior is reflected in the relative magnitudes of the shear veloci ties at the pool and at the riffle. The high flow situation (CPR2 and APR2) is more uniform, and so the differ ence between the riffle and the pool shear velocities is smaller than in the low flow case (CPR1 and APR1). 1 1.05 1.1 1.15 1.2 1.25 1.3 1.35 1.4 1.45 1.5 0 0.05 0.1 0.15 Q (m 3 /s) < U ∗ r > / < U ∗ p > CPR APR APRV Figure 11. Ratio of riffle to pool wall shear stresses. This is evident from Figure 11, in which <U ∗r > and <U ∗p > are the riffle and pool cross sectional shear velocities, respectively. The convergence with discharge shown by the figure is often observed in natural pool-riffle sequences and has important implications for the self-maintenance of the structures. According to the figures, the CPR case has a higher convergence rate than the APR configuration.

Consequences of this difference in behavior for high and low flow conditions may have other implications for the design and maintenance of pools and riffles in urban streams. The constriction of the walls starts playing an important role when the flow depth raises to more than 1/5 the width, which is not uncommon.

Under this condition, higher shear stress zones are located approximately at 1, 3, and 5 times the depth from the walls and may or may not coincide with the position of an artificially placed pool. If the bankfull discharge is regarded as the one responsible for the pool maintenance, the placement of the pool can be done in order to match one of the high shear stress zones for bankfull flow.

4.2 Vegetation effects

Vegetation inhibits to some extent the topographic effects. Increased roughness raises the water levels and slows down the flow velocities. The plant zones force the flow towards the centerline both for low (APRV1) and high (APRV2) flow, generating only one high velocity core. Two strong circulation cells are located in the central zone but secondary flow patterns over the plants are less defined. For the APRV2 case, two incipient high velocity cores at the channel sides sug gest that the effect of the plants may decreases for higher flow.

The similitude between the APRV1 and APRV2 experiments can be seen in Figure 11.The figure shows that the ratio <U *r >/<U *p > changes considerably less than in the CPR and APR cases.

5 SUMMARY AND CONCLUSIONS

Detailed 3D velocity measurements on a laboratory

model have provided important information regard

ing the effects of topography and vegetation on the

flow dynamics of pool-riffle sequences in constricted

waterways. After analyzing flat bed (FB), centered

Morphological rehabilitation and flood protection by controlled river

dynamics – a physical model

U. Stephan & M. Hengl

Institute for Hydraulic Engineering and Calibration of Hydrometrical Current-Meters, Vienna, Austria

ABSTRACT: According to the results of a physical model it is shown, how to change the state of a gravel

bed river from erosion to a morphological dynamic river system connecting again river and wetlands. The basic

idea is to raise the bed level with help of a ramp and to initiate a self-acting bank erosion process increasing

the river width. In addition, the currently straight river morphology is converted into a meandering one. The

physical model provided valuable experiences regarding self-acting bank erosion and meander development.

These measures might be used for river restoration, but must be analyzed in each specific case regarding their

suitability for improving a river-wetland-system.

1 INTRODUCTION

Many rivers in Central Europe such as the Salzach,

Isar, Inn, Danube or Drau, show a heavy degrada

tion process which has evolved from various human

activities in the past such as straightening and con

stricting the river or bed load entrapment in the catchment. As a typical consequence the river system adjusts in a long-term geomorphologic manner to these human influences with various awkward effects. Bed erosion of many rivers has progressed to such an extent that bank structures as well as bridge piers have become endangered. The groundwater table has decreased remarkably. The river wetlands have been cut off from the river itself, which is closely connected to a loss of habitats and of population diversity in the wetland ecosystems. In addition, the flood run-off occurs chiefly on the main channel. Thus, wetlands are flooded less and tributaries are detached from the main river. Loss of retention areas deteriorates the downstream flood protection as well as the wetland ecosystems.

Even more unfavorable, if not dangerous, is a phenomenon called “Sohldurchschlag” or sudden river bed break-down, which could be observed in many alpine rivers such as the Inn or the Salzach, e.g. Hengl (2000), WRS (2000). The term describes a change in the erosion process due to the presence of fine sediment layers below the gravel bed of a river. If the mean river bed intersects the gravel bed because of the progressive erosion process and reaches these fine

sediment layers below the gravel bed, the geomorpho

logic consequences can no longer be predicted. The erosion process is increased tremendously because of the greatly increased erosion potential of these fine materials. The extent of damage from the above mentioned effects, i.e. endangering of buildings near the river bank and in the river, decreasing groundwater table, destruction of bank protection works, among others, is intensified. Therefore, the river restoration planning stage of the river Salzach downstream of Salzburg is presented as an example of how to change a state of a river from erosion to a morphological dynamic river system connecting again river, tributaries and wetlands. The main goals of the river restoration measures are to sustainably stabilize the river bed regarding bed load input from the catchment, to guarantee flood risk protection, to raise the river bed, to provide a dynamic river morphology and, finally, to connect again river and wetlands. 2 BASIC CONCEPT Within the Water management frame study Salzach, a concept for a solution was developed meeting morphological, hydraulic as well as ecological demands (WRS 2001a). The main idea is to raise the bed level with help of a ramp. The ramp axis is directed towards the river bank and, thus, initiates self-acting bank erosion which, finally, leads to a dynamically curved river morphology. This construction combines a few important solutions: On the one hand, the river bed is raised while bed load transport fills the deposition wedge upstream old river c u r r e n t r i v e r b e d connection to the wetland connection to the wetland bank erosion bank erosion 130 m (planned river width) ramps new river p l a n n e d r i v e r b e d 100 m (current river width) 2 ramps (slope 8%) with island bank erosion

Figure 1. Principles of the solution concept for raising the river bed and improving the morphological state of the river.

of the ramp. Hence, the mean water level is also raised

as well as the groundwater table. The former leads to

a more frequently flooding of the wetland system and,

thus, to an improved connection between river and wet

land. In addition, the river width is increased due to the

self-acting bank erosion process. This, first, compen

sates the raised water level due to the raised river bed in case of floods and, secondly, causes an improved morphological as well as ecological diversity of the river bed. During the filling process of the deposition wedge upstream of the ramp, the bank erosion temporarily enables continuous bed load transport downstream of the ramp and, thus, prevents further bed erosion. On the other hand, raising the river bed reduces the risk of "Sohldurchschlag" due to a thicker gravel layer covering the fine sediment layers below the gravel bed. The principles of the concept are shown in Figure 1.

For each measure, which is thought to be a solution for a problem, it has to be considered that the guidelines for the future morphological situation of the river-wetland-system are reasonable and realistic (Stephan et al. 2003). On the one hand, the selection of suitable solutions must be based on both the past and the current morphological situation of a river. On the other hand, any contemplated measures must take natural morphological processes into account. Thus, natural bed load input, river geometry as well as discharge of the current river must be suitable for a meander morphology in the future.

To analyse the current morphological situation of a river, the approach developed by da Silva (Yalin &

da Silva 2001) may be used (Fig. 2). This method sug

gests that the morphology (macro bed forms) of a river

depends on two factors: the ratio of bed width to flow

depth (B/h) and the ratio of flow depth to mean grain

size (h/d m). When the bed width changes, flow depth changes also, as do the ratios B/h and h/d m . Figure 2 with B as the river width, h the flow depth, J the bed slope and d m as the mean grain size of the bed material shows that the current possible morphological situation of the river ranges between alternate bars and meanders for the whole extent of discharges, that is the discharge for beginning sediment transport up to the design discharge with a return period of 100 years. Due to the recommended river width of B= 130 m, a fundamental morphological change of the river is not to be expected. For the proposed solution, the morphology will not change essentially. But the planned measures would be doomed to fail, if these geomorphologic boundary condition were not considered. 3 DESCRIPTION OF THE MODEL The main components of the planned river training works were tested in a physical model scaled 1:50. The physical model mainly focused on – a proper ramp geometry to initiate the self-acting bank erosion process and to ensure a proper hydraulic function for energy dissipation and scour protection; – needed measures to control the bank erosion process; – analyses of time variability of the sediment input downstream of the ramp due to the bank erosion process; – analyses on the development of the meanders in longitudinal direction and the needed bank protection measures; – bed load transport capacity of a meandering river reach in equilibrium. 1

Figure 2. Macro bed forms of the river Salzach – current

and planned state of the river (adapted fromYalin & da Silva 2001).

Figure 3. Plan view of the physical model.

A numerical sediment transport model simulating the long term bed level changes of the whole, 60 km long river reach was based on the latter. The design dis charge with a return period of 100 years amounts to some 3100 m 3 /s. An important part of the concept is the contribution of wetland areas and tributaries as flood retention areas to the flood run-off. Thus, only 2000 m 3 /s of the design discharge remain in the main channel, 1100 m 3 /s flow in the wetland areas as it resulted from a 2d-flow model. Therefore, the model area was limited to the river itself and the river adjacent areas and the flood run-off in the wetlands was neglected.

Due to limited space, the physical model was 53 m long and 10 m wide reproducing 1.5 meander wave lengths downstream of the ramp. Figure 3 shows the model section including both the final state of the river and the straight river how it appears today. Mean der wave length and width were planned to 1500 m and 130 m, respectively. Thus, the meander angle resulted in 18.6 ◦ and the meander amplitude for the inner and outer curve in 80 m. To limit the self-acting bank erosion in advance, a bank protection was built according to this meander geometry. The ramp building

consisted of two parallel ramps sloped 1:12 separated by an island. Each of the ramps was 60 m wide. Ramp curvature and ramp size were defined according to Platzer (2000). Due to fine sediment layers below the gravel bed of the river, the need for an extensive scour protection right behind the ramps arose. The initial state of the model shows a 100 m wide straight river with a trapezoidal cross section, two parallel ramps and a control groyne to initiate the bank erosion process (Fig. 4). The downstream boundary condition for the physical model regarding the stage-discharge-relationship resulted from the 2d-flow model. The sand used in the physical model was quartz sand with a mean grain size of d m = 33.4 mm, calculated according to Meyer-Peter & Mueller (1948). 18 sample at different locations of the model were analyzed regarding the sieve curve. The results are shown in Figure 5a. The remarkable scattering of the samples

might be explained by the method of how the sand was

brought into the model area, since the sand was blown

into the model. Figure 5b shows the sieve curves of the

sand used for bed load input being almost the same as

the bed material.

The bed load was added continuously using a con

veyer belt (Fig. 6), but was not distributed equally over

the river width, since the ramps were situated in a

curve. The input ratio between left and right part of

the river width was 3:2.The input rates were calculated according to Jäggi (1992) for a 130 m wide river with a bed slope of 0.9%. The measurement program comprised measurements of water and bed levels as well as bed load measurements. The former were conducted within 54 cross sections covering a channel reach of 2.35 km in nature using ultrasonic probes. The bed load was collected in a sedimentation trap mounted on four pressure gauges at the model outlet and weighed continuously considering buoyancy effects.

Figure 6. Conveyer belt for bed load input upstream of the ramps.

The experimental program was divided into two

main parts: The first part contained the self-acting bank erosion and development of the meanders without bed load input at the model inlet simulating the situation after putting up the ramps. This part took 700 hours. During the second part, the longitudinal changes of the river bed depending on bed load input into the river reach as well as the bed load transport capacity of a curved river morphology were investigated. The total experimental duration amounted to 3608 hours. A detailed description of the physical model is given in WRS (2001b).

4 RESULTS

4.1 Changes of the ramp building and scour protection

The right part of the double ramp had to be turned to the left by 8 ∘ to improve the flow downstream of the ramp for better initiating the self-acting bank erosion. In addition, the height of the ramp head was reduced by 30 cm.

The hollow shaped scour protection right behind the ramp was 1.1 m deep and 1.5 times the length of the ramp. The hollow itself was lined with two rip-rap layers. Following the hollow, a river reach of, again, 1.5 times the ramp length was covered with stones sized 300 to 500 kg with a stone density of one stone per 2 m 2 . Despite of the solid scour protection, scour

depths up to 5 m are to be expected.

4.2 Bank protection and controlling of flow

The morphological development of the river reach

downstream of the ramp is mainly influenced by groynes. Depending on the extent of bank erosion of the outer bank the length of the flow directing control groynes at the inner bank is increased to regulate the bank erosion process. Thus, the formerly straight river develops into a meandering one. Figure 7 shows the final state of the first meander curve behind the ramp building. At the inner bank of the meander, generally no bank protection measures are needed. From the ford to the vertex of the meander curve, the groyne distance at the outer bank was 100 m and the length of the groynes was 25 m. From the meander vertex to the following ford, the flow direction must be turned. Thus, the flow attack at the outer bank was increased and the groyne distance reduced to 75 m as well as the groyne length increased to 30 m. The groyne heads should be protected separately due to occurring deep local scours. The groynes at the outer bank of the meander stabilize the curved morphology of the river and prevent further bank erosion as well as a fundamental shift of the main channel. Consequently, there is no need to set up the groynes at the outer bank unless the maximum extent of bank erosion is reached. 4.3 Morphological development (bank shift, volume of bank erosion, depth variation) The development of the curved river morphology in the physical model resulted from experimental runs with varying discharges. The return period of the discharges ranged from 1 to 100 years with intermediate low discharge phases and, consequently, little sediment transport. 700 experimental hours, which correspond to 19 years in nature, almost finished the meander development and bank erosion process. The meander geometry, derived from the Farguesch laws

Figure 7. Control groynes at the inner bank to direct the flow to the outer bank and bank protection of the outer bank (final

state of the measures). 0 2 4 6 8 10 12 14 16 18 20 0 2 4 6 8 10 12 14 16 18 20 s h i f t o f t h e r i v e r b a n k [m / y r] 0 4 8 12 16 20 24 28 32 36 40 b e d l o a d i n p u t [1 0 ^{3} m ^{3} / (y r . k m)] shift of the river bank bed load input s e t u p o f t h e s e c o n d c o n t r o l g r o y n e time [yr]

Figure 8. Mean shift of the river bank and volume of bank erosion in a meander assuming a 3 m gravel layer height in the

river-adjacent areas.

(Schaffernak 1950), emerged to be too small regarding

both the meander wave length and the meander ampli

tude and had to be increased by 10% and reduced by

20%, respectively. The groynes in the outer bank may

be used for adapting the meander geometry. Bank shift due to the bank erosion process mainly depends on the flow shear forces acting on the banks as well as on the bank material. In the physical model, the same material was used for both the river bed and the river banks. The shift velocity (Fig. 8) was calculated

Figure 9. Flow depths [m] for a discharge of Q= 500 m 3 /s.

assuming the height of the gravel layer in the river

adjacent areas being not larger than 3 m considering

fine sand deposition in the wetlands. The bank shift

caused an increase of the river width from formerly

100 m to 130 m.

Figure 8 also shows the volume of bank erosion

resulting from the bank shift. Putting up a ramp leads

to a temporary deficit in bed load transport down

stream of the ramp due to the filling of the deposition

wedge upstream of the ramp. Unless the bed load

material from the catchment passes the ramp, the

self-acting bank erosion process needs to balance the

downstream bed load deficit.Therefore, it is important

to know grain size, type and layer height of the mate

rial of the river-adjacent areas, since the bed load input

downstream of the ramp mainly depends on the geo

logical characteristics of the river banks. To meet this demand in the frame study of the Salzach, extensive soil investigations in the river-adjacent areas were performed. During the experiments as mentioned above, the bed levels were measured regularly within 54 cross sections. Analyses on meander development and bed level variations were based on these measurements. In particular, the latter are an important morphological pattern, since the ecological diversity is strongly enhanced by a morphological diversity of the river bed. Figure 9 shows the meander development with groynes being at the outer banks in four steps from the beginning until the end of the experiments. The dark areas mark the flow concentration at the outer banks. With progressive meander development, bed level variations and, hence, the morphologic diversity is increased.

Figure 10. Bed level variations of a river reach of 2.2 km for the current (2001) (a) and the planned (physical model) (b) state

of the river Salzach.

In addition, Figures 10a and b show various cross

sections of a 2.2 km long river reach of the Salzach

comparing the current and the future state of the river.

The current state of the river (a) with a straight river

morphology in a 100 m wide channel bed does not

show any bed level variations for the river reach at all.

An ecological diversity is not supported by this obvi

ous monotonous situation. Unlike the current state,

the planned meandering state (b) exhibits a wide vari

ety of different channel widths as well as different

channel depths caused by longitudinal changes of

bends and fords. Both, shallow, low flowing cross sectional

parts and deep parts with high flow velocities occur in this channel reach. Depending on discharge and bed load transport, the local morphological pattern of the river changes with space and time. 4.4 Bed load transport capacity The final series of experimental runs focused on investigating the bed load transport capacity of a meandering river reach, which was expected to differ from a straight one. To calculate the bed load transport capacity, the channel reach has to be in equilibrium, 0 50 100 150 200 250 300 0 250 500 750 1000 1250 1500 1750 2000 discharge [m ³ /s]

Figure 11. Transport equation of the physical model compared to transport equations of Hunziker (1995) and Zanke (1999).

i.e. the quantity of bed load input and output is to be the

same within a certain period. The difference between

input and output should not exceed 2%.

The results of the physical model were compared

to the transport equation of Hunziker (1995), which

also was used in the numerical sediment transport

model, as well as of Zanke (1999) (Figure 11). Both transport equations were derived for a straight channel. To achieve the same bed load transport for both the physical model and the theory, the calculated bed load transport had to be reduced by a constant β. The slightly different values of β result from different methods of analysis of Hunziker (1995) and Zanke (1999).

However, the transport capacity of a meandering channel turned out to be less than the transport capacity of the straight one with the same channel width. This might be explained by the increased sinuosity of the meandering channel causing longer flow paths for the bed load, a reduced channel slope and, hence, a reduced shear force at the channel bed.

5 CONCLUSIONS

According to the results of the physical model, the planned river restoration measures turned out to be suitable for sustainably stabilizing the degrading river bed and, thus, ameliorating both the morphological and the ecological state of the river-wetlandsystem. The river can adjust to changing boundary conditions such as discharge and modify its bed. The ramps stand up to the design discharge and raise the river bed in front of the ramps to better connect river and wetlands.

Destruction of herbaceous vegetation by flood flow on a floodplain in a

recovery process

S. Sugio

University of Miyazaki, Miyazaki, Japan

K. Watanabe

Saga University, Saga, Japan

ABSTRACT: This research focuses on examining the

destruction of the herbaceous vegetation on an excavated floodplain in the recovery process. The methods of examination were (i) drawing the distribution chart of the vegetation on the floodplain, (ii) surveying the physical condition of the floodplain, (iii) testing the tensile load to cut off the caulis and the pullout load to extract the roots of the vegetation, (iv) simulating the two dimensional steady flow at the peak of the flood and (v) estimating the maximum size of the transported bed material on the floodplain and the drag force acting on the canopy of vegetation. From these investigations we found that some parts of the vegetation clusters on the floodplain may be destroyed by transport of the bed material. However, almost all of the other parts can be destroyed by the tensile load due to the drag force on the canopy.

1 INTRODUCTION

The vegetation in a river channel plays an important role in the ecosystem. However it becomes an obstacle to flood flow and affects the transport of riverbed mate rial. Therefore, the growing situation of the vegetation becomes an important aspect in river management. Up to the present, although the destruction of woody veg etation due to floods has been examined in various ways, the examination of herbaceous vegetation has been minimal.

The Kita River is a first class river, which flows in the northern part of Miyazaki Prefecture in Japan. In this river, the heavy rainfall of Typhoon No.19 in 1997

caused a severe river disaster and severe damage in the basin.A special emergency project to protect from fur ther severe flood disasters was executed for the channel of the Kita River. In this project, it was requested that the excellent natural environment of this river be con served, and a fixed degree of safety against flooding secured. Lowering the flood levels in a river reach by increasing the discharge capacity of the river channel is possible by enlarging the conveying cross section and by reducing the roughness of the river. In the Kawasaka district of the Kita River, the cross section was enlarged by excavating the floodplain and the trees in the chan nel were removed. In excavating, the water zone and the river banks were to be disturbed as little as possible in order to conserve the natural environment. The revegetation has been monitored to clarify the recovery process of the vegetation after excavation. In monitoring, the destruction of the herbaceous vegetation was observed on the floodplain in the Kawasaka district. This paper describes the monitored results of the revegetation and examines the mechanism of the observed destruction of vegetation. 2 RESEARCH FIELD A point bar formed on the left convex side of the bend of the Kawasaka district in the Kita River, has developed and become a floodplain. This floodplain between the 14 km and 13 km sections was selected as the research field. This floodplain was excavated on average by a thickness of two meters and flattened in March 2000 according to the execution plan for the river improvement of the special emergency project for the Kita River. A check field of this research is the floodplain between the 12.2 km and 11.4 km sections in the Honmura district which was not excavated. These locations are shown in Figure 1. 2.1 Vegetation in Kawasaka In the Kawasaka district, woods of Quercus acutissima and Rosa mulfiflora Thunb. thrived before the excavation of the high ground on the floodplain, and the river 15 km 12 km 11 km

the Kawasaka district. However, the vegetation was destroyed in half of the floodplain due to the flood as shown in Photo 7.

4 VEGETATION DESTRUCTION AND VEGETATION DISTRIBUTION AFTER FLOOD

Figure 2b shows the vegetation distribution chart surveyed after the flood. Comparing this chart with that for before the flood shown in Figure 2a, it can be seen that vegetation disappeared in half of the floodplain, though some parts remained on the low water channel side of the floodplain.

As for the vegetation destruction situation, the following four types were found.

(i) Vegetation disappeared by the roots

(ii) Only the roots remained

(iii) The canopy disappeared, but caulis and roots

remained

(iv) Vegetation was buried in river bank area.

In the drawing of Figure 2b, the areas of vegeta

tion where only the roots remained are included in

the barren ground assuming that the vegetation was

destroyed. Though the composite cluster of Solidago

altissima Linn. andVerbena brasiliensisVell. remained

on the levee side of the floodplain, many canopies of 0 20 40 60 80 100 0.01 0.1 101 Grain size (mm) A c c u m u r a t e d w e i g h t (%) 1 00 A B E F G H J B E Figure 6. Grain size distribution curves. Verbena brasiliensis Vell. were cut off. On the other hand, no significant vegetation destruction occurred on the floodplain in the Honmura district. The grain size distribution curves are shown in Figure 6 by the solid line for the bed material on the floodplain after the flood and by the dotted line for one before the flood.Though the grain sizes are almost the same at the various points on the floodplain before the flood, a significant difference in the grain size distribution was caused in these points after the flood. Gravels larger than 26.5 mm in size occupy the major portion of the grain size distribution at Points E and H. Soils smaller than 0.5 mm in size are the major component at Points A, B and G where the percentages vegetation cover are high. 5 NUMERICAL ANALYSIS 5.1 Basic equations The flow at the peak of the flood was numerically investigated. Two-dimensional St. Venant shallow water equations in a generalized curvilinear coordinate system used were; where ξ , η= axes in curvilinear coordinates; r= radius of curvature; u, v= velocities in the ξ , η

directions; p= ρg(h+ z); ρ=water density; g= gra

vitational acceleration; h= flow depth; z= bed eleva

tion; ε= coefficient of eddy viscosity; τ ξ , τ η = bed

shear stresses in ξ , η directions; F ξ , F η = drag forces

acting on a dead grass lump in the ξ , η directions; and

N = number of grass clumps per unit area. The bed

shear stresses were expressed by using the coefficient of Manning's roughness n, as

The coefficient of eddy viscosity was expressed as

where κ =Karman constant= 0.4; and u ∗ = shear velocity.

5.2 Drag force

Many clumps of dead grass twined around canopies of Verbena brasiliensis Vell. were observed after the flood in October 2001 and also after a small flood in July 2002. Therefore, the force acting on each canopy is regarded as the drag force acting on the dead grass clump. Regarding a circular plate with diameter of D as a grass clump, the drag force can be expressed as

where u δ = velocity at the height δ of the clump from the bed; and C = drag coefficient= 1.0. The velocity u δ can be given from the Manning-Strickler equation as

The scale of the grass clumps in the flood frow is uncer tain. The diameters of clumps ranged from 6 cm to 12 cm in the survey after the floods. In this study, each clump is considered to be a circular plate with diam eter of 10 cm. Since the water depth on the floodplain was over 4.0 m and the length of the vegetation was 45 cm to 190 cm, roughly 70 cm on average, all of the vegetation must have been submerged and the height

of each clump δ is assumed to be half of the vegetation

length, δ= 45 cm herein. By using this value of δ, F ξ

and F η are expressed finally as, respectively, Table 1. The number of dead grass clumps. Cluster Value of N (1/m 2) Phragmites japonica Steud 0 Celosia argentea Linn. 2 Solidago altissima 0 Verbena brasiliensis Vell. 10 Persicaria hydropiper 0 Setaria glauca 0 Verbena brasiliensis Vell. 2 and Solidago altissima The numbers of dead grass clumps are different from each other due to the kind of vegetation and thier density. For example, the grass clumps in the cluster of Verbena brasiliensis Vell. numbered about ten per 1 m 2 from the survey after the flood. Based on this value, the number N at each analytical point was estimated from the distribution and density of vegetation before the flood in 2001 as shown in Table 1. 5.3 Analytical conditions and velocity distributions The analytical domain including the floodplain at the Kawasaka district was selected between the 13.0 km and 14.4 km sections.The domain was divided by 50 m in the ξ direction and each cross section was divided into 24 meshes with intervals of 7.5 m to 10.5 m. Values of the coefficient of Manning's roughness were taken as 0.031 for the main channel and 0.035 for the floodplain according to the results of a 1-D simulation of the flood in 1997. Taking the flood on October 16, 2001 as the flow to simulate, the peak discharge of 1,600 m 3 /s was taken as the boundary condition at the upstream end. The water level of 10.63 m at the 13.0 km section was taken as the downstream boundary condition. This value was obtained from a 1-D simulation of the flood by using the measured peak water level of 9.74 m at the 12.0 km section. Figure 7 demonstrates a numerical result of the flow velocity vector. It can be seen that the low water channel deviates to the right levee between the 14.0 km and 13.4 km sections and velocities are increased there due to the floodplain formed on the convex side of bend. Velocities were 2.2 m/s to 2.8 m/s in the low water channel and 0.8 m/s to 1.8 m/s on the floodplain. In particular, velocities near the center part of the floodplain were significantly decreased due to the cluster of Verbena brasiliensis Vell.

Low water channel 13.2 km 13.4 km 13.6 km 13.8 km 14.0 km 14.2 km 14.4 km

Figure 7. Velocity vector distributions.

6 DESTRUCTION OF VEGETATION

6.1 Mechanism of destruction

The effects of flooding on the vegetation have been classified by Ishikawa (1996) into the following four kinds: (1) destruction by the transported bed material, (2) destruction of the physical condition by the flow, (3) burying by the transported bed material, and (4) adverse effect to the physiological activity caused by submergence. The vegetation in the Honmura district was destroyed due to the flood in 1997. Main cause was burying by the bed material. This type of destruction should be considered by the estimation of tractive shear stress related to bed material transport under flood.

Many clumps of dead grass twined around canopies were observed after the flood due to Typhoon No.9 in July 2002. A photograph of a dead grass clump is shown in Photo 8. It is considered that these dead grasses were washed away in the upper reaches and twined around canopies of vegetation on the flood plain during the rising of the water level. When the drag force acts on each grass clump, vegetation is constrained to the flow direction. A comparison between the drag force and tensile load should be considered.

6.2 Movement of bed materials on the floodplain

From the simulated results, the values of shear veloc

ity u ∗ on the floodplain were 11.0 cm/s to 12.6 cm/s.

This means that the maximum size of gravel moved

by the shear stress can be estimated to be 1.5 cm to

2.0 cm. Therefore, it is considered that gravels smaller

than this size moved during the flood. According to

the grain size distribution curves shown in Figure 6,

the percentage of gravels with diameters greater than

2 cm at Point E was almost 50% before the flood.

This is the reason why the bed elevation was not Photo 8.
Dead grass clump twined around canopies of Verbena
brasiliensis Vell. significantly deformed by the flood as
shown in Figure 5. 6.3 Distribution of drag force acted on
grass lump Figure 8 shows the distribution of the simulated
combined drag force F acting on a grass clump twined around
a canopy of vegetation on the floodplain. The horizontal
axis denotes the distance from the top of left levee. The
value of F is roughly 1 N to 10 N. In the figure, the
vegetated areas before and after the flood are also shown.

7 TENSILE LOAD OF HERBACEOUS

VEGETATION

A tension test for various kinds of vegetation was car

ried out to clarify the tensile load to cut off the caulis

and the pullout load to extract the root. A schematic

diagram of the testing method is shown in Figure 9.The

caulis of the vegetation was bound with a string, and

a load was attached to the other end of the string. The

load when the caulis was cut or the root was extracted

was measured. Strings were bound at the joint of the Suspension rod Caulis Load String w Figure 9. Schematic diagram for tension test method.

canopy for the tension test of the caulis and at the lowest part of the caulis for the root pullout test. In addition, in the test of tensile load, the lower part of the caulis was rolled in a suspension rod to prevent the load from acting on the root part.

The measured results are shown in Table 2. The results show the tensile load of the joint of the canopy is smaller than the pullout load of the root for many kinds of vegetation. From this result, it is understood that cutting the caulis is easier than extracting the root.

8 DISCUSSIONS OF VEGETATION

DESTRUCTION

In the composite cluster of Solidago altissima Linn. andVerbena brasiliensisVell. between the 13.7 km and 13.8 km sections, many canopies ofVerbena brasilien sis Vell. were lost in the flood. Since the drag force acting on a dead grass clump is greater than the tensile load as shown in Figure 8a, it is considered that the drag force caused the destruction of Verbena brasiliensisVell. by cutting canopies in this area.At the 13.7 km section (Figure 8b), the drag force decreased because of the decreased velocity due to the resistance of the cluster of Verbena brasiliensis Vell. Then, the destruction of this cluster was only partial.

The cluster of Celosia argentea Linn. between the 13.6 km and 13.7 km sections almost disappeared by the roots as shown in Figure 2b. According to the simulated results for the tractive force, it is consid ered that gravels with diameters smaller than 2 cm were transported in the barren ground and in the low density vegetated area. Since the percentage veg etation cover was small in the cluster of Celosia argentea Linn. as shown in Figure 3, it can be pre sumed that gravel movement destroyed the physical condition in this cluster and the root pullout load of Celosia argentea Linn. must have decreased. On the

other hand, the tensile load of the caulis is larger than the drag force. Therefore, it is reasonable to consider that the caulis of Celosia argentea Linn. was not cut and its cluster was washed out by the roots. At the 13.6 km section, the composite cluster of Solidago altissima Linn. and Verbena brasiliensis Vell. was not destroyed, because the drag forces were smaller than the tensile load as shown in Figure 8c. The cluster of Verbena brasiliensis Vell. at the 13.5 km section was also not destroyed for the same reason, as shown in Figure 8d. The cluster of Persicaria hydropiper along the edge of the floodplain almost survived as shown in Figures 2b. It can be considered that the large drag force near the low water channel could not destroy Persicaria hydropiper because of the flexibility of the caulis. Values of root pullout load for Phragmites japonica Steud and Setaria glauca are larger than the drag forces as shown in Figure 8d. Therefore, both clusters at the 13.3 km section were not destroyed and survived as shown in Figure 8e. 9 SUMMARY As mentioned above, various field investigations were carried out on the herbaceous vegetation of the floodplain of the Kita River. The destruction of the herbaceous vegetation due to the flood flow was then examined. The results obtained are as follows: (1) Part of the herbaceous vegetation on the floodplain in the recovery process was destroyed due to a flood flow with a maximum discharge of 1,600 m 3 /s caused by Typhoon No. 21 on October 16, 2001. (2) The destruction situation can be classified roughly into the following four types: (i) vegetation disappeared by the roots, (ii) only the root remained, (iii) the canopy disappeared, but the caulis and roots remained, and (iv) vegetation was buried in the river banks. (3) Many clumps of dead grass twined around canopies of Verbena brasiliensis Vell. were observed after a small flood in July 2002. (4) Through a numerical analysis of the flood flow on the floodplain, it is recognized that the reason why a clear change of riverbed elevation did not take place on the floodplain in the Kawasaka district was due to lack of movement of gravel larger than 2 cm in size in floods. (5) It was found from simulated results that a drag force of 2–10 N acted on canopies of the vegetation in large parts of the floodplain. (6) Through tension tests for various kinds of vegetation, it became clear that cutting the caulis is easier than pulling out the root. (7) It is confirmed that the disappearance of the canopy of Verbena brasiliensis Vell. was caused by cutting the caulis due to the drag force acting on a dead grass clump.

(8) It is inferred that disappearance of vegetation by the root is due to both movement of gravels with small

diameters and the action of the drag force.

(9) It can be presumed that the vegetation on the low water channel side of the floodplain was prostrated by the flow-induced force and survived the flood because of the flexibility of the caulis.

ACKNOWLEDGEMENT

The investigation in this paper was partially supported by research funds from the River Ecology Research Group of Japan. A new bed for the river Inde: a case study with special view on the risk of depth erosion

P. Kamrath, C. Schweim, S. Briechle & J. Köngeter

Institute of Hydraulic Engineering and Water Resources Management Aachen University,

Aachen, Germany

ABSTRACT: This paper presents the results of research about a river relocation in a German coal mining area. The river Inde resides in the lignite dismantling area called the “Rhineland”, which is enclosed by the three towns Aachen, Cologne and Mönchengladbach. In the year 2005 the contemporary riverbed will be intersected as a result of the brown coal mines forward movement to the east and the continued use of lignite as energy source for the neighbouring power plants. Long time enduring critical shear stresses throughout flood events could cause depth erosion, which would damage or eventually destroy the sealing layer and therefore flood the pit mine as a worst-case scenario. Hence, the aim is to give the new river as much freedom as possible and to eliminate any uncertainties regarding the flood protection of the coalmine at the same time.

1 INTRODUCTION

The planned riverbed consists of a variable geometry and cross sectional shapes separated in one main chan nel and two flood plains. According to modern aspects of river-design a partly meandering river was chosen where diverse flow patterns are beneficial to the river ecology.

The new part of the river will cover a reach of 12.0 [km] (Fig. 1). The river Inde has a mean dis charge of 4.3 [m 3 /s]. Its new riverbed shows a bed slope of 1.2 [%] and a mean width of the channel of 13.70 [m]. The riverbed of the new Inde is denoted by a wide bandwidth of different roughness regions. For numerical simulations a one-dimensional view is not sufficient, because the lateral resolution of the results would not be detailed enough for erosion forecasting purposes.

The transport of the bed material was tested in the institute's laboratory. Hence, the main influencing parameters regarding the bed load are the materials critical shear stress τ c and the mass erosion capacity respectively. In addition to the bare materials critical shear stress the influences of sparse vegetation and rip ples caused by the construction method are important aspects to consider in the model (Fig. 2, top). For this purpose a vegetation-erosion algorithm is applied to

the numerical model.

As a consequence to the sparse and slow growing

vegetation the shear stresses are computed for varying

scenarios. At first a scenario for the time immediately
Figure 1. The relocation of the river Inde. after flooding
the new part of the river is predicted when settlement
processes are not finished yet and plants are sparse.
Secondly at another point of time in the far future when
settlement is finished and vegetation is dense. Except of
erosion stability forecasting during annual repeating
floods, the initial bed load during an only every one
hundred years occurring event is interesting, too.

5 +800 – 0 +600).

2 THE MODEL

2.1 Simulation of flow characteristics

The flow processes in the river are dominated by

a very heterogeneous river geometry and roughness

distribution. To assure the hydromechanical efficiency

as well as to get information about the occurring shear

stresses at different flood events the two-dimensional

depth averaged model RISMO is used. RISMO has

been developed at the Institute of Hydraulic Engi

neering and Water Resources Management and has

been applied for several two-dimensional simulations

(Rouvé & Schröder 1993).

The numerical model solves the shallow water equa

tions with the finite element method. The shallow

water equations are obtained by vertical integration

of the Navier-Stokes equations and the continuity equation (Kuipers & Vreugdenhill 1973): with where H is the flow depth, U i are time-averaged horizontal velocities, x i are the Cartesian coordinates, S is the water surface elevation, F the outer force, ρ the density of water and ν the cinematic viscosity. A wet-dry algorithm considers bank overflow and partly submerged regions. The flow calculation yields the velocity and the depth of flow for each node for a given discharge and for a set of boundary conditions like the bottom roughness and outflow water level. The simulation is carried out from downstream to upstream to use the results from one section as the outflow boundary condition to the next one. When the flow calculations are completed a decoupled sediment transport module is used to calculate transport rates. The influences of the ripples and the sparse vegetation are all covered into Manning's roughness parameter n. The whole reach of the new riverbed is divided into sections with about 8000 elements each. 2.2 Applied roughness The open pit mine offers a material as a side product which is used for the new riverbed. It consists of a mixture of gravel, sand and loess with a characteristic diameter d ch of 15 [mm]. Resistance to flow is typically characterized by a roughness coefficient. The most commonly used equation for flow resistance is the Manning equation. All other forms of resistance parameters as the Chezy C parameter or the Darcy-Weisbach friction factor f can be converted into Manning's coefficient n. The roughness of the bare material was tested in an earlier physical experiment in order to transfer the results into the numerical model (Baur et al. 1997). From a series of tests the roughness was determined to be n= 0.019 [s/m 1/3]. The estimation of roughness is very precise, as long as no heterogeneous influences are considered. Unfortunately, the flood plains of the new river Inde consist of ripples and a very sparse vegetation layer (Fig. 2, top). The ripples width is approximately 2.0 [m] and their height about 0.6 [m].

To take these structures into account, an approach

recommended by van Rijn (1993) is chosen:

In Equation 5 above n R [s/m 1/3] is the added Manning

roughness resulted by ripples or dunes, k s [mm] is the

equivalent sand roughness parameter, γ r [-] is called

a presence factor (γ r = 1.0 for ripples and γ r = 0.7 for dunes) and r [m] is the height of the structures.

2.3 Influence of sparse vegetation

The influence of the sparse vegetation on the ground is neglected. Only larger plants e.g. willows and shrubs are simulated. Plants on the floodplain and along banks can increase or even decrease the effective flow resis tance.The Manning's resistance coefficient for vegeta tion is calculated in conformity with the Cowan (1956) method for additive resistance and based on the work of Copeland (2000). According to his research, the modulus of plant stiffness E s is critical to the calcula tion of resistance because of the flexibility of the plants and the deformation of leaf masses due to the flow forces. The modulus of plant stiffness is calculated by:

where F 45 is the force to bend the plant to an angle of 45 ∘ , D s is the thickness of the stem and h the plants heights as to see in Figure 3. With the typical stiffness of willows the roughness for submerged vegetation can be computed by following equation:

with:

A s Total cross sectional area of a plant [m 2]

A i Frontal area of a plant blocking flow [m 2]

u τ Shear velocity [m/s]

Y 0 Flow depth [m]

M Plant density [1/m 2]

R h Hydraulic radius [m]

Equation 7 is applicable only for submerged flow

defined by depth Y 0 > 0.8 h. At present time, approx

imately one willow or shrub for each 50 [m 2] with

E s = 1.5 · 10 8 [N/m 2] can be found on the flood plains.

Hence, the resulting Manning's roughness coefficient

for the river Inde is chosen to be n= 0.05 [s/m 1/3].

The ripples are obviously the parameter with the high

est influence. For the moment when the new part of Figure 3. Methodology for measuring the force F 45 to calculate plant stiffness E s . the river is flooded, the influence of sparse vegetation is insignificant. 2.4 Critical shear stress value The value of the critical shear stress relies on the degree of fractional ground cover V , which ranges from zero to one. V max = 1 is the maximum percent cover that can be supported in a given environment. Unfortunately, only few data sets exist to constrain the relationship between the critical shear stress τ c and V . In the absence of better information, a linear relationship is a good approximation (Tucker 1999). where τ cs is the critical shear stress for an unvegetated surface and therefore primarily a function of the grain size and τ cv is the added critical shear stress under 100% vegetation cover. The transport capacity then depends mainly on vegetation cover and is commonly written like: The transport capacity q s depends on the difference of the fluid shear stress τ and the critical shear stress τ c . At present time, the coverage V is about 10%. With τ cs = 6 [N/m 2] as resulted by experiments in a flume and τ cv = 50 [N/m 2] as the maximum value under full coverage the critical shear stress immediately after flooding the Inde is assumed to be approximately 11 [N/m 2]. 2.5 Erosion processes The rate of erosion is calculated with one of the common sediment transport formula. It is the method

of Meyer-Peter & Müller (1949) which derives the

sediment transport capacity:

with:

q s transport capacity [kg/m · s]

ρ F bulk density of material [2650 kg/m 3]

u τ shear velocity [m/s]

d ch * characteristic particle size [15 mm]

Fr Froude number due to [-] particle= f(τ, d ch)

Fr * c critical Froude number [-] due to particle

Q s flow rate with effect on [m 3 /s] transport

k St roughness coefficient due [m 1/3 /s] to flow

k r roughness coefficient due [m 1/3 /s] to particle

By comparing the rates at two following cross sec

tions the model predicts erosion or deposition within

the element. By dividing the difference of one sec

tions inflow and outflow with their distance one gets

the change in bottom elevation for each time step:

In Equation 11, d is the distance between the cross sec

tions. Therefore, the derivative of the bottom elevation

in time is equal to the derivative of the transport capac

ity in x-direction. There are no long-term changes in

river morphology predicted by the numerical model,

because there is more demand on the local accuracy of

the estimated initial shear stresses than on long-term

prediction.

3 APPLICATION

3.1 General

The main intend is to predict depth erosion and the

total area with shear stresses above the critical value

with the help of a numerical model. Therefore differ

ent vegetation coverage levels and specific times are

investigated.

In 2005 the old riverbed will be finally intersected

and the new one will be flooded. Thus, another aspect

is to study the influence of the ripples to the computed

shear stress values and to suggest, whether a removal

is needed for flood protecting reasons or not. Hence,

one main thought is central: minimization of the total

area with shear stresses above a critical value. This

chapter presents the results and compares the different scenarios. The focus is set on sections A and B which are built in the next year (Fig. 2, bottom). 3.2 Influence of settlement Especially in the first years after cutting the old river and flooding the new part in the year 2005 any flood events could produce great damage, because there is no protection by any vegetation. Because the new riverbed is being built close-by the open pit mine which was refilled with material just a few years ago, the bottom elevation will change over the next 20 years between 0.1 [m] and 0.6 [m]. Thus, as a first step, the influence of the unfinished settlement on the shear stresses should be examined. Figure 4 shows the computed shear stresses at river km 5 +400 for two different moments at a discharge of 111.0 [m 3 /s]. On the left the computed values for the year 2005 are shown as predicted and on the right the results for the year 2020 are plotted. It is obvious for this section, that values of shear stresses are minor in the year 2005, when vegetation coverage is little. Table 1 compares the total critical area. For the summation a critical shear stress value of τ c = 11 [N/m 2] is assumed for both cases. Growing of vegetation between the year 2005 and 2020 is therefore neglected. During an every one hundred years occurring flood the size of the area where erosion is possible increases due to the settlements about 50%. It is important that the risk is not higher in the beginning compared to a later specific time. Figure 4.

Influence of the unfinished settlement: Computed shear stresses for 2005 (left) and 2020 (right) at km 5 +400 . Table 1. Summation of critical area for section “B” at two different specific times. Section B 2005 2020 [km 3 +300 - 5 +800] [m 2] [m 2] Scenario SHQ * 7961.4 13,534.2 HQ ** 100 53,751.3 76,157.1 * Q= 22.35 m 3 /s, summer flood (approximately 5 times a year). ** Q= 111.00 m 3 /s.

3.3 Influence of ripples and dunes

The ripples on the flood plains are caused by the

construction method of the new riverbed. The ripples

result from the construction equipment which consists

of the typical machines in open pit mines, normally

used to remove the enormous quantities of earth. A

comparison of calculated shear stresses with and with

out ripples should help to decide, whether the ripples

should better be removed or not. Figure 4 shows the

shear stresses at the same Inde km 1 +750 for both cases.

Figure 5 andTable 2 clearly illustrate the great influ

ence of the ripples at the flood plains. Although water

depth becomes smaller and velocities are computed

bigger for the case without ripples, the calculated shear

stresses are in general of higher values. The influ

ence of the strong roughness dominates.After virtually

removing any ripples, the summated critical area is

diminished to 29.8% for the HQ 100 (111.00 m 3 /s) case

and 70.9% for the SHQ (22.35 m 3 /s) case.

3.4 Influence of vegetation

The vegetation coverage on the flood plains is central

to avoid depth erosion. Thus, when the relocation of

the Inde was planned in the early 1990s and first exper

iments were carried out, it was assumed that the flood

plains are covered with a dense layer of vegetation by

100% after a very short period of time. This predic

tion was wrong.The used material is a side product and

was located at a depth of approximately 200 m below

Figure 5. Influence of the ripples: computed shear stresses

for removed ripple roughness (left) and with ripples at the

flood plains (right) at km 1 +750 .

Table 2. Summation of critical area for section “A” for the

scenarios with and without ripples.

Section B With ripples Without ripples

[km 3 +300 - 5 +800] [m 2] [m 2]

Scenario SHQ 30,639.2 8924.5 HQ 100 99,258.3 69,705.4 the surface. Therefore the percentage of nutrient substances is very little and flora needs more time to grow than usual. That’s why it is of great interest to predict the degree of fractional ground cover which is needed to bisect the total area with supercritical shear stresses. In Figure 6 the critical area A Ero is plotted against the degree of fractional ground cover V and the critical shear stress τ c respectively. The vertical line at V = 10% (τ c = 11 N/m 2) denotes the present state. When the plants grow, the figure yields clearly that the critical area becomes smaller. The point when the area is bisected differs for every case. But in general a critical shear stress about 20.0 [N/m 2] and a degree of ground cover about V = 28% is sufficient to reduce the endangered area by 50%.Anyway, this is the total critical area which is endangered that depth erosion can occur. But because erosion and sedimentation are conditional to the derivative in x of the transport capacity and the shear stress (see Equation 11) respectively, both only occurs when the shear stress values change rapidly. 3.5 Depth erosion Figure 7 shows, that the initial depth erosion velocities are varying between 0 and

2.0 [cm/min]. Typical floods at the river Inde last between one and four days, but the duration of discharges above 25 [m 3 /s] is less than half a day. Extrapolating an initial velocity of 0.1 [cm/min] results to depth erosion about 0.77 [m] in 12 hours. The alteration of the riverbeds bottom due to erosion has effects on the hydromechanics and therefore on depth erosion velocity, too. But nevertheless for flood protection reasons higher velocities should not be permitted during a flood event. Thus, even when the growth of vegetation helps keeping the Figure 6. Influence of the degree of fractional ground cover to the total area with supercritical shear stresses.

total endangered area small, some cross sections need

to be stabilized to increase τ c .

Conventional stabilization methods (e.g. bed cov

ering layers) as well as local widening of the riverbed

geometry as an alternative are suggested operations

to eliminate the risk at the identified points. For all

sections with velocities higher than 0.1 [cm/min] an

enhancement of vegetation is not sufficient, but is sug

gested as well, because it improves stability for the

whole reach of the new Inde. Thus, the new part of the

river still keeps its natural character, except for those

sections listed in Table 3.

4 CONCLUSIONS

This paper presents the results of numerical model

The complex flow in groyne fields: numerical modelling compared

with experiments

W.S.J. Uijttewaal

WL | Delft Hydraulics, Delft, The Netherlands

ABSTRACT: Groynes are effective as river training structures. At low water levels the main stream is confined,

keeping the navigation channel at a proper depth. The relatively high flow velocities at the tip of a groyne cause

strong separation effects with possible consequences for the stability of the bed.At higher water levels groynes are

submerged, providing more space for the river in lateral direction up to the river banks. In those circumstances

groynes also act as an extra flow resistance. In order to explore possible optimization of the effectiveness

of groynes at various stages the flow around different groyne types is investigated. Experiments are performed

concurrently with numerical simulations. It turns out that

the dynamics of the flow structures which are generated

downstream of the groyne have a big influence on the circulation dynamics in the groyne field.This paper focuses

on the large-scale flow structures in relation to flow separation. The large scale motion causes the instantaneous

flow fields to deviate strongly from the mean flow fields emphasizing their role in the momentum and mass

transfer from the main stream to the groyne fields. The importance of the large scale dynamics suggests that these

should be included in order to model the flow properly. To that end horizontal large eddy simulation (HLES) is

applied to the experimental cases. When compared with standard turbulence models like k-ε, HLES performs

much better in predicting the overall flow pattern including separation as well as the areas of high turbulence

intensities. However, the submerged cases with flow separation in the horizontal and in the vertical plane caused

bigger problems to be modeled accurately.Apparently, the stronger three-dimensionality requires a more detailed

analysis with a high vertical resolution. Apart from the conclusions regarding the numerical simulations of such

complex flows also conclusions regarding the optimal groyne shape could be drawn. The shape of the groyne tip

can be adapted such that the horizontal shear is minimized causing a weaker vortex shedding. This can be done

by decreasing the slope of the groyne tip in cross-stream direction or by making the groyne permeable.

1 INTRODUCTION

The large variability in river discharge and the expected

problems associated with climate changes, increases

the demand for a proper regulation of the water level

especially with respect to flooding at high stages and navigation in periods of drought. An effective way to fix and confine the flow in a narrow and deep part is by applying groynes. Groynes are usu ally constructed in the form of impermeable dikes perpendicular to the river bank. At normal discharges the flow is deflected from the erodible bank and con fined by a relatively narrow cross section resulting in high flow velocities. Such an arrangement allows for the formation of a channel with the proper navigable depth even at low discharges. At high discharges the groynes are submerged and the lateral confinement is governed by the dikes which are generally located on the flood plane, sufficiently far away from the river axis.The shape and the arrangement of groynes as they are frequently found in North-Western Europe is the result of decades of what could be called evolutionary design. Given the available construction materials the design has been adapted to the predominant flow conditions United Nations (1953). With the changing climate and the changing viewpoints with respect to the environment and the increasing importance of the ecology a reconsideration of the current river environment appears appropriate. Considerations in this respect are: • Increasing the discharge at high stages. • Keeping the navigation channel at proper depth. • Increasing the biodiversity.

In order to explore the possible improvements that can be made to the river, it is necessary to have the dis posal of a realistic and accurate way of modeling the flow. Naturally the flow is not the only important prop erty, but a proper insight in the flow is a prerequisite for the forecasting of e.g. sediment transport and eco

logical developments, Przedwojski (1995), van Mazijk (2002), Arlinghaus et al. (2002).

Unfortunately it is not always possible to perform a full scale analysis in comparing field measurements with numerical simulations. The intermediate step of a physical scale model is therefore an approved way to validate the proper representation of the physical processes as implemented in the numerical model.

For the purpose of investigating new groyne designs as well as determining the suitability of numerical sim ulation techniques, a number of experiments has been performed and compared with numerical simulations Uijttewaal (2004). The complexity of the flow in a groyne field provides a test case with respect to many properties. For the groyne designs used in this study the relevant properties are:

- Flow separation in the horizontal and vertical plane, at a sharp edge as well as a straight smooth wall.
- Large vortex structures and gyres.
- Flow through a permeable obstacle.
- Inhomogeneous distribution of turbulent kinetic energy and shear stresses.

A satisfactory representation of these properties will be a hard requirement for a numerical model. Once the reliability of the numerical simulation is estab

lished, it can straightforwardly be used for a number of other applications.

2 PROBLEM DESCRIPTION

Accurately modeling the complex flow in groyne fields requires a proper representation of the relevant physical processes in both the physical and the numerical model. Especially in a flow dominated by separation and vortex shedding, the turbulence and its dynamics are considered as very important.

Until now little systematic research has been performed on the effects of the groyne shape on the flow field and its dynamics. The possible advantages of a new groyne design should be known in advance in order to justify modifications to be made on the prototype scale. With the present knowledge and means it is hardly possible to make reliable predictions and to explore new groyne designs.

3 AIMS

In this study we would like to find out what modifications in the groyne design can lead to a more smooth and quiet flow field. This to provide the means to manipulate the flow and to prevent scour. With respect to the numerical modeling it is important to know how well the present models perform. In view of new developments with respect to Horizontal Large Eddy Simulation (HLES) it is especially important to explore the possibilities of this promising technique in civil engineering applications. An important aspect in this respect is the implementation of the relevant geometrical details determining the properties of the groyne. Given the large scale applications and high

Reynolds numbers encountered in practice, performing a full three dimensional LES with sufficient resolution to justify a standard sub-grid model appears unlikely for the coming decades. We therefore have to deal with numerical models with a limited resolution and some remaining degrees of freedom, like the implementation of sub-grid phenomena and boundary conditions and the grid dimension in the vertical direction. 4 APPROACH Four different groyne designs were tested in laboratory experiments on a schematized and scaled physical model. For a few cases the observed mean flow field and turbulence properties were compared with the results obtained from a numerical model. 4.1 Experiments In order to test the groynes and validate the numerical model, a number of flow conditions and geometries were implemented. These cases were also used in an earlier study on groyne optimization (Uijttewaal et al. 2002, Uijttewaal 2004). In a physical model scaled 1:40 with respect to a prototype river reach, a schematized bathymetry was realized consisting of an array of groynes situated on a shallow part near the bank. Since the simulated river width was much larger than the range influenced by the groynes it appeared sufficient to mimic only one half of the river. A top view of the flow facility is sketched in figure 1. Five groyne fields were built in a flume 30 m long and 5 m wide. The bed of the main channel was 8 cm lower than at the transition to the groyne fields. The level rises towards the bank to an elevation of 15 cm. With a water level of 25 cm in the main channel, the most shallow part in the groyne field was 10 cm deep and the groynes are just emerged. For the submerged cases presented here a water level of 30 cm was used, providing a 5 cm thick water layer flowing over the groyne crest. With a mean velocity of 0.35 m/s in the main channel and an estimated velocity of approximately 0.1 m/s in the groyne fields, the Main stream (0.35 m/s) 3 m 2 m g r o y n e 5 th groyne field 4.5 m 30 m 4 th groyne field PTV-area g r o y n e x y Mixing layer Sec. gyre Prim. gyre 3 rd groyne field

the main flow features.

Figure 2. Cross-sectional views of the four groyne types as

used in the experiments.

flow can be considered as fully turbulent everywhere

in the domain.

The various types of groynes that were tested were designed with respect to minimization of the shear induced vortex formation downstream of the groyne tip. Four different groynes are depicted in figure 2. Type A is considered to be the reference case and rep resents the design as it is found in many rivers with a slope of the groyne tip of 1:3. With type B the slope at the groyne tip has been adjusted to make it more gen tle (1:6) in order to broaden and weaken the mixing layer thereby reducing the formation of large vortex structures. Another way to achieve this is by mak ing the groyne permeable. Type C consists of a pile sheet made of square rods with sides of 1 cm spaced such that in the near bank area the blocking fraction is 50% and 40% near the main channel. Combining the possible advantages of type B and C results in a hybrid groyne D which is partly permeable. An extensive measurement programme has been performed in order to test the design with respect to the required flow properties (Uijttewaal et al. 2002). Measurement techniques used to comprise particle tracking velocimetry (PTV) and laser Doppler anemometry (LDA). The focus is on the area around and downstream of the groyne tip, the location containing the largest shear and highest turbulence intensity. This area is indicated by gray squares in figure 1 and covers 1.5 m by 1.5 m. Floating particles of 3 mm diameter were distributed homogeneously over the domain and recorded with a 1kx1k digital camera at 30 Hz during 5 minutes. Adjacent areas were recorded in separate experiments. The small differences in camera calibration and orientation, in experimental conditions and lens distortion, impeded a seamless connection between the different areas. The observed errors are however sufficiently small to allow conclusions in the comparison with the numerical model. 4.2 Numerical model Given the complexity and the dimensions of the domains that have to be dealt with when used for fullscale applications, a two-dimensional depth averaged

description of the flow is the starting point. The results of the simulations should therefore be seen as a test as to what extent the efficient depth average modeling is suitable for our applications. It will be clear in advance that strongly three-dimensional features as occurring with submerged groynes are not likely to be fully covered by the model. The numerical hydrodynamic modelling system Delft3D-FLOW approximates the non-linear shallow water equations in two or three dimensions. These equations are derived from the fully three dimensional Navier Stokes equations for incompressible free surface flow, assuming hydrostatic pressure. The contribution of 3D turbulent eddies to the vertical exchange of horizontal momentum and mass is usually modelled through a vertical eddy viscosity computed by means of a k-ε turbulence model. Present questions in river engineering, however, require a more detailed description that resolves the dynamics of the flow, covering a range of turbulence scales, that reaches from the small scale 3D turbulence, through quasi-2D turbulence up to the largest geometry scale. A proper description of quasi-2D turbulence is especially important when dealing with flow dynamics in groyne fields. The classical approach would be to follow the concepts of unsteady Reynolds-averaged Navier-Stokes as mentioned above and accordingly design a closure for quasi-2D turbulence. Previous work however has shown the disadvantages of such

an approach (Nassiri et al. 1999, Bijvelds et al. 1999).

We therefore prefer to simulate the quasi-2D turbu

lence and still model the 3D turbulence with the well

known closures.To this end we have applied the depth

averaged option of Delft3D-FLOW in combination

with horizontal large eddy simulation, further referred

to as HLES. This concept will be used to describe the

important dynamical variations of the flow which are

necessary to obtain a better understanding of com

plex processes such as erosion and sedimentation in

a groyne field and around a groyne tip.

A particular type of turbulence closure is required

for representing the action of the unresolved part of quasi-2D turbulence. The latter turbulence closure is called subgrid-scale (SGS) model as it depends on low pass filtering of the spatially varying flow field by the choice of the mesh size. The sub-grid scale model as applied in this study has been described extensively in Uittenbogaard & vanVossen (2003). In brief the SGS eddy viscosity accounts for the direct energy loss by bed friction. Rather than spatial filtering, a simple temporal recursive high-pass filter is applied on the resolved velocity field. This filter removes the slow or steady large-scale contributions to the strain rates that enter the sub-grid model. It has been successfully tested in shallow and stratified flows.

To be able to compare the measurements in the phys ical model directly with the simulations, the numerical model was applied to the same geometry. The mesh size Δx of the model sets limits to the scales that can be resolved, typically of the order of 6Δx. The important energy containing horizontal eddies should typically be larger than this size. Further restrictions are imposed by the geometry of the groynes that can be represented and the details of the flow pattern around them. It is important in this respect to avoid influences of the grid implementation on the separation of the

flow at the head of the groyne. An advantage of the geometries as used here is that flow separation occurs at the relatively sharp groyne tip. Because of the com bination of a straight flume with groynes perpendicular to the flow a curvilinear grid does not have an added value.A choice is made for a very fine rectangular grid with a typical mesh size of 5-10 cm, being of the order of the water depth, and yielding about 68,000 active horizontal grid points. In the depth averaged case we have obviously used only one layer.

At the upstream boundary we defined a Riemann boundary with the velocity of the main channel (0.35 m/s) and the downstream boundary condition is formed by a constant water level corresponding to the water level in the scale model. The roughness of the main channel and the groynes is characterised by a Nikuradse roughness k nikuradse = 0.6 mm, and is based on measurements in the main channel in the scale model. Friction caused by the side walls in the groyne field was accounted for. Because of the fine grid it was possible to include the shape of the groynes of type A and B in the bathymetry. In the emerged situation we placed socalled ‘thin dams’ at the crest to prevent numerical disturbances caused by overtopping of the groynes. To be able to simulate the dynamics in the case of permeable groynes of type C and D we prefer to model them as dry points in the numerical grid, but this is only possible if the groynes are not submerged. In case of submerged permeable groynes an additional roughness value needs to be defined to account for the effect of the groynes. 5 RESULTS

In this section the velocities as measured at the freesurface with the PTV-method are compared with the depth-averaged results of the numerical simulations. Although the flows can be considered as shallow different results are expected due to this method of comparison. It will however be clear that the gross features of the flow should be similar. As a starting point the standard groyne, type A, is considered in non-submerged conditions. For that case the groyne field can be considered as a shallow cavity where the flow separates at the upstream groyne tip as sketched in figure 1. The mixing layer that develops between the main stream and the groyne field plays a role in the momentum transfer to the groyne field circulation. For the chosen width to length ratio of the groyne field a circulation pattern is expected consisting of two counter-rotating gyres which causes a second separation point along the straight side wall. These characteristics are well reflected in the results shown in figure 3, which shows the magnitude of the flow velocities in an area that ranges in streamwise direction from 0.5 m upstream of the groyne to 4 m downstream and in y direction from the bank (y= 5 m) into the main stream. In the lower part of the graph the main stream direction is from left to right as indicated by the arrow. The agreement between the numerical and experimental data is good. The same holds for the characteristic enhanced turbulence intensity as found in the mixing layer downstream of the separation point and around the stagnation point at the upstream side of the groyne. In the numerical simulation the mixing layer turbulence is more pronounced while the fluctuations in the upstream part of the groyne are underestimated. Despite this mismatch, the large scale motion appears sufficiently two-dimensional to be represented by a depth averaged model. As soon as three-dimensional effects start to play a significant role the discrepancies between the experiments and the depth averaged model increase. slope 1:6) typically contains strong vertical veloc

ity components. In both the mean flow pattern and

the turbulence intensities clear differences are found.

Comparing figure 4-left with 4-right, the flow pat

tern around x= 0 m is symmetric. The flow over the

groyne tip is asymmetrical in the experiment because

of the flow separation in the vertical plane. The sep

aration downstream of the groyne tip gives also rise to an enhanced production of turbulent kinetic energy in this area which can obviously not be reproduced by the numerical model (not shown). Similar effects are found with the submerged case of groyneA, figure 5.The flow over the groyne crest gives rise to separation in the vertical plane with clear consequences for the effective resistance of the obstacle. Important differences between the experiment and the

simulations are therefore found in the mean velocities over the groyne which are generally overestimated by the numerical model (see figure 5-top and 5-bottom left), in the asymmetry in the flow pattern upstream and downstream of the groyne and in the production of turbulent kinetic energy which is clearly under estimated. A clear improvement is obtained with a 3D-approach of 20 layers (figure 5-right). The asym metry in the flow over the groyne is clearly reproduced and the maximum velocity is significantly reduced. Such computation are rather expensive and not fea sible for general applications. An even more realistic solution is expected from the use of a non-hydrostatic model. Further complications appear when the groyne is made permeable as in the cases of types C and D. The amount of water that flows through the groyne field is determined by the effective resistance of the pile sheet. It is however far from trivial to implement the effective properties in a realistic manner, since the resolution does not allow the simulation of all flow details around the piles. A few tests have been made on the configuration of the partially permeable groyne D, for which the experimental results are depicted in figure 7-left. The gradual increase of the area blocked by the groyne going from the channel towards the bank, combined with the permeable part on top gives also rise to a smooth velocity profile.The mixing layer extends

over more than 1 m, resulting in a horizontal velocity gradient half of that with groyne A. Still the velocity near the bank (y> 3.5 m) is small with a small recirculation zone in the downstream part of the groyne field. The obstruction by impermeable part and the turbulence production by the flow through the groyne give rise to these low velocities, in combination with a relatively high turbulence level downstream of the groyne. The simplest implementation of this flow impediment, is an additional surface roughness on top of the nonpermeable part of the groyne. In figure 6-left it is clearly seen that this leads to an unrealistic solution. The roughness hardly affects the flow and the major effects are caused by the bathymetry around the impermeable base of groyne D. The alternative implementation of the permeable part of the groyne in the form of dry points is an improvement but there still is a significant discrepancy with the experiments. Blocking the flow through the groyne has a clear effect on the flow through the groyne field and the formation of a mixing layer at the interface with the main stream. A combination of both the increased roughness and the dry points leads to a more satisfactory solution, figure 7-right. Clearly the resistance of the groyne and the disturbances generated by the piles are both necessary ingredients that govern the flow field. The comparisons with the experiments of figure 7-left show that not only the pattern of the mean velocity is similar in shape and amplitude, but also the distribution of the turbulence intensities. The most important difference is found just downstream of the grid. The extra turbulence produced by the flow through the goynes is not well represented by the model, partly due to insufficient resolution. 6 CONCLUSION This study shows that the different groyne designs used, give rise to a variety of flow phenomena where flow separation and turbulence production are important. main stream drives a circulation in the groyne field.

The horizontal velocity gradient in this area gives

rise to the enhanced production of turbulent kinetic

energy. The strength of the velocity gradient depends

on the velocity inside the groyne field and the shape

of the groyne tip. By adapting the shape of the groyne,

the turbulence properties in the mixing layer can

be manipulated. Making the groyne permeable sup

presses the recirculation and weakens the shear in the mixing layer. At high water stages the flow over the submerged groynes separates downstream of the groyne crest resulting in an increased flow resistance and small velocities in the groyne field. Knowledge with respect to the relationship between the geometrical properties of the groyne and the hydrodynamical consequences provides us with clues for e.g. optimising the conditions for a certain envisaged habitat for biological species; high versus low exchange rates

with the main stream, high versus low velocities and

turbulence intensities etc. The different turbulence

production mechanisms associated with the horizontal

and vertical flow separation as well as the wall and bot

tom boundary makes a numerical simulation of such

flows troublesome. It is clear that we have tested the

numerical model against a number of cases, which are

known beforehand to cause difficulties. Especially the

submerged case containing typical three-dimensional

effects is not very likely to be properly represented by a

depth averaged model. Also the permeable and hybrid

groynes are problematic when the resolution does not

allow for resolving the flow in the wake of the rods and

in between the rods. Nevertheless, the important phe

nomena of the complex flow in groyne fields could be

reasonably well simulated after sufficient adaptation

of the simulation configuration and boundary condi

tions. Obviously, it is preferred to have a model that

does not need tuning of certain boundary conditions

or an unrealistic implementation of an obstacle in the

form of roughness elements.

This study has however helped us in finding the

important aspects that have to be taken into account

when modelling complex flows as found in groyne

fields. It is expected that with this knowledge fur

ther improvements to our modelling approach can

be made, leading to a simulation tool that is of

help for a detailed optimisation of the hydrodynamics

in groyne fields and its consequences for morphol

ogy and ecology. Important properties in this respect

are: exchange between main stream an groyne field,

velocity magnitude, turbulence intensities, local bed

shear stresses, etc.

ABSTRACT: Groynes are widely used in the Netherlands,
mainly to promote or maintain nautical depth and

a stable main channel. Most of them have been designed and constructed more than a century ago. Since then

damage to the groyne head, settlement of the crest or outflanking of some groynes has occurred. A mathemat

ical model study, with a 1-dimensional morphodynamic model, has been carried out to examine the average

sedimentation that may be caused by damaged groynes. Based on the work presented in this paper, our under

standing of the rate of sedimentation, the effects on the flood water levels and the effects of groyne repair has

increased. A challenging outcome is that, although repair should be carried out for river stretches where nautical

depth is critical, in other stretches we may consider delaying repair to reduce flood levels. The paper ends with

suggestions for further research.

1 BACKGROUND

During the last 150 years, approximately 3600 groynes

have been constructed in the main Dutch rivers and

channels. Groynes in Dutch rivers have four functions:

- reducing the risk on the formation of ice dams;

- maintaining nautical depth for inland navigation;

- riverbed fixation;

- bank protection and land reclamation between

groynes.

The present design method of groynes is mainly

done using ‘rules of thumb’, some of them dating

from the 19th century and mainly based on trial and

error. Up to now groynes have fulfilled their functions

fairly well. However in recent years, extreme river

floods have raised the priority for flood protection measures including optimisation of groynes. These extreme floods caused us to regard groynes as obstructions which increase the extreme flood levels. Long term trends such as climate change, increase in size and engine power of inland navigation, as well as the increasing need for maintenance efficiency, compel us to reassess groyne design and groyne maintenance.

2 RESEARCH OBJECTIVES

In this research we seek to develop practical rules for the optimisation of groyne design and groyne maintenance. The most important function groynes have at present is to maintain nautical depth in the fairway. Therefore any changes in groynes might have effect on sedimentation, and as a consequence may bring about costly dredging.A second important aspect is that flood waves should pass the river smoothly with a minimum of resistance so as to avoid flooding. This means that the flow channel should preferably have as few obstacles as possible. Obviously these are two conflicting aspects. From the point of view of flood management, there is a tendency to lower existing groynes. However, this leads to sedimentation of the navigation channel which is undesirable from nautical point of view. By experimenting with different groyne designs we seek to provide the best design for these two main functions. Another approach is to focus on groyne maintenance. Groynes may sometimes have deteriorated in height, the groyne head may have steepened or the attachment of the groyne with the floodplain may be lost (outflanking by which a bypass channel may develop). An example of the ouflanking is shown in Photograph 1. The attendant reduction of flow obstruction is favourable for flood wave passage. However, as a secondary effect the reduced obstruction will cause sedimentation of the main channel, which in turn affects the nautical depth. The question rises which of the two effects is most dominant. The present paper will address this question and will deal with the pre

diction of the potential sedimentation for the damage types mentioned before.

3 RESEARCH METHOD

3.1 Typical sedimentation and erosion pattern

The bed pattern near groynes is strongly 3 dimensional, as illustrated in Figure 1 in which multi beam measurements are depicted for a characteristic section of the Waal river in the Netherlands. The com plex bed pattern is due to the complicated flow pattern near the groynes and in between the groyne fields. A precise method for prediction of these patterns of erosion and sedimentation is not available up to now. However, damaged groynes will cause an overall sedi mentation in the main channel in between the groynes on both sides of the fairway.With a 1-dimensional mor phodynamic model such an overall sedimentation can

Photograph 1. Outflanked groyne in the Waal river.

Figure 1. Multibeam measurements of bathymetry near

groynes. be computed rather well. In such a model the sedimentation width can be specified, as well as the pattern of sedimentation, i.e. evenly distributed over the width or linearly with the depth, the latter being the default situation. 3.2 Mathematical model A 1-dimensional morphodynamic model, based on the SOBEK program package, was used in the present study. To this, a 90 km stretch of the Waal river was schematised, taking one characteristic cross-section, including a main channel section, a groyne section and a floodplain section, see Figure 2. The hydraulic performance of the model was calibrated and validated against measurements at different flow rates. A morphologic validation was beyond the scope of the present

investigation. Rather, tests have been performed to check the effect of grid spacing, the required time to arrive at a morphological stable bed, the influence of the time-step and the influence of numerical parameters. The sediment influx to give a stable bed condition in the reference situation (with no damaged groynes) was determined by trial and error. The sediment influx was set at values of 0.021 m 3 /s and 0.0312 m 3 /s for Q 50 (50% exceedence discharge= 1467 m 3 /s) and Q 90 (10% exceedence discharge= 2400 m 3 /s) respectively. These were the two steady-state discharges with which the model was operated. Furthermore a schematised flood wave was applied, starting with a steady-state flow rate of 2000 m 3 /s (corresponding to Q 60) and a subsequent flood wave with a peak discharge of 3000 m 3 /s (corresponding to Q 95); after the flood wave the Q 60 was maintained for 10 years. 3.3 Damage situations applied to the model In this model three types of groyne damage have been modelled with two damage intensities: - groyne head steepening: the standard slope is 1:3.5 (vertical to horizontal). Damaged slopes were 1:2 and 1:1; Figure 2. Characteristic cross-section (vertical scale strongly exaggerated).

- groyne height decrease: a decrease of 0.1 m and of

0.2 m was applied;

- groyne outflanking: a shortening of the groyne of

some 15 m and 30 m has been applied.

Each damage pattern was introduced in the model

as a corresponding increase in flow area of the main

channel at the cost of the flow blocking area of the

groyne section.

The simulations have been done with one, four and

eight successively damaged groynes. It was assumed

that the groynes opposite the main channel were dam

aged as well in the same manner. In total 48 model runs

have been made, combining the aforementioned flow

rates, types of damage and number of groynes. In each

of these cases groyne damage resulted in sedimenta
tion in the cross-sections with the damaged groynes.
Just downstream of it, a scour hole develops which
gradually extends downstream in time.
Another effect of groyne damage is the water level
reduction near the damaged groynes. This reduction
extends upstream as a backwater curve. This effect
is favourable for extreme flood levels. However, as a
secondary effect sedimentation will occur which will
decrease river depth and will negatively affect flood
level reduction. Simulations are required to indicate
the net effect.

3.4 Repaired damage

Once damaged groynes are being repaired, related sed
imentation migrates as a shoal downstream. At down
stream locations the temporary sedimentation will be
accompanied by a slight increase in water level. For
the repaired groynes, the water levels will increase
substantially and will attain the original equilibrium
levels.

4 RESULTS

4.1 Sedimentation rates

The simulations yielded equilibrium sedimentation
rates as shown in Table 1.
These results have been obtained for a permanent

discharge of Q 90 and are independent of the number

Table 1. Review of equilibrium sedimentation rates.
Sedimentation

Damage type Intensity (m× 10 −2)

Head slope steeepening 1:2 6 1:1 10

Crest height −0.1 m 4 −0.2 m 7

Outflanking ≈15 m 14 ≈30 m 27 of subsequently affected groynes. The sedimentation area, obviously, is directly related to the damaged groyne fields and extends from the downstream affected groyne to the upstream one. The results show that for the damage types under consideration considerable sedimentation may occur. Especially outflanking causes serious sedimentation, but the consequences of the other damage types cannot be ignored either. In case of an unfavourable combination of damages and discharges, sedimentation might reach up to about 0.5 m. It should be remarked that the flow rate influences the sedimentation. The equilibrium sedimentation for Q 90 is 2 to 4 times as large as for Q 50 . Sedimentation for the schematized flood wave was in between the results for the permanent Q 90 and Q 50 discharges. We consider the outcome for the Q 90 discharge as most realistic, albeit possibly somewhat conservative. Further analysis showed that the sedimentation rates can be expressed very well in terms of an increase in cross-sectional flow profile. The computed sedimentation show a nearly linear increase with the increase in flow profile (see Figure 3). In Figure 3 the dependency on the flow rate is also clearly visible. It should be remarked that groyne height reduction is not relevant for the Q 50 flow condition, as the water level does not exceed the crest of the groynes in that situation. The results show that for damage intensities other than have been considered here, a good prediction can be made based on linear interpolation. 4.2 Development of sedimentation The development of the sedimentation pattern, upon the occurrence of damage, is important as it may take a considerable time to reach equilibrium. The simulations, basically carried out for steady-state conditions (with Q 50 and Q 90) give no definite answer to this. Reaching equilibrium for the Q 90 discharge took less Figure 3. Sedimentation against flow area increase.

Figure 4. Illustrative example of sedimentation

development.

than 1.3 years in the model.Taking into account the rel

atively high discharge of Q 90 , the true time for reaching

equilibrium in the Waal river will be in the order

of magnitude of maximum 10 years. Consequently,

sedimentation is likely to occur within a relatively

short time. An illustration of the timely development

of the sedimentation and the temporary scour hole

downstream is shown in Figure 4.

4.3 Sediment migration after repair

The sand wave that migrates downstream after repair

of the groyne(s) has been simulated in the model for

the permanent Q 90 discharge.Together with the migra

tion of the sand wave, the scour hole migrates farther

downstream, starting from the downstream end of the

damaged groyne field. The travel time of the sediment

wave was found to be about 3.5 years over a distance of

5 km. Measurements of sand wave propagation in the

Waal river show travel speeds which are in the same

order of magnitude.

Both types of waves show a clear decrease of inten

sity during downstream migration, as can be seen in

Figure 5. After migration over 5 km, the height of the

sand wave reduces to half the original value.

4.4 Consequences for flood levels

The increased flow area after groyne damage, as well as the incidental sedimentation pattern, affects the flood levels.

Groyne damage results in an increase of flow area which causes the flood level to decrease. The sedimentation however, increases the flood levels. This effect is however smaller than the flood level decrease. The implications on the flood levels have been checked for the most serious damage, i.e. for the case of outflanking by some 30 m. In the equilibrium situation Figure 5. Typical decrease of sedimentation and scouring during downstream migration, after groyne repair. the net effect on the flood levels is some -5 mm for the arrangement with 4 damaged groynes. This flood level reduction tends to increase for a larger number of damaged groynes. For the Waal river this reduction is of significance, as regards the costs involved to arrive at such a reduction by measures in the floodplain. 5 CONCLUSIONS The sensitivity analysis with a 1-dimensional morphodynamic model yielded practical results as regards the effects on sedimentation and flood water levels after the occurrence of groyne damage. Three types of groyne damage have been considered: steepening of the groyne head, reduction of groyne height and outflanking of the groyne. Major conclusions are summarized as follows. 1. Groyne damage results in significant local sedimentation and lower flood water levels. The sedimentation ranges from some centimeters to some decimeters, depending on the type of damage. Hence, a combination of damages may potentially cause up to 0.5 m sedimentation as an average in the stretch with damaged groynes. 2. The sedimentation may require additional dredging to maintain nautical depth. 3. After repair, the sediment that accumulated during the period that the damage exists, migrates downstream as a shoal over some 10 tot 20 km and gradually reduces in height. 4. The flood level reduction may increase to about 1 centimeter for an arrangement of more than 4 groynes (in the case of major outflanking). For less intensive damage it may be in the order of magnitude of millimeters. 5. The findings lead to a challenging concept for groyne maintenance: take action for repair at river

stretches where the nautical depth is critical and consider delay of repair at the remaining river stretches. The objective of the latter is to reduce flood levels. This can be a realistic option when the damage is not progressive, as can be expected for head slope damage and groyne settlement with the protective layers still intact.

6. The dependency of sedimentation and flow rate stresses the need to apply realistic discharge scenarios to the model for proper predictions to be used in a strategy for optimized maintenance of groynes.

6 FUTURE WORK

Study on groyne design for the Dutch rivers will continue. The following studies are foreseen:

- A case study on a characteristic groyne damage event in the Waal river, to analyse the effects of the maintenance strategy applied in the past and to verify the bed level changes with the predictions from the present model. When positive, this case can be extended to a major part of the Waal river and a longer maintenance period. - Verification of the present 1-dimensional morphodynamic model with a 2-dimensional (depthaveraged) morphodynamic model. - Identification of potential hazardous sedimentation events, i.e. by combining unfavourable flow events and accumulated groyne damage. - Development of an optimised maintenance strategy for the Waal river based on actual groyne conditions and realistic discharge scenarios. Herein also the effect of vegetation growth on the groynes has to be considered, as well as the

present maintenance strategy of cutting willow trees at the groynes after some 5 years. At river stretches with critical navigation depths, the repair costs of the groynes can be balanced against the costs of maintenance dredging. Alternatively, the latter may possibly be skipped at the cost of reduced ship freight. - Implementation of field tests of innovative concepts of groynes, e.g. with an adjustable crest, in a pilot stretch of the Waal river. - Extension of the above for other major rivers in the Netherlands. The environmental impact of dams and weirs: technical issues related

to the minimum vital flow release

C. Comoglio

Dipartimento di Georisorse e Territorio, Politecnico di Torino, Torino, Italy

ABSTRACT: The awareness about impacts on fluvial ecosystems caused by dams and weirs has recently

increased in the Italian regulatory framework and the release of the minimum vital flow is now going to be

introduced as compulsory for all the new projects and existing sites.

In this paper are identified and discussed the main technical issues that this new legal requirement will

determine (technical adjustments in old structures, discharges monitoring and modulated release, flow availability

in downstream reaches, release through fish passes, environmental monitoring programme, etc.) and that should

be managed through appropriate institutional guidelines and adequately analysed and solved for each site in

order to effectively pursue the quantitative and qualitative safeguard of water resources.

1 INTRODUCTION

The use of river water for electricity production, irriga
tion and other purposes can influence the rivers hydro
logical balance and cause significant environmental
impacts involving directly and indirectly many com
ponents of the fluvial ecosystems. Generally the more
relevant impacts take place in the downstream reaches
because of the alterations of the river hydraulics due
to the withdrawal of significant discharges. In partic
ular the reduction (or in many cases the absence) of
the discharge in the downstream river sections and,
consequently, the alteration of the hydraulic param
eters (water level, stream velocity, flow area and
wetted perimeter), can alter the water quality and cause
significant impacts upon the river biocoenoses.

The release of a limited water discharge from
dams and weirs in the downstream river reaches, the
so-called minimum vital flow (or instream flow or
environmental flow) is the main and essential miti
gation measure that can be adopted in order to reduce
the environmental impacts and safeguard the involved
ecosystems.

The concept of minimum vital flow (MVF) appeared
for the first time in the Italian regulatory framework in
1989 with the article 3 of the National Law 183/1989:

it stated that a rational use of water resources at

watershed level must guarantee a minimum constant

vital flow in downstream reaches despite the existing

system of water abstraction.

Afterwards, the article 5 of the Decree 275/1993

stated that the release of the minimum constant vital flow must be considered in the water abstraction licences, taking into account the requirements of river water quality and seasonal balance safeguard and the opportunities of saving, reusing and recycling this natural resource. The Law 36/1994 introduced new elements which developed the definition of the concept of MVF towards ecological criteria: sites with significant withdrawals must be regulated in order to guarantee the flow required for the life in the downstream reaches and to safeguard the involved ecosystems balance. This regulatory scenario and the absence of explicit criteria for the minimum vital flow calculation led different authorities (mainly the Regions of Northern Italy) to the definition of own local technical rules aimed at quantifying the discharge to be released downstream the abstraction sites, mainly based on hydrological criteria. An interesting definition of the minimum vital flow was given by Regione Piemonte in 1995: it is the flow which, inside a watercourse, has to be released in order to keep vital at any time the efficiency and quality conditions of the concerned ecosystems. The new legal requirement became compulsory for new projects and on the occasion of the renewal of the water abstraction licence of existing sites. Afterwards, in 1999, two regulations introduced new elements for a uniform and systematic application of this release requirement, realigning the wide variety of local initiatives. With the article 12 of the Decree 79/1999 the release of the minimum constant vital flow in downstream reaches for new water abstraction sites (only for hydroelectric use with a mean annual

nominal power higher than 3.000 kW) became com

pulsory and a necessary element to be specified in the

water abstraction licences.

The Decree 152/1999 introduced a new approach in

the water resources safeguard, previously associated only to pollution problems, stating that the qualitative and quantitative aspects must be managed in an integrated way at hydrographic basin level, fixing specific targets of environmental quality for each significant watercourse. The minimum vital flow must be a fundamental element of the future Plans of watershed safeguard and must be taken into account while defining the measures aimed at ensuring the water balance of each basin. Furthermore all the existing sites must be regulated in order to release a discharge calculated using national guidelines.

While the above mentioned guidelines have not been yet defined (making formally inapplicable the legal requirement) and the local technical rules are still in force, recent initiatives are being developed by the Watershed Authorities (institutions composed of State and Regions to manage the watersheds of national importance). In particular the River Po Watershed Authority (widest italian hydrographical basin with a surface of 71.057 km 2) defined, with the Decision 7/2002, new criteria that will have to be applied to the whole territory.The minimum vital flow is made up of an hydrological component and an environmental component:

where k = experimental hydrological parameter defined for each watershed; q MEDA = average annual specific natural discharge [l/s · km 2]; and S = basin surface [km 2]. The criteria for the calculation of the environmental component MVF env and its range of application shall be defined by each Region inside every Plan of watershed safeguard taking into account the watercourse morphology, the interaction with groundwater, the anthropic pressures upon water qual ity, the presence of naturalistic, touristic or social interests. All the new projects shall comply with the previous release requirements, while for the existing sites two relevant deadlines have been fixed: all sites must respect the release of the hydrological component by the end of year 2008 and the release of the environ mental component, where defined, by the end of 2016. While the regulatory framework is developing towards the gradual application of the minimum vital flow release to the whole territory, the number of existing dams and weirs currently subject to this requirement is still not relevant: in Regione Piemonte, which has been one of the first local authorities to face the problem and to define specific rules, less than 13% of the total number of existing sites is releasing a compulsory flow. 2 TECHNICAL ISSUES RELATED TO THE MINIMUM VITAL FLOW RELEASE Especially in the environmental

field the attempt to fix univocal criteria and rules often conflicts to the wide variety of different situations and problems which can occurr in reality. This remark applies also to the definition of the criteria for the minimum vital flow calculation, where, even despite accurate hydrological and environmental models, the real availability of natural discharges and the sensitivity of the involved fluvial ecosystems can significantly vary along the same watercourse. Therefore, the hydrological and environmental criteria for the MVF calculation should be adequately adapted and calibrated on every site. In this way, through a detailed analysis of the natural peculiarities of the site and the definition of an adequate monitoring system, the value obtained applying the criteria fixed by law can be assessed in terms of efficiency in guaranteeing and safeguarding the fluvial ecosystems. Despite its usefulness in terms of environmental safeguard, this approach is costly and would be unlikely accepted by the owners of the sites unless imposed by law, especially considering that it can lead to an increase of the discharges that should be released and, consequently, to a further reduction of productivity and proceeds. A preliminary analysis of the environmental scenario and an assessment of the environmental impacts of a dam or a weir is required as compulsory only during the authorization phase for new projects, according to national and regional laws concerning the environmental impact assessment (EIA) procedures, and, in some cases, for the renewal of expired concessions. The environmental impact study (EIS) targets are the evaluation of the most probable environmental impacts caused by the project and the definition of appropriate mitigation measures and monitoring systems to be implemented after the site construction. Within the authorisation phase some efforts should be usefully made by the competent authorities in order to address the scope of the EIS also towards the prediction of the real environmental effectiveness of the value of MVF obtained through the mere application of the criteria defined by the current regulations: in this way regional or national guidelines could better define the contents of the EIS and the analysis to be developed for new projects of dams and weirs. Finally, when the criteria for MVF calculation will be defined by law and applied to the whole territory, two main key-issues will have to be faced: the technical adjustments to be implemented in existing sites (especially in old structures) and, in every site, the evaluation of the calculated MVF capability to guarantee the efficiency and the quality of the involved ecosystems. For the second issue specific technical aspects

to be considered and solved for each site will be:

- discharge monitoring;
- flow availability in downstream reaches;
- modulation of the releases;
- release through fish passes;
- environmental monitoring programme.

While the provision for releasing the minimum vital flow can be quite easily managed during the project phase, before the infrastructure construction, the technical problems which have to be faced in adapting existing sites to the new legal requirement can be relevant and are mainly related to the typology of the considered structure (concrete dam, earth dam, movable weir with sluice-gates, fixed weir, temporary weir, etc.), to the local geomorphology, to the amount of water to be released and to the possible need to release the discharge through a fish pass. It has to be outlined that if the “natural” discharge coming from upstream is lower than the fixed value of MVF adequate devices and settings will have to be implemented in order to guarantee the downstream release of the whole flow.

In fact, in the regulatory framework the release of the minimum vital flow is considered a requirement to be respected at local level (in the section immediately downstream the dam/weir) and in every instant (if the

“natural” discharge coming from upstream is lower than the fixed value of minimum vital flow nothing will have to be withdrawn and all the flow will have to be released downstream).

All the previous elements contribute to the technical and economic feasibility of the structure adjustment and, together with the loss of productivity due to the MVF release, can determine a relevant economic effort by the sites managers. In order to achieve an homo geneous and efficient implementation on the whole territory appropriate technical guidelines should be defined by the competent authorities adressing the sites managers towards the best available technolo gies and the most suitable and economically viable solutions to be applied depending on the different typologies of water abstraction sites. In this way Regione Piemonte is now operating, with a specific research developed by Politecnico di Torino, through a preliminary review of the main characteristics of all the existing sites and inspections on representative cases and interviews and discussions with their managers: the results will be a technical guideline which will help the sites managers in complying with the new legal requirement.

While the obligation to measure the abstracted

discharges and the consequent periodical data trans

mission to the competent Authorities has recently

become compulsory for all sites, there is not a sim

ilar precise legal requirement to assess the compliance

to the MVF release, which, nevertheless, can be con

trolled by the competent Authorities through direct inspections in every moment, especially if anomalous flow conditions inside the watercourse are observed. In this scenario the site manager could usefully install adequate devices for the measurement and the recording of both the discharges (abstracted and MVF) and the consequent transmission of the recorded data, even in real time. In this case the previous continuous measures could adequately integrate the existing institutional monitoring network, providing new elements for the knowledge of the watershed hydraulic balance. The choice and installation of such devices should be discussed with the competent authorities (or addressed through specific guidelines) and their periodical calibration should be carried out with the supervision of institutional personnel in order to guarantee the reliability of the measures. Furthermore the constant respect of the MVF release should be easily verifiable on site by anybody through proper devices showing in real time the value of the flowing discharge. The measurement of the MVF released at the dam/weir section proves the compliance to the legal requirement but not the discharge availability in the downstream river reaches. In fact, depending on the geomorphological and hydrogeological characteristics of the watercourse, the flow could split in many canals or be drained by a river-bed substratum of high permeability, becoming unavailable for the ecosystems needs. The river aptitude to keep in every downstream section the flow distribution of the released discharge in conditions compatible with the environmental safeguard targets is strictly linked to the river slope and width, the sequence of riffles and pools, the granulometry and permeability of the substratum and to the interactions with the surrounding aquifers. All the previous elements should be assessed during the project and operational phases in order to evaluate the adequacy of the calculated MVF, implementing, if necessary, adequate mitigation measures such as the increase of the value of released discharge or the setting of a channel inside the watercourse aimed at guaranteeing the constant presence of flow and hydraulic conditions sufficient for the biocoenoses needs. The Plans

of watershed safeguard will contain useful elements regarding the basin water balance which could be helpful in outlining the relationships between surface and groundwater and in defining the river reaches more critical in terms of flow availability due to local geomorphologic characteristics. Since fluvial ecosystems are dynamic, in order to maintain viability and resilience, a range of natural variation in the hydraulic regimen is required and consequently the release of a constant discharge, even if complying with the law, can lead to significant impacts upon the river biocoenoses (fishes and aquatic macroinvertebrates, aquatic and riparian vegetation, etc.). For this reason, especially in reaches of particular naturalistic interest, a preliminary analysis of the watercourse peculiarities could address to a release modulation depending on the more critical period for the involved species, particularly taking into account the ichthyofauna critical/sensitive periods (migrations, spawning and juvenile phases). In this sense the knowl edge of the main peculiarities of the fluvial ecosystems is essential and should be seeked not only during the project phase but also for the adjustment of existing sites. Specific analyses should be addresed to identify the most sensitive species and the period where proper caution should be taken in managing the site in order to avoid negative influences upon the biocoenoses. The previous information can be used both for the man agement of the releases and for the scheduling of the maintenance operations which can cause an increase of water turbidity and solid transport that usually can affect the survival of eggs, larvae and juveniles.

In some cases, particular needs for increasing the

released discharge in limited periods of time can be related to a punctual anthropic presence, such as, for example, when the influx of tourists increases the pressures on water quality and consequently a proper dilution of the pollutants is required, or when the touristic use of the river (canoeing, kayaking, etc.) needs an additional flow.

Then, because of the afore mentioned reasons, the installed hydraulic devices will have to be capable to adequately modulate the downstream release for every circumstance with a consequent increase of the related costs. However, in case of modulated releases, the annual schedule of the additional flows should be included in the water abstraction licence and con trolled through the installed monitoring system of the abstracted and released discharges.

The impact of dams and weirs on the river bio coenoses is also relevant because the interruption of the fluvial ecosystem continuity due to the infrastruc ture can affect fishes migrations and drift phenomena with consequent loss of biodiversity and alterations of the population structure of the involved species. Since the most of the Italian ichthyc species, espe cially in Alpine streams (Northern Italy), are pota modromous and do not have a significant economical

value, except for some interested by sportfishing (mainly Salmonids), fish passes are uncommon (in Regione Piemonte the previous devices are adopted by about 8% of the total number of existing sites) and, where applied, compensatory (e.g. periodical restocking) rather than mitigatory measures were pre scribed. A recent local initiative has to be outlined: in 2000 Provincia di Torino defined a regulation which imposed as compulsory the installation of fish passes for the new projects of water abstraction and also for the existing sites on the occasion of licence renewals or extraordinary maintenance works; the requirement applies also to hydraulic works which can interrupt the fluvial continuity. Nevertheless, due to the fact that existing dams and weirs shall soon face adaptation works in order to comply with the MVF release, the competent authorities should seize the opportunity to reorganize the whole sector evaluating if the previous discharge, or part of it, must be released through a fish pass in order to restore the river longitudinal connectivity.This approach should be related to an appropriate knowledge of the watercourse fishes populations and of the characteristics of each species in terms of migratory behaviour during their life cycle. The analyses should consider the whole watershed identifying the potential contribution of each river reach upstream every dam/weir in terms of biological significance for the involved species (availability of spawning grounds, trophic availabilities, etc.) in order to evaluate the real usefulness of such devices and to plan priorities in restoring the ecosystems continuity. A specific section of the Plans of watershed safeguard could usefully deal with the previous aspects. Appropriate technical guidelines could provide the main criteria for the fish passes design, specifying the preliminary hydrobiological and hydrological analyses to be carried out in the project phase, the elements on which the choice of

the fish pass typology (artificial by-pass channel, rockramp, vertical slot, denil, weir fishways, etc.) should be based (with particular regard to the infrastructure characteristics and local peculiarities), including its location in the infrastructure (on or near the riverbank, in the most upstream point reachable by migrating fishes, etc.), the attractivity of the facility (hydraulic conditions at the downstream entrance, etc.) and the devices available for its protection (screens, deflectors, etc.), its efficiency monitoring (direct inspections during migration periods, installation of counting devices, etc.) and its maintenance. If the design discharge of the fish pass, defined through hydrobiological and technical considerations, is lower than the MVF value, an additional flow shall be released in order to comply with the legal requirement: in this case the site owner should manage two different hydraulic devices, and provide for an adequate measurement system of the two discharges. Although the total or partial release of the MVF through a fish pass will certainly increase the costs (construction, maintenance, monitoring) that the sites owners shall face, the restoration of both the flow availability in downstream reaches and the fluvial ecosystem continuity can be considered a necessary measure which shall be no more ignored. Finally, the efficiency of all the previous measures should be periodically checked and verifed through an appropriate environmental monitoring programme. While the implementation of a specific monitoring system is compulsory for projects subject to the environmental impact assessment procedure, for existing sites it could be essentially addressed to evaluate the

fulfilment of the environmental targets for which the

MVF has been set and a fish pass has been required;

then it could be included as a specific requirement

in the water abstraction licence. This approach should

not release the competent authorities from their insti

tutional duties charging the sites owner of excessive

costs. The definition of adequate indicators, parame

ters, methods and frequencies should take into account

the local peculiarities and be consistent and integrable

with the institutional monitoring network of the water shed qualitative and quantitative characteristics. In this way, virtuous initiatives adopted by the sites man agers, such as the voluntary adhesion to environmental management systems (ISO 14001 and EMAS), could be appropriately stimulated by the competent institu tions since now through the introduction of specific incentives and facilitations.

3 CONCLUSIONS

The release of the minimum vital flow can be con sidered the main measure for the mitigation of the environmental impact of dams and weirs and the Italian legislation is going to introduce it as compulsory for all the sites. For a useful implementation of this requirement the discharge values obtained applying the normative criteria should be assessed for every site in order to check their efficiency in terms of guarantee ing and safeguarding the fluvial ecosystems. Specific technical issues to be considered and solved for each site are the monitoring of the released discharges, the evaluation of the flow availability in downstream

Calculation and visualization of fish movement in the flow with artificial structures

Hiromichi Ohashi & Yasuyuki Shimizu

Hokkaido University, Hokkaido, Japan

ABSTRACT: From the engineering and biological view point, it is important to understand the movement

of fish in the flow with artificial structures (e.g. fishway) or natural bed topography (e.g. bar and pool). There

have been a large number of works on river flow with structures or fishway including numerical computational

studies, however, the interaction between real river flow and fish movement have not been clarified. In this

paper, an attempt is made to understand the fish movement in the flow by numerical experiment and flow

visualization technique. Flow field is calculated by 2-dimensional unsteady, non-compression continuity equation

and momentum equations. Momentum equations are separated into the advection phase and non-advection phase.

CIP numerical scheme, known as high accuracy numerical calculation, is used in advection phase and central

difference method is used in the non-advection phase and diffusion phase. The fish movement is calculated based

on the momentum equation of fish derived by the characteristics of fish (e.g. drag and thrust of fish, relation

between body length and swimming speed, and relation between swimming speed and sustained time).According

to these calculations, the movement for fish in the flow is indicated and visualization of result is shown.

1 INTRODUCTION

In Japan, river improvement works are often made to

increace flow capacity, especially in urban area. After

river improvement, the ascent of fish is interrupted

because bed slope becomes steep or by the influence of

artificial structures. Therefore in order to make ascent

easy, fishways are installed in rivers where the channel is difficult for fish to ascend. There are a large number of and many kinds of fishways in Japan including Makomanai river, Hokkaido, Japan. Figure 1 is the example of fishway in Makomanai river, Hokkaido, Japan.There are a large number of researches and studies about fishway, fish habitat and fish characteristics. A study of hydraulic characteristics in fishway was made by Izumi et al (1999), an analysis of fish habitat model in relation to the factor that our humanbeings cause was made by Franzin et al (2003) and an experiment to investigate biological evaluation of fish in fishway was made by Wada et al (1999). Characteristics of fish movement was, however, never indicated by the numerical calculation considering the realation with unsteady flow in the fishway.

In this study, the fish movement when the artificial structures, especially fishways, are set in the flumes is indicated by the numerical calculation. Specifically, each fish is calculated in the flow using the momentum equations of fish after flow calculation is made.

Figure 1. Fishway in the Makomani River. Furthermore verification of fish movement by the difference of conditions in the fishway (e.g. exist or not the non-submerged obstacles) was made. 2 NUMERICAL CALCULATION OF FLOW 2.1 Calculation model Flow field is calculated by two-dimensional, unsteady, incompressible flow. The continuty equation and

momentum equations are showed as follows.

where, t is time, x and y are co-orthogonal coordinates,

u and v are depth averaged velocity components in x

and y directions, respectively. h is flow depth, H is

water surface elevation (= h+ η). τ x and τ y are bed

shear stress in x and y directions, respectively. ρ is

water density and g is acceleration due to gravity. τ x

and τ y can be written using Manning's Equation as

follow.

where, n m is Manning's roughness coefficient. D x , D y

are given by the following equations.

where, v t , kinetic eddy viscosity is written as follow.

where, κ is Karman constant, u ∗ is shear velocity and

calculated by

Flow equations of (1)–(3) are calculated numerically

using finite difference method with computational

grids in co-orthogonal coordinate system. From Eq. (1)

and (2), momentum equation in x direction can be

expressed as follow: To solve momentum equations, these equations are separated into two phases of adveciton and nonadvection. A high-order Godunov scheme known as the CIP(Cubic-Inrepolated Pseudo-Particle) method, proposed byYabe & Ishikawa (1990) and modified for the calculation of open channel flow by Nakayama et al (1998), is adopted for advection phase. An assumption is made that at very small time increasements, the change in time of the velocity components at a point in space can be broken down into the time evolution of the inhomogeneous terms and the time evolution at a point due to the advection of the field. Eq. (10) is separated into three phases of advection, nonadvection and viscous term as follows. The solution ofAdveciton phase for small t is simply

approximated as: The trick then is to find the value of u at points in space which generally do not lie on the numerical grid points, as specified by the right hand side of Eq. (14). If liner interpolation is used to fine u at points not on the grid, the first order Godunov method is attained. A more accurate solution requires higher order interpolation, and thus high order Godunov schemes. In the CIP method, a cubic interpolation of u is proposed, and when the interpolation is combined with Eq. (14) the resultant equation for u at grid point i, j and time t+Δt is given by: in which, And coefficients a 1 -g 1 are expressed as follows:

Figure 2. Calculation flume. in which, In Eq. (24), Sigmoid function is employed. Eq. (12) is calculated from the continuity equation by taking the divergence of the momentum equations and solving for depth as a Poisson equation. And Eq. (13), the viscous term, is approximated using central finite differences. In the same way, velocity component of transverve direction can be computed. Each velocity component is defined in the center of two faces of the computational cells, and depth is at the center of the cell. This method has been explained in detail by Shimizu et al. 2.2 Flume for calculation In this study, flow field in 4 flumes are calculated. Figure 2 shows the detail of the flumes for each case. These flumes are decided based on the real condition

of Makomanai River in Hokkaido, Japan. In all flumes,

the length and the width are set as 30 m and 4 m, respec

tively. In Run (1) it is assumed that the middle part of

the flume became steep after river improvement. In

Run (2), (3) and (4), fishways are set in the steep part

in Run (1), respectively. Flume in Run (2) corresponds

to the weir and pool fishway. In Run (3) and Run (4),

addition to Run (2), non-submerged obstacles are set

regularly and irregularly, respectively.

The slope in Run (1) is set as 1/30, and 1/500 in

the middle part which became steep and in the flume

except for the middle part. In Run (2), (3) and (4) the slopes in upstream and downstream are, as well as Run (1), set as 1/500 and in the middle part the vertical drops are made. The total of drops is equal to the difference of middle part in Run (1).

2.3 Boundry conditions

As boundry conditions, the discharge and depth are given in the upstream and downstream, respectively. The velocities are set as 0 in and around obstacles which are not submerged.

2.4 Hydraulic conditions

The discharge is given as 0.15 m 3 /s based on usu ally condition in the Makomanai river. The Manning's roughness coefficient is set as 0.014.

2.5 Numerical conditions

Computational grids in the downstream and trans verse directions are 100 and 30, respectively. The time steps for computations are set to be 0.01 seconds. Calculations are continued for 200 seconds from the beginning.

The calculation is made by these calculation model, calculation method and conditions.The computational flows are created by repeating the later half (from 50 sec to 100 sec) of the flow for 6 times in the 4 flumes, respectively, after calculation because calcu

lation time, 100 s, is not enough to grasp the fish

movement completely and initial flow is unstable.

Figure 3. The result of flow calculation. Figure 3 shows the result of calculation in Run (4) by neutually tracer. It is shown that the complicated flow occured around non-submerged obstacles. 3 CALCULATION OF FISH MOVEMENT In this study, the calculation of fish movement is carried out by the characteristics and calculation method of fish movement shown as follow. The following characteristics are proposed by Itazawa et al (1991) and Hirose et al (1994). 3.1 The characteristics of fish swimming It was assumed that the fish always tries to keep its body parallell to the flow direction, as it cannot swim perpendicular to the flow. Therefore the fish always ascends the river along with the flow but in the opposite direction. 3.2 The characteristics of muscles In general, fish has 2 kinds of muscles known as the “ordinary muscle” and the “red muscle”, respectively. The red muscle can keep being used for a long time as long as the oxygen is supplied without becoming tired. The ordinary muscle can put out to burst up the speed momentarily, but cannot be maintained for a long time because of generating the lactic acid. Fish usually swims in the river using only the red muscle without using ordinary muscle. Ordinary muscle is used only, for example, to avoid danger or to ascend rapid stream. Consequently, the speed of the fish can be characterized as crusing speed (U cur) when only red muscle is used, and Maximum swimming speed (U max) when both muscles are used. Furthermore, these speeds depend on the size of the fish.The value of cruising speed and the maximum swimming speed are usually considered to be about 2-5 BL/s and 10 BL/s, respectively, where BL is the length of the fish. Moreover, the maximum swimming speed is assumed to be maintained only for a few seconds, since fish can use the ordinary muscle only momentarily. In this study, the maximum swimming speed is able to be adapted for fish swimming even after swimming completely at

U max for maximum maitained time based on the above

mentioned characteristics in the case that fish swims

at cruisig speed or stops moving for constant time.

3.3 Calculation method

The method to estimate the fish swimming speed by

the momentum equation for fish movement based on the Newton's Second Law was adapted for calculation of fish movement in this study. Because in the case that fish swimming speed are estimated from flow velocity directly, fish turns for many times by the influence of flow rapidly changing at the place where flow is highly fluctuated (e.g. behind obstacles) as the result that direction of fish movement only depends on the flow direction on its moments. Hovever, the swimming direction depends not only on the present flow direciton but also previous direction of fish movement as a result of using the momentum equation for fish. The momentum equation for fish movement is shown as follows.

where, T and D are the trust and drag of fish, respectively. The acceralation of fish is computed by difference of the trust and drag. The drag of fish D is written as follow.

where, ρ is water density, C_d and U are the drag coefficient and relative velocity of fish, respectively. In general, the drag is the sum of the skin friction and pressure drag. In this study the pressure drag, however, is ignored because the pressure drag of streamlined body is small relative to the skin friction. The drag coefficient is decided based on the shape of fish, it is

set to be 0.008 in this study. For the trust of fish, T ,

is separated into 2 kinds by the difference of muscles

fish using as previously mentioned. In the case of using

both muscles, the red muscle and ordinary muscle, the

output is maximum and the trust is written as follow

with assumption that the trust is equal to the drag if

fish swims at constant speed.

where, U max is the maximum swimming speed. In the

case of using only the red muscle, the trust is written

as follow because the trust is equal to the drag if fish

swims at constant speed. where, U cru is the cruising speed. Seleciton of equation depends on the strength of the flow. In the case that the flow velocity is larger than 0.8U cru , then the ordinary muscle is used, T max is used and T cru is used in the other case (flow velocity is less than 0.8U cru). 3.4 Initial condition of fish movement Initial conditions of fish movement for calculation are set as follow. In this study the calculating fish is assumed to be the Sweetfish that inhabits in Makomanai River. The length of fish is 20 cm. The maximum swimming speed (U max) and crusing speed (U cru) of fish are 12 BL/sec and 4BL/sec, respectively. The maximum swimming speed can be used for 8 sec, after that it can be used for 1 sec every 10 sec. Five fishes are assigned in calculation and they are placed at downstream location when calculation begins. 4 RESULT OF CALCULATION Figure 4 shows the result of calculation in each four flumes. Solid lines and dotted lines in each rectangles represent the paths of fish movement in the flume. In Run (1) the paths are stopped at the middle way. fish-1 fish-2 fish-3 fish-4 fish-5 fish-1 fish-2 fish-3 fish-4 fish-5 fish-1 fish-2 fish-3 fish-4 fish-5 fish-1 fish-2 fish-3 fish-4 fish-5 Figure 4. The result of calculation.

It means that fishes could not travel to upstream. In

Run (1), compared between the leftside and rightside

in the flumes, it is found that the paths in the leftside

became thicker. It means that repetition of ascent and descent of fish by the flow in the steep part. In Run (2) all five fishes can ascend because all paths reached upstream oppositely. It is shown in Run (3) that four fishes out of five can reach upstream and each fishes meandered around the non-submerged obstacles dif ferent from Run (2). In Run (4), two fishes out of five can go to upstream and meandered around the non-submerged obstacles as well as Run (3).

5 CONCLUSION

It is indicated that not only the ability of fish to ascend, but also the difference of flume configurations.At first the effect of fishway is clarified because no fish which could ascend at all in Run (1). However, fishes are able to ascend in Run (2), (3) and (4) which structures (e.g. vertical drops, pool, non-submerged obstacles) are set. Next there are two big differences in Run (2), Run (3) and (4). Firstly, one is that fishes meandered for many times in Run (3) and (4) because the flow is con stantly changing in transverse direction by the influ ence of non-submerged obstacles. Secondly, some fishes can reach upstream, while others could not in Run (3), (4). There are several reasons. Fish could not ascend by the influence of turbulence around non submerged obstacles, and fish cannot go beyond non

submerged obstacles, because flow velocity becomes

fast here. It is not clealy indicated that the ascent of fish

is difficult in the narrow place from the Figure 4, but

we could verify it from the animation from calculation.

There are no outstanding difference compared to

Run (3) and Run (4), but it is found that flow which

An experimental study of velocity fields and flow patterns in aligned deep slot fishways

ABSTRACT: This paper is a study of the flow pattern taking place in a specific design of aligned deep slot

fishways. The analysis is based on an experimental study in which the flow velocities and the water depths were

measured in a laboratory model of the fishway. A spatial 3 dimensional mesh was used to measure the 3 velocity

components. To measure the water depth a bidimensional mesh was used. Sills of different heights were placed

in the slot in order to analyze its influence in the flow pattern. For each different sill, several discharges were

used. As a result of the study, the relationship between the discharge and the different characteristic water depths

(medium, maximum and minimum depths in the pool) as well as the discharge equations were obtained for each

different sill. Three different flow patterns were observed in function of the height above the bottom of the pool.

Finally, the slot velocity and the maximum velocity in the pool were analyzed.

1 INTRODUCTION

One of the most important direct effects of the

hydraulic constructions in rivers is the perturbation of

fish circulation, which, in some cases, can lead to the

disappearance of some migratory specimens (Larinier,

1998, Zhong & Power, 1996).

The most common solution to this problem is the

construction of fishways to allow the upstream migra

tion of the fish. The aligned deep slot fishways, which

are studied in this paper, are a new design which is

still not used at the present time in practice. This new

design is an hybrid between the aligned vertical slot

design and the deep slot design. The difference with

the vertical slot design, in which the slot goes down

straight to the bottom, is that a sill is placed in the bot

tom of the slot. In this way a strong vertical velocity

component appears in the slot, destroying the quasi

bidimensional behaviour of the vertical slot fishways.

The object of this study is to analyze the modifications

introduced in the flow pattern by the sill and to char

acterize the hydraulic behaviour of this new kind of

fishways.

A basic design which will be referred to as config

uration T1 (Fig. 1) was chosen to perform the study

(Teijeiro, 2001; Pena, 2003; Puertas, 2004). In Table 1 D c B D L d p T1 dc L Dp b Figure 1. Basic design and dimensions of a configuration T1 pool. are shown the real and the parametric dimensions of the pool. The bottom slope is 10%. The height of the different sills placed in the bottom of the slot are 100, 200, 300, 400 and 500 mm. 2 EXPERIMENTAL PROCEDURE The experimental work was carried out at the CITEEC (Centro de Innovación Tecnolóxica en Edificación e Table 1. Enxeñería Civil) at the University ofA Coruña (Spain).

The fishway model consisted on a metallic struc

ture of 12 m long with a 1× 1 m 2 rectangular section.

The fishway was divided into eleven pools: a head

tank receiving the water from an upstream reservoir,

nine active pools and a tail tank. The experimental

measurements were recorded in pool number 7.

A conceptual state of uniform flow (Rajaratnam

et al., 1986, 1992) was used, so that the mean depth

measured at the middle transversal section was the

same in all the pools. At the lower end of the flume a

tailgate causing overflow was used in order to impose

the necessary boundary condition to obtain a uniform

flow for each different discharge.

A cartesian positioner was placed over the exper

imental pool in order to automate the positioning

of the measurement instruments. Two measurement

devices were placed on the cartesian positioner, but not

simultaneously: a depth probe and ADV velocimeter.

Velocities were measured by means of a Doppler

effect velocimeter (MicroAcoustic Doppler Velocime

ter SonTek).

Velocity measurements were carried out in planes

parallel to the flume bed with 10 cm in between, start

ing at 5 cm from the channel bed up to as close as

possible to the water surface. In each plane, data

points were distributed forming a 10× 10 cm mesh,

reduced to 5× 5 cm in critical zones. Therefore a

three-dimensional mesh of 10× 10× 10 cm for the

measurement of velocity was maintained. Table 3. Sills and discharges used. Depth measurements in the pools were evaluated following a bidimensional mesh with data points at a 10× 10 cm maximum separation in between. Calibration tests were performed prior to each working day. After a previous experimental test, a measurement frequency of 15

Hz was chosen. 2.1 Sills and discharges studied In Table 3 are summarized the different cases which were tested. In all cases the bottom slope of the fishway was 10.054%. 2.2 Discharge equations The discharge equations, which relate the adimensional water depth and discharge, were evaluated. The

Table 4. Discharge equations for the different sill

heights. The adimensional discharge is related to the adi

mensional water depth. r 2 is the correlation coefficient.

Q A z10 = 0.7939y 0 /b − 0.583 r 2 = 0.9956

Q A z20 = 0.8185y 0 /b − 1.040 r 2 = 0.9862

Q A z30 = 0.8571y 0 /b − 1.666 r 2 = 0.9746

Q A z40 = 0.8174y 0 /b − 1.981 r 2 = 0.9968

Q A z50 = 0.7741y 0 /b − 2.264 r 2 = 0.9978

water depth is adimensionalized by the width of the

slot, while the discharge is adimensionalized as:

where Q A is the adimensional discharge, Q is the

experimental discharge, g is the gravitational con

stant and b is the real width of the slot. The discharge

equation can be expressed as:

where y 0 is the mean water depth in the transversal

section of the middle of the pool and α, μ and β are

proportionality coefficients.

The discharge equations obtained from the experi

mental data are shown in Table 4, where Q A z10 , Q A z20 ,

Q A z30 , Q A z40 , Q A z50 , account for the adimensional dis

charge corresponding to each different sill height: 10,

20, 30, 40 and 50 cm.

It was verified that the discharge and the water depth are linearly correlated (β coefficient is equal to 1) and that the proportionality constant α, as well as the coef ficient μ depend on the basic design of the pool and on the height of the sill.

All the discharge relations are almost parallel to each other, which shows that, independently of the sill used, the sensitivity of the design to variations in the discharge remains invariable.

2.3 Characteristic water depths

The characteristic water depths are those by which the free water surface can be represented. As it was done in the analysis of the vertical slot fishways (Puertas, 2004), the following characteristic water depths are defined: maximum water depth in the pool, y max , water depth in the vertical slot, y b , mean water depth, y m , minimum water depth, y min . The water depth in the vertical slot is defined as the difference between the free water surface and the upper part of the sill. There fore, the depth at both sides of the sill is bigger than the depth in the slot, being the difference of the same order of magnitude than the height of the sill. For Table 5. Relation between the characteristic water depths and the adimensional depth y 0 /b. In all cases a good correlation was found, being the minimum correlation coefficient equal to 0.98. Sill (mm) y max /b y b /b 100 1.0156 y o /b + 0.458 0.9984 y o /b – 0.538 200 1.0432 y o /b + 0.324

0.9788 y o /b − 1.027 300 1.0673 y o /b + 0.221 0.9032 y o /b − 1.268 400 1.0962 y o /b + 0.063 0.8233 y o /b − 1.565 500 1.1072 y o /b − 0.042 0.9464 y o /b − 2.656 y m /b y min /b 100 0.9844 y o /b + 0.070 0.9618 y o /b − 0.356 200 0.9849 y o /b + 0.086 0.9499 y o /b − 0.303 300 0.9903 y o /b + 0.064 0.9914 y o /b − 0.454 400 0.9893 y o /b + 0.074 1.0206 y o /b − 0.565 500 0.9848 y o /b + 0.103 0.9096 y o /b − 0.080 the calculation of the minimum water depth it is not considered the slot depth. A general relation between the mean water depth in the central transversal section and any of the characteristic depths was used: where Y is any of the characteristic water depths defined above (y max , y b , y m , y min), b is the width of the vertical slot, y 0 is the mean water depth in the central transversal section and α ′ and β ′ are proportionality coefficients. The computed equations are shown in Table 5. The values of the characteristic water depths are proportional to the flow discharge, as well as to the height of the sill.The water height over the sill depends on the discharge but it is independent of the height of the sill. 2.4 Free water surface In general it can be found a certain similitude between the patterns found for the free water surface and those to the vertical slot fishways (Puertas, 2004): - There is an area of high water depths upstream the slot. - There is a strong diminution of the water depth in the slot. - The minimum water depth occurs downstream the slot, where a circular depth depression exists. - After this minimum, in the downstream direction, another area of high depths exists next to the transversal vertical wall which separates the pools. 0 Cm 50 100 150

Figure 2. Isodepth lines in the aligned deep slot fishway.

The plot corresponds to a discharge of Q= 0.055 m 3 /s and a

sill of 0.10 m height.

Apart from these general similitude between the

vertical slot and the deep slot designs, there are two mainly differentiating characteristics:

- The position of the circular water depth depression which occurs downstream the slot.
- The distribution of the isodepth lines.

For the vertical slot design, the position of the water depth circular depression is downstream the slot in the direction of the opposite corner of the pool. In the aligned deep slot design, the depression moves upstream towards the transversal pool separation wall.

The second difference is the distribution of the isodepth lines. In the vertical slot design the isodepth lines are approximately perpendicular to the diago nal which goes from the slot to the opposite pool corner, while in the deep slot design they are almost perpendicular to the fishway longitudinal axis (Fig. 2).

Another important property observed is that the free water surface pattern remains invariable to the height of the sill. Each design has a characteristic pattern which depends only on the configuration of the ver tical walls that define the pool and which does not depend on the sill placed in the slot.

Finally it was verified that the pattern of the free water surface is also independent of the flow discharge. This behaviour was observed for all the experimental

discharges used.

3 VELOCITY FIELDS

3.1 Horizontal velocity fields

The introduction of the sill in the vertical slot has a great importance in the velocity field. In the verti cal slot design, the flow is quasi bidimensional, the vertical velocities are almost zero and there are not important differences in the velocity fields which occur at different vertical levels. This allows to charac terize the flow pattern independently of the level over the bottom of the fishway (Puertas, 2004). When the sill is introduced, this behaviour is no longer true. The horizontal velocity field varies with the height over the bottom and the vertical velocity cannot be neglected, specially near the slot. One of the aims of this study was to find several flow patterns which allow to describe the flow independently of the discharge and the sill used. Different flow patterns must be defined in order to be able to represent the velocity field in horizontal levels below the sill as well as in horizontal levels above the sill. Three different flow patterns at three different levels were found after analyzing the experimental data. The first one (Fig. 3) occurs at 5 cm above the bottom of the pool, no matter which discharge neither which sill is used. A second pattern was found (Fig. 4) which represents the velocity field in levels higher than 5 cm but lower than the upper border of the sill. The horizontal velocity field pattern occurring in levels situated over the sill up to the free water surface varies with height. The strongest difference takes place near the sill. Nevertheless, it can be defined a general flow pattern which represents quite accurately the flow field.This third pattern is shown in Figure 5. It is in the slot section where the velocity direction varies most strongly with height. In Figure 5 two directions are defined in the slot. At the deepest levels, the velocity

Figure 3. Flow pattern of the horizontal velocity field in a plane situated at 5 cm above the bottom of the pool.

Figure 4. Flow pattern of the horizontal velocity field in planes located between 5 cm above the bottom of the pool and the upper border of the sill.

direction turns left, being almost parallel to the transversal wall, while in the most superficial levels the velocity remains perpendicular to the slot. As it has been said, in the deep slot design, the vertical velocities are not negligible. Near the slot the flow

Figure 6. Experimental values of the mean velocity in the

slot for different discharges and different sills.

moves up, it is then propelled away from the slot, and

when it reaches the opposite vertical wall it moves

down. The absolute value of the vertical velocity is

usually smaller than the horizontal components, being

usually smaller than 20 cm/s. However, as it is shown

by the experimental results presented, it is of great

importance in the global behaviour of the flow in the

fishway.

3.2 Slot velocity

The velocity in the slot (V s) was calculated at different

heights. For each height three different experimental

points were used to compute the mean value of the

velocity.

In Figure 6 it is represented the mean velocity in

the slot for each different discharge and each differ

ent sill. As it can be seen, all values are quite similar

independently of the discharge and the sill used. A

mean velocity of 48.82 cm/s can be considered as

representative of all situations.

3.3 Maximum velocity

The maximum velocity (V max) is another characteris

tic velocity that can be used to define the hydraulic

behaviour of a fishway. 0 40 80 120 160 200 0.020 0.040 0.060 0.080 0.100 Q (m 3 /s) V m a x (c m / s) Sill 10 cm Sill 20 cm Sill 30 cm Sill 40 cm Sill 50 cm Average Figure 7. Second maximum velocities. Maximum velocities for each different discharge and sill, computed as the mean value of the maxima at different measurement planes situated below the sill. As it was expected, it was necessary to define two different maximum velocities.The first maximum corresponds to the points situated above the sill and the second maximum to points situated below the sill. The maximum velocity is defined as the mean of the different maxima occurring at different measurement planes. For the first maximum, only the planes situated above the sill are considered while for the second maximum the planes considered are those ones situated below the sill. The first maximum velocity is shown in Figure 7. Different discharges and sills are represented. As the maximum velocity is almost independent of the discharge, a mean value was calculated, obtaining a velocity of 101 cm/s. The second maximum velocities (planes situated below the sill) are plotted in Figure 8. As it can be

seen, the maxima increase with the discharge up to

a highest value which is very near to the first max

imum (planes situated above the sill) represented in

Figure 7. For all discharges, the second maximum is

smaller than the first maximum. It should be expected that for bigger discharges both maxima agree.

The velocities measured oscillate in a very wide range. The biggest value measured was 174.7 cm/s. The location of the biggest velocities is always near the slot.

4 CONCLUSIONS

The aligned deep slot fishways are an hybrid design between the so called deep slot fishways and the aligned vertical slot fishways. Therefore, its hydraulic behaviour has common points with the two original designs.

The discharge equations which relate the discharge and the water depth are linear, as it happens in the vertical slot design. However, the equation depends on the height of the sill placed in the slot. The bigger the sill, the bigger the water depth in the pool.

The configuration of the free water surface is independent of the discharge and of the sill used.

It has been found three different flow patterns which allow to represent the horizontal velocity field. Depending on the level over the bottom of the pool, one pattern or another appears. The three patterns found can be summarized as follows:

(1) Independently of the sill used, at a level of 5 cm

over the bottom of the pool, the streamlines follow

the pattern shown in Figure 3.

(2) For planes situated at a higher level than 5 cm but

below the upper border of the sill, the flow pattern

is represented in Figure 4.

(3) The planes situated at a higher level than the

upper level of the sill follow the pattern shown in

Figure 5. The velocity direction is perpendicular

to the slot for planes near the free water surface.

At lower levels, the velocity direction turns left.

Although the vertical velocity component is much

smaller than the horizontal components, it has a great

importance in the development of the flow pattern in

the pool.

The mean velocity in the slot can be considered

almost constant and independent of the discharge and

Estimating effect of navigation on fish habitats in inland waterways

C. Engelhardt, A. Sukhodolov & C. Wolter

Institute of Freshwater Ecology and Inland Fisheries, Berlin, Germany

ABSTRACT: The swimming performance of juvenile fishes can be insufficient to overcome return current

velocities induced by navigation in inland waterways. A method to assess habitats of fish on the basis of return

velocity computations is introduced using general physical principles. A simple analytical model is presented to

determine the return velocities in a canal of known dimensions and for a vessel of certain draught and speed.

Field measurements were performed in the Oder-Havel canal to evaluate the mathematical model. Comparing

predicted values of return velocity for the investigated waterway with thresholds of maximum swimming speed

for juvenile fishes a habitat bottleneck could be shown. Suggestions are given as to how the navigation impact

on fish can be minimized by canal shoreline design.

1 INTRODUCTION

Navigable inland waterways were always important

for the economic development of society; nowadays

their total length exceeds half a million kilometers

worldwide (Kubec & Podzimek 1996). Aside from

their primary functioning as navigation routes, inland

waterways provide habitats for sundry species of

aquatic animals and plants. Although the necessity of

limiting the cruising speed of vessels because of chan

nel protection considerations became an exploitation

policy long ago, the ecological aspect of the problem

was not considered rigorously either in design of chan

nel or in navigation rules hitherto. In part this situation

accounts for the lack of knowledge about the effects

of navigation on dynamics of populations for species

inhabiting inland waterways.

A vessel propelling in a canal expends energy to

overcome the resistance of fluid. That energy is mainly

transformed into a complex pattern of currents and waves trailing astern. Helmholz fan, propeller wash (U_p), slope supply flow (U_s), and return currents (U_r) moving in opposition to the direction of the vessel's motion (Figure 1) are the principal constituents of the pattern. In width-restricted canals, when commercial tugs towing loaded barges cruise with the speeds close to navigation limits, the return currents maintain extremely large velocity values (Simons et al. 1981; Mazumder et al. 1993). The magnitude of these currents may greatly exceed the swimming abilities of larval and juvenile fishes and thereby cause high larvae mortality (Wolter & Vicinskas 1997; Arlinghaus et al. 2002). As the young-of-the-year fishes are important

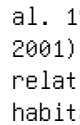

Figure 1. Schematic representation of currents generated by a vessel cruising in a canal (after Blaauw et al. 1984).

indicators of habitat quality (Schiemer et al. 2001), it seems possible to establish quantitative relationships between side effects of navigation and habitat quality by means of comparison of return current velocity and swimming abilities of juvenile fishes. To develop this relationship to the level of a practical computational scheme therefore requires predicting the return velocity for the given characteristics of the canal as well as for typical vessels in addition to predicting swimming abilities of juvenile fishes as a function of the body length. Although vessel-induced waves and currents have been intensively studied in the shipbuilding applications (Jiang 2001), available computation schemes are either complex (Stockstill & Berger 1999) or rely heavily on purely empirical approaches (Maynord & Siemsen 1991; Maynord 1996). More

over, both advanced numerical models and empirical methods require that significant amount of data be collected prior to computations. Numerical models need detailed data sets pertaining to the geometry of the channel and a vessel, characteristics of hydraulic resistance and eddy viscosity (Stockstill & Berger 1999), while development of empirical relationships requires numerous observations. Therefore, there is a need to develop a simplified computational scheme based on fundamental physical laws which can be operated upon a few parameters.

Fish swimming performance depends on a variety of biological and physical factors. Observations undoubtedly indicate that the principal factor is the body length (Wardle 1975; Videler 1993; Haefner & Bowen 2002). Correspondingly, swimming performance was assessed by a model for maximum swimming speed on the basis of the white lateral muscle's contraction time and the relation between tailbeat frequency and forward motion (Wardle 1975).

Present study is focused on the development of a simplified model of return velocity in a straight prismatic canal with still water and its applications to describe effect of navigation on fish habitats. The model was derived from advection-diffusion equation

and tested on the original data set of field observations.
B h h 0 y

Figure 2. Schematic representation of canal’s crosssection

with a vessel.

Figure 3. Commercial navigation in the Oder-Havel canal in Germany. 2 RETURN CURRENT MODELING A moving vessel expends energy to overcome resistance of water while propelling in a waterway. The kinetic energy gained by water from the interaction with the vessel has to be transported away and dissipated during the transport. This energy transfer can be described by the advection-diffusion equation where t= time, x= vector of coordinates, u= vector of characteristic velocity of the kinetic energy transfer, D= coefficient of kinetic energy diffusion, and k = dimensionless kinetic energy=U 2 h/U 2 0 h 0 , U 0 and U = velocities of the vessel and water, h 0 and h= draught and the canal depth respectively (Figure 2). In inland waterways the canal widths are usually comparable or smaller than the length of commercial vessels (Figure 3) while their draughts at load are slightly smaller then the canal depth. Therefore, accounting for significant cruising speeds of vessels, the ship-induced disturbances occupies the whole water column and reach the banks so quickly that the maximum of return velocities is observed in a crosssection while a ship still passing by. These circumstances allow significant simplification for equation (1). Thus, it is reasonable to consider only depth averaged, steady state energy transfer with constant coefficient of diffusion which for the transverse direction writes to as where y= cross-canal distance counted from the centerline of the ship’s hull. The condition of steadiness is here T = period of drawdown wave.

Substituting the variable ζ= ∂k/∂y yields

and after integration converts to

where C = constant of integration.Applying an inverse

transformation to (5), one obtains

that with a substitute for the distance η= y/B writes as

where B is waterway-width. Integration of equation (7)

yields

where C 2 = constant of integration. C 2 is a small and

can be neglected at long distances in still water k ≈ 0.

Now substituting expressions for kinetic energy into

(8), one obtains

Finally, one can rewrite equation (9) to as

Despite that general relationship of the coefficients α

and β to the parameters of the flow are known, their

values have to be determined experimentally because

of lack of a suitable mathematical description for

diffusion coefficient D, and the unknown value of C 1 .

Equation (3) can be rewritten to account for a

specific case u= √ gh

which is a well recognized group velocity limit in the

shallow water canals. The value of coefficient γ is

expected to equal 1, and the practical threshold to sat

isfy condition (11) is an order of magnitude, that means

that the period of ship passage should be at least 10

times longer then the time of disturbance wave travel

from the ship to the bank. Equations (10) and (11) comprise a simple model allowing predictions of return velocities in a canal of known dimensions for a vessel with the certain draught and speed.The model requires, however, some parameters that can be obtained experimentally for the certain geometry of the canal (for example trapezoidal shape) and similar types of vessels. 3 FIELD MEASUREMENTS 3.1 Study reach The artificially constructed Oder-Havel canal is a 150 km long inland waterway connecting watersheds of the Oder and the Havel rivers in the northeastern lowlands of Germany. It was opened for navigation in 1620, last modified in 1914; its channel is 34 m wide and 3 m deep, with a steep bank (slopes of 33%) protected by rip-rap embankment. The field measurements

were performed in a reach of the canal located at 63.5 km (52 ∘ 85 ′ N; 13 ∘ 73 ′ E). 3.2 Measuring system and equipment During the passage of vessels in the study reach the records of instantaneous velocity vectors were collected using acoustic doppler velocimeter (ADV) manufactured by Sontek, Inc. This instrument consists of an ADV probe mounted to submersible field electronics. The sampling volume of the probe is located 10 cm from the sensors and is <0.25 cm 3 in size. The resolution of the ADV is 0.1 mm/s with a noise level of 1% of the velocity range at a sampling frequency of 25 Hz. A special moveable platform was constructed to enable accurate and stable positioning of the measuring systems (Figure 4). Figure 4. Moveable platform for ADV sensors mounting installed in the cross-section of the Oder-Havel canal, 63.5 km.

Hydrographic survey of the waterway reach, posi

tioning of ADV sensors and the determination of

coordinates for vessels were performed with a total

station Elta ® R55 (Carl Zeiss Geodetic Systems,

Germany, distance 5 mm, range 1300 m). The draught

was recorded from the draught scale of the vessels,

and the length, width and capacity were obtained

Figure 5. Example of velocity records sampled with ADV in the Oder-Havel canal during the passage of three commercial

tows (the registration numbers of tows are displayed in textbox). from the official calibration registers. Speed of vessels was calculated from time consumed by each vessel to pass a defined reference reach. Water levels were recorded using pressure loggers (DL/N, STS Co., Sirnach, Switzerland) mounted into perforated steel pipes and placed close to the locations of ADV probes.

3.3 Measurements and data processing

For altogether 17 commercial tows the flow velocities

were measured close to the bottom (0.15 m) at three

locations across a transect of the Oder-Havel canal

simultaneously at sampling rate of 25 Hz. The record

ing started as soon as a vessel became visible from

the site and continued until the water surface became

practically calm.

The software package ExploreV 1.5 (NortekUSA) was used to process the results of ADV measurements. Prior to computations of the statistical characteristics of turbulence, each record was inspected visually to identify possible problems such as spikes, trends, or abrupt discontinuities in the time series. Post-processing of the data involved removal of the defective portions of the time series using the data clipping capabilities of the software, spikes detection with a set of criteria implemented in the ExploreV and the recovering of bad samples with linearly interpolated values. Editing of time series thus allowed to exclude errors associated with spurious signals emerging from interaction of acoustic signal with large floating particle in the stream such as woody debris.

4 RESULTS

A coordinate system with a streamwise x direction aligned with the direction of vessels motion, a transversal y direction, and a vertical direction z, originating at the canal bed and directed toward the free surface is adopted herein. 0 1 2 3 4 τ = (t-t 0) / T -1.0 -0.5 0.0 0.5 1.0 1.5

Figure 6. Dimensionless velocity records. An example of measured velocities and water levels is shown in Figure 5. Analysis of velocity fluctuations and changes of water level allows to unambiguously determine different elements of the vessel’s wake pattern. It can be also seen that velocity patterns display apparent similarity, though there are definite differences in length, load and speed of vessels. Records of velocity and water level were processed to obtain the periods of drawdown waves and mean values for return currents U R (calculated as an averaged value for the time interval corresponding to the period of drawdown wave). The measured velocity patterns can be scaled with those two parameters (Figure 6). The data plotted in Figure 6 were smoothed using boxcar procedure to eliminate fluctuations of higher order. Close correspondence between return velocity and small scatter in the data thus confirm that vessel length and speed are the most valuable parameters controlling the formation of return currents. At the same time records exhibited larger scatter for slope supply currents that most probably included the effect of a tug hull and peculiarities of propeller-generated currents individual for different types of tugs. Close examination of individual patterns of return velocity as the result of zooming and resizing (Figure 7) supports the acceptance for the condition of steadiness (3). Comparison of measured pattern and accepted in the model (10) is presented in Figure 7b. Periods of drawdown waves and their approximates calculated from length and speed of vessels are shown in Figure 8. A line corresponding to the linear regression between these parameters outlines the area of perfect agreement.These plots reveal that the period of drawdown wave can be simply estimated for a vessel with a certain size. Transverse distributions of dimensionless return velocities and their comparison with model (10) are presented in Figure 9. Standard least squares procedure yielded values for parameters α= 2.24 and β= 2.52 (R 2 = 0.92). The data indicate close agreement with the solution by model (10) indicated as the solid line in Figure 9. 5 DISCUSSION AND CONCLUSIONS A simplified analytical model for predicting return currents developing in the area of drawdown wave accompanying the passage of large commercial vessels in the canals is presented. The comparison of the model’s prediction with the results of field observations indicated a good performance of the model. This allows recommending the model for use in ecological studies as a tool of estimating the effect of navigation on different species of the aquatic life. Below we present an example of

the model application for characterization of fish habitats. 0 40 80 120 160 200 time, s

Fish swimming performance was assessed according to a general model of maximum swimming speed on the basis of white lateral muscle's contraction time and the relation between tailbeat frequency and

forward motion (Wardle 1975). According to this

estimation, a 15 mm long fish larvae swims with

a maximum speed of 0.22 m/s, that is considerably

below the navigation-induced return current velocity.

The lower level of return current for the Oder-Havel

canal of 0.7 m/s would be performed by a 47 mm

long fish for less than 20 s (Wardle 1975). However,

when larvae of common freshwater fish species hatch

at total length of less than 10 mm and swim free

River flow forecast by means of selected black box models

A. Piotrowski, P.M. Rowiń´ski & J.J. Napiórkowski

Institute of Geophysics, Polish Academy of Sciences,
Warsaw, Poland

ABSTRACT: Performance of two different types of approaches were investigated with respect to the daily river

flow predictions. The first approach is Multi-Layer Perceptron Artificial Neural Network, the second one, based

on the deterministic chaos concept, is so called Phase-Space Reconstruction (PSR) model. Both models were

applied to daily river flow data collected from several gauges, located in river reaches in western Canada. Each

data set consists of more than 10000 consecutive daily measurements. The method based on the phase-space

reconstruction theory has been applied despite the fact that the authors doubt in the existence of deterministic

chaos in the river system. Classical phase-space method may be applied only to single time series data. In the

present study an extension was proposed, in which time series from additional gauge stations added to the system.

Comparison of models' performance was made for this extended and classical approaches for both phase-space

reconstruction and Artificial Neural Networks models.

1 INTRODUCTION

An accurate forecasting of river flow is a fundamen

tal problem in hydrological sciences. In recent years

application of black box type models to runoff pre

diction has been gaining more popularity due to their

easiness of employment and relatively low number of

variables involved. Multi-Layer Perceptron Artificial

Neural Networks (ANN) are probably most broadly

used for forecasting (Hsu et al. 1995, Campolo et al.

1999, Campolo et al. 2003, Dolling & Varas 2002, Chibanga et al. 2003 and many others). They are the simplest among the non-linear neural network models, nevertheless they are capable of making very accurate forecast, when proper set of input variables is taken into account. On top of that they are easy to be trained, contrary to, for example, radial basis functions networks. ANN approach is sometimes called global approximation approach as it deals with all set of historical data values to optimise network weights, which means that all known information about the system is used to make a relevant forecast.

A methodologically different approach, though still quite popular, pertains to phase-space reconstruction (Jayawardena & Lai 1994, Porporato & Ridolfi 1997, Sivakumar et al. 2002). It is a local approximation approach and it has been developed in the framework of the deterministic chaos theory. The presence of low-dimensional chaotic behaviour in the rainfall runoff process is a matter of an ongoing debate (see e.g. Schertzer et al. 2002) and it will not be discussed in detail herein. Let us only note that the main idea of this approach corresponds to the possibility of the reconstruction of the phase-space from a discrete set of values for a given observable scalar such as water stages at a given gauge station. The authors of the present study will benefit from the phase-space reconstruction method which in fact is a way of finding the most similar

situations in historical data and applying only these selected parts of data set for forecasting. It seems that this method may stand alone as a reliable tool without linking it to the existence or nonexistence of a hypothetical deterministic dynamical system leading to disordered solutions. According to Sivakumar et al. (2002), the phase-space reconstruction method is better than ANN approach when dealing with autoregressive forecast problem. Further in the paper it will be shown that such conclusion is premature and in case of the selected Canadian river reaches both ANN and phase-space reconstruction methods boast similar performance of forecasting daily runoffs. Additionally an extension, further called as quasi-phase-space reconstruction method, will be proposed and this method will allow for the use of the data from more than one gauge station. As expected this method will improve the results considerably. The comparison of the results of two black box models will be presented according to the following scheme: – version A: as inputs only historical runoff data from the same gauge are applied for bothANN and phasespace reconstruction approaches;

– version B: forecast is made for the same gauge as

in version A, but input data set consists of data

from 2 or 3 gauges. Additional gauge for version B

is selected at the same river where the forecasting

gauge or its main tributary is placed.

For each case 3 consecutive measurements from

particular gauge were treated as input variables which

means that we have 3 input variables in version A, and

6 or 9 in version B.

2 FLOW DATA

Long enough data sets collected in 5 western Canadian

rivers (Figure 1) are applied in the analyses (Environ

ment Canada 2003). Table 1 presents the duration of

daily data sets, location of the main gauge (used for

the forecasts, denoted by number 1) and the additional

gauges (applied in version B only, denoted by number

2 or 3). Each data set contains more than 10000 daily

measurements, and 5 river reaches are considered in

the study. It seems to provide sufficient information to

* mountainous terrain, ** steppe. compare the performance
of all the considered models. In each case the daily river
flow forecast was made for last 5000 measurements. Those
5000 measurements were not taken into account during ANN
training process, but they were only used to compare
performance of both models at each river reach. The ANNs
were trained with the use of the earlier records (larger
than 5000 elements in each case). 3 MODELS APPLIED In this
section attention is focused on the implementation of some
anticipatory nonlinear methods based on Deterministic Chaos
and Artificial Neural Networks for prediction of the
inflows. 3.1 Artificial Neural Network approach Multi-Layer

Perceptron Artificial Neural Networks have become widespread in recent years and the researchers often claim that they provide a useful tool for the predictions of river flow. Three layer networks with sufficient number of hidden nodes are usually applied due to the continuity of the relevant function. Every network contains an appropriate number of input and output nodes which is equal to the number of input and output variables, and the assumed number of hidden nodes. There is no effective rule for the estimate of the number of hidden nodes. In this study it usually turns out to be close to the number of input nodes, but in each case it is experimentally verified. The ANN nodes in neighbouring layers are linked via weighted connections. The values of those weights can be adaptively modified during the process of training the network. In this study, due to the relatively simple architecture of all the networks, Levenberg-Marquardt nonlinear optimisation algorithm was adopted (Press et al. 1989). Shortly the Multi-Layer Perceptron network (see Figure 2) operates in the following way: signals s i (i= 1, …, N) from the input nodes (e.g. values of input variables normalized to 0-1 interval) are multiplied by v j w ij input layer hidden layer output layer Figure 2. Multi-Layer Perceptron Artificial Neural Network scheme.

proper weights w ji (j= 1, … K), connecting the neuron

from which signal has been dispatched and a suitable

neuron in the second layer.

In the second layer the weighted sum of all the

inputs are computed and then transformed by logistic

function

giving the output value of a neuron in the second layer:

Afterwards the weighted signals z j (multiplied by

proper weights v j), are transferred to the neuron of

the third layer. In the neuron of the third layer the new

weighted sum is computed

and after de-normalization of the output, the sought

(forecasted) value may be determined. This is a feed

forward network, which means that there is only one direction of the flow of information, from the input to the output layer.

3.2 “Phase-space reconstruction” approach

Another method used in runoff forecasting studies is motivated and based on the theory of dynamical sys tems (Kantz & Schreiber 1997), i.e. the time evolution is defined in some phase-space. For a purely determin istic system, once its present state is fixed, the states at all future times are determined as well. So it is essen tial to establish a phase-space for the system such that specifying a point in this space specifies the state of the system and vice versa. Then one can study the dynamics of the system by studying the dynamics of the corresponding phase-space points.

Characteristic for chaotic systems is that in many cases the corresponding attractors turn out to be strange attractors of the fractal structure with a non integer dimension (Kudrewicz 1993, Ott 1993).

Since it is natural to describe a deterministic dynam ical system as an object in phase-space, it is also most natural to use a phase-space description for approximation of the dynamic of the system. Such approximate dynamics can be useful for prediction.

The reconstruction of a vector space which is equiv

alent to the original state space of a system from a

scalar time series is the basis of almost all nonlin

ear methods. Scalar measurements is a projection of unobserved internal variables of a system onto an interval on real axis. It is obvious that even with a precise knowledge of the measurements it may be impossible to reconstruct the state space of the original system from the data. Fortunately, we are rarely keen of obtaining a whole, precise description of the process. It is usually enough to determine its good approximation. Hence a reconstruction of the original space is not really necessary for the data analysis. It is sufficient to construct a new space such that the attractor in this space is “equivalent” to the original one (Kantz & Schreiber 1997). The classical situation, as treated in hydrological sciences, though being a matter of serious debate (e.g. Schertzer et al. 2002) is the following. A sequence {x i }, x i ∈R 1 , i= 1, . . ., N, of measured values is given. In order to find an approximation of the deterministic system one considers the function F defined by the following relationship with a properly adjusted number m, called embedding dimension and a given time delay . Hence, the so-called quasi phase-space composed of m-element subsequences y i m is considered The function F in Equation (4) is a dynamical process in the space R m , which according to the embedding approach (Takens 1981) forms an attractor in R m , if the original process is a deterministic chaos. To determine proper embedding dimension from a finite sample of points one determines, for example, correlation integral C N (m, r) for several embedding dimensions (Grassberger & Procaccia 1983). Then correlation dimension D is determined as the slope of function ln C N (m, r) with respect to ln(r), in a respective range of sufficiently small r, such that the function behaves as a linear one (one expects C to scale like power law, C(r) ∝ r D). Now using Takens theorem, one can put m= 2D+ 1 as the searched embedding dimension. One can proceed then to the stage of determining the prediction model for the relationship F in Equation 4. It is possible for deterministic chaos case: as the process is really deterministic and due to existence of an attractor. The considered prediction model has the form of a function such that it approximates the function F , or even less – a “acomponent” of F , being prediction of a future value of state. where T is a prediction horizon. Such a function depends on the time instant i of making prediction,

and on the horizon T of this prediction. Thus, one can seek for a function that would determine a good approximation of the value x i+T of the given sequence {x i }. Our computations do not confirm the straightforwardness of the application of the described approach and we become skeptical about its correctness. Correlation integral for data described in Section 2 revealed no obvious scaling region as the indicator of self similar geometry. The saturation value of D (which is just the lower bound of box dimension) with increasing m was not clear at all. We are also aware of the occurrence of noise in the applied data, so the question arises whether those data can be analyzed within the deterministic system.

As a consequence of the above we applied a part of the method derived within the deterministic chaos theory, but as mentioned in Introduction there is no need to decide whether the chaos exists in the system under consideration. We keep the name of the method as the “phase-space reconstruction” approach (Jayawardena & Lai 1994, Sivakumar et al. 2000) to show its origin but we do not claim we have applied the embedding theorem. A method of delays as a realization of the “phase-space reconstruction” approach has

been selected for the purpose of the present study. In order to make a forecast one constructs m-dimensional data vectors from measurements spaced equidistant in time (temporal sequence of measured values at the selected gauge) which creates an analogy to the phase-space.

Further the principle of the applied method lies in the search of K-points from the d-dimensional point set that are placed at the smallest distance (according to some assumed measure) from the points representing the current situation. In other words we are interested in finding K vectors of the length m from the past, most of all resembling the current situation. We do assume one day time delay which allows us to use the consecu tive recordings from the gauge station. Thus we obtain an autoregressive forecast for each day (version A).

In the present study it was assumed that m= 3 which proved to produce reasonable results.

3.3 Quasi “phase-space reconstruction” approach

We proceed similarly as in Section 3.2 but this time we test whether the similar forecast is possible using data collected from more than one gauge. Intuitively more information should lead to a better forecast.

Being remote from the rigorous treatment of the deter ministic chaos we may “extrapolate” the previous

considerations from scalar observables (water stages)

to vectors. This time we build 2m-dimensional quasi “phase-space” where the first d-vector is made of the consecutive measurements from the first gauge and the second d-vector is made of the consecutive measurements in the second gauge station (time delay is again assumed as one day). One should note that the measurements from different gauges may have different standard deviations, so the scale related to the first three components and the last three components may be heterogeneous, that can impact the search for N closest neighbours in this space. Fortunately in our case the performance of forecast made using data sets divided by standard deviation is almost the same as for raw data and therefore no normalization was necessary. The above describes the technique for daily runoff forecast in version B. 4 COMPARISON OF APPLIED METHODS The comparison will be made for both versions A and B by means of correlation coefficient applied to measured and predicted daily or (in one case) 4-daily runoff volume increments (seeTable 2). Such approach shows the performance of the model much better than the correlation applied to just actual runoff volumes where almost all results are close to unity independently of the quality of results. As it was expected inclusion of additional gauge station (version B) improves the results quite significantly for both “phase-space reconstruction” as well as ANN (Figures 3-8). The only exception is the lower Fraser river. The addition of data from the gauge station at Texas Creek did not help the “phase-space reconstruction” technique.The exemplification of this fact is seen in Figure 4. Note that all the Figures 3-8 are prepared for a selected period of about one month only, out of 13 years time series. For clarity the relevant period was chosen to reveal especially large changes in the daily river runoff. This is worth mentioning that in version A all ANN and phase-space models show similar performance. Table 2. Figure 8. Comparison of four lead day runoff forecast for Prince Albert gauge station, on North Saskatchewan river, obtained

from ANN and quasi “phase-space reconstruction” models in versions A and B.

This result is different from the one of Sivakumar

et al. 2002 who considered daily river flow data set from only one gauge station in Thailand. A very short time series was analysed in that study, and the authors removed half of the data set because large differences were observed in those two parts of time series. In that study the phase-space model performance was much better than ANN.

Note that in version B in case of South Saskatchewan river prediction made by ANN is very good indeed and better than that by quasi “phase-space reconstruction” (see Figure 6). In case of quasi “phase space reconstruction” the difficulty lies in the fact that it is quite hard to find enough vectors (3 delayed data from three gauges) in 9-dimensional space similar to the current data allowing for the evaluation of relevant linear regression coefficients.

An astonishing fact is that in version B in respect to North Saskatchewan River, 4-daily runoff forecast (Figure 8) proves to be better than the daily predictions (Figure 7, Table 2). It is the result of the selection of additional gauge at the distance corresponding to flow routing during the time period of 4 days.

5 CONCLUSIONS

The present study that was based on long enough time series from five river reaches shows that the method

analogical to the phase-space reconstruction derived in the framework of deterministic chaos theory is use ful for runoff predictions even if we have no evidence about the existence or non-existence of chaos in the considered river systems. It has also been shown that contrary to what is suggested in some hydrological articles,Artificial Neural Networks may provide accu rate enough forecasts, in many cases even better than those based on “phase-space reconstruction”. On top of that it has been shown that the use of additional information from other gauges improves significantly the forecasts based on both ANNs and “phase-space reconstruction”. Such proposal has not been consid ered in respect to “phase-space reconstruction” in literature so far.

Merging of river training and restoration in river basin management

N. Tamai

Kanazawa University, Kanazawa, Japan

ABSTRACT: River training works have been executed for flood control or flood damage mitigation and water

resources development. Human impacts, for instance, reservoirs, flood levees, straightening of channels, intake

structures and so on, have altered natural rivers to great extent. Now river engineers are requested to cope with

ever increasing flood peaks and to work for restoration of altered rivers. In some cases river training works and

restoration are understood as a choice between two things. But the author points out that this is a fault of dualism.

When our target is to make basin-wide utility maximum, we cannot resort to conventional flood control

schemes. We need to pay much attention to non-structural means including floodplain management and river

restoration. Floodplain management is one of tools for demand control in land use. River restoration is one of

ways for human demand control. In river restoration it is essentially important to give more space or freedom to

rivers. This will be accomplished by human demand control. River restoration is a symbolic slogan to accomplish

a multiple purpose project considering flood damage mitigation and conservation of ecosystems for river basin

management.

1 INTRODUCTION

River training works have been executed for flood con

trol or flood mitigation and water resources develop

ment. Human impacts, for instance, reservoirs, flood

levees, straightening of channels, intake structures and

so on, have altered natural rivers to great extent. Now

river engineers are requested to work for restoration of

altered rivers. In some cases river training works and

restoration are understood as a choice between two

things. But the author points out that this is a fault of

dualism.

Human impacts on natural environment becomes

bigger and bigger since industrial revolution. One

clear example is global warming. Human activities

developed to exceed capacity of natural environment.

Human impacts have reached to an extent to exceed a righting moment of environment in the latter half of the 20th century. Then nature cannot recover its original state and entered into an irreversible process of deterioration. Under such conditions we need asset management to conserve nature as finite resources. When we understand the essential features of nat ural asset of a river basin, we will obtain a unified view of entity of a river basin including natural dis turbances, human impacts and responses of a basin system, and succession of ecosystems in a basin. We need to change paradigm from selection by dualism to coexistence by consensus among all stakeholders. 2 FLOOD CONTROL AND A NEW CONCEPT OF BASIN MANAGEMENT At first interaction between human activities and their consequences in river basins is summarized in the area of flood control. The goal of this chapter is to establish a new concept for amalgamation of flood control/ flood mitigation and river restoration. 2.1 Does flood control investment bring about safer society? Design flood discharge increases as flood control works develop. In Figure 1 the historical increase of the fundamental design discharge in case of theTone River that has the largest basin area in Japan is shown. In the present Master Plan authorized in 1980 the fundamental design discharge is 22,000 m 3 /s in which peak cut 6000 m 3 /s is planned by reservoirs and a diversion channel. The river channel and flood levees are designed to cope with the allotted discharge of 16,000m 3 /s to the river channel. In this master plan a probabilistic approach was adopted for the first time in determination of the fundamental design flood. Starting from the basin-wide river improvement work planned in 1901, observed maximum discharge was adopted as the design flood until the master plan of 1949. It is clear that the design discharge increased as we make efforts for flood control works and total invest

ment to flood control increases. In other words flood control works brought about larger amount of peak discharge.

The design flood of the Yodo River that plays a major role for water resources in Osaka area experienced a similar increase. Why does this anomaly happen? The key factor of this anomaly is feedback from human activities in a river basin to a river channel. When flood control works succeed into a certain level, human settlement to a river basin increases and economic activities develop under safer situation from threatening of flooding. Higher rate of urbanization and economic activities tend to develop with positive feedback with each other.

Comparison of the variation of the design discharge with societal items, population and gross domestic product, is shown in Figures 2 & 3. We can recognize good correlation of an increasing rate between the design flood and GDP. But we had sharp reduction in GDP just after theWorldWar II.Therefore, tendency in GDP curve shows unusual disturbance around 1945.

Flood control works creates safer living conditions in a river basin. Goals of investment for flood control are to protect floodplain from flood for more safe space for human beings and higher economic products.

In this sense Figure 2 shows that goals of flood con

trol projects are accomplished in Japan because GDP

showed good growth in the 20th century.

But urbanization and higher economic activities

generate negative side effects on a river channel.

Urbanization means decrease of forest areas and agri

cultural land, and increase of non-permeable areas.

These changes cause larger amount of runoff and

faster convergence of water into river channels. In par

allel with higher economic activities human society

needs much wider space and in consequence, rivers

are confined into a narrow space between flood lev

ees. Infiltration in forest and agricultural land reduces

and temporary storage capacity in river basins is lost

by housing projects and industrial activities. Conse

quently, the fundamental design flood from a river 0 5,000

Figure 1. Historical variation of the fundamental design

discharge of the Tone River in the Master Plan. basin

increases and arrival time of floods becomes short as we develop river improvement works. Ironically river channels receive bigger flood and water stage becomes higher as a consequence of river improvement works. Therefore, advanced level of flood control projects and larger return period do not necessarily mean that our life becomes safer. 2.2 How can we create comprehensively safe society? As we see in the section 2.1 series of flood control works generate larger design flood. This means that a flood control project needs another flood control works of a larger scale in the future. A typical chain to show the consequences is as follows. In this expression an arrow shows resulted changes of social and hydrological factors in a river basin. A flood 0 5,000 10,000 15,000 20,000 25,000 30,000 1880 1900 1920 1940 1960 1980 2000 design flood (Tone River) national population GDP basinwide population Figure 2. Comparison of the variation of the design discharge of the Tone River with societal items (Unit is as follows: design discharge, m 3 /s; national population, 10 thousand persons; GDP, 10 billion yen, adjusted as of 1980; basin-wide population, thousand persons). 0 5,000 10,000 15,000 20,000 1880 1900 1920 1940 1960 1980 design flood (Yodo River) national population GDP Figure 3. control project is executed. → The river channel has

larger conveyance of flow and becomes safer against

flooding. →Increase of population in river basins

occur. → Urbanization develops. → Higher indus

trial activities develop. → Land use in riparian zones

develops. → Increase of peak discharge is generated

by the change of hydrological processes in a river

basin. →Riparian zones become vulnerable to flood

ing again. → A new project for higher level of flood

control becomes necessary.

We need to remind that flood is a consequence of

human settlement. There is no damage even if the water stage becomes extremely high in a river basin under purely wild conditions. Under wild situation a high flow is only a scene of natural disturbances and we recognize no flood damage. This fundamental characteristic is shown in Table 1.

The development of projects and recent tendency related with flood control are summarized in Table 2. Traditionally river engineers were engaged in flood control projects or flood protection projects. Engineers hoped that they were able to control peak discharge and water stage by constructing regulating structures of a flood in a river basin. Engineers tended to con sider that when the objectives of the master plan were accomplished, safety level for residents in a river basin was satisfied according to their calculation. But most of engineers considered only behavior of flood in river channels that they constructed. They did not pay much attention to human reactions in a river basin. Human behavior in a river basin is more dynamic than that engineers considered in a planning stage. Once soci ety is given a safe condition in a river basin, land use is altered to satisfy people’s desire that never stops expanding.

Developments of human activities in a river basin

continuously require additional flood protection works

Table 1. Difference in high flow and a flood by human

factor. Natural condition With human settlement

High flow High flow Flood, damage Table 2. Classification of projects related with floods. Typical facilities Project Objectives Basic strategy or systems Flood control • Reduction of the peak discharge Structural means • Reservoir • Reduction of the water stage • Retarding basin • Diversion channel Damage mitigation • Flood plain management Non-structural means • Insurance • Evacuation from flood plain • Hazard map • Rescue systems as described in a previous section. Through experiences we gradually understand the following facts in river basins. Firstly, even if a mater plan is completed, a larger flood that exceeds a project level is possible as natural phenomena. Secondly, development of river basin makes damage potential in flood-affected area higher and higher. Thirdly, judgment of safety level by that of each facility, for instance, levee height, reservoir capacity, conveyance of river channels and diversion channels, is insufficient. Safety level of facilities is calculated for a single purpose of the facility and it does not explain safety level for residents. Voices to require real safety of residents not the safety of facilities became strong during recent decades and importance of “non-structural means” is recognized in society. We understand that we cannot control flood that occurs as a natural event but we can only mitigate flood damage by “structural means” combined with “non-structural means”. The target of non-structural means of flood control is to decrease damage potential. For example, in 1997 executive order by the President of the US already requested to avoid further development activities in floodplains below the water stage of a flood the return period of which is 100 years. 3 AMALGAMATION OF RIVER RESTORATION WITH FLOODPLAIN MANAGEMENT 3.1 Dilemma caused by human impacts The discussion stated above is summarized schematically in Figure 4. The figure shows that development of river improvement works, which is shown by a thin solid line in Figure 4, steadily increases safety. A safer river basin is quite attractive for land developers and industrialists. They start turning forests and agricultural fields into residential and industrial areas. Land use change is accelerated by population increase in urban areas. Due to increase of non-permeable land surfaces in a river basin, peak discharge increases and arrival time of flood decreases. According to our experience urbanization occurs explosively as shown in

Figure 4 where solid squares stand for human impacts and their consequences, such as, population, urban ization, peak discharge, etc. When urbanization rate exceeds certain level, say 50%, river improvement works become very difficult because available land is quite limited and land price becomes too expen sive although we suffer from frequent floods with higher damage potential. Reducing factors shown by triangles in Figure 4 show reduction of redundancy with hazards, such as, arrival time of flood, resilience for evacuation, etc. Reduction of these factors corre sponds to the increase of vulnerability of urban areas against flood.

In Figure 4 a bold solid line shows basin-wide utility or safety.The basin-wide utility is not a simple increas ing function like safety by river improvement works. Safety of river improvement works indicates safety of a river channel. Once better condition is achieved, “increasing factors” and “decreasing factors” in a river basin emerge as human or social responses as are

0

10

40

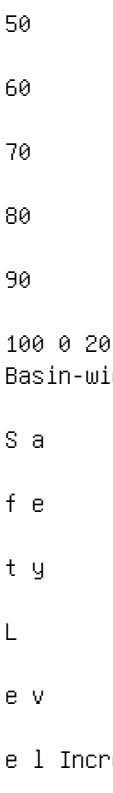

Figure 4. River improvement works and basin-wide utility

(Modified from a figure in the final report of the Forum for

Public Involvement and Basic Plan ofYoshino River (2001).).

Table 3. Summary of a feedback loop in basin development projects and their social influences. Associated changes in a river basin Objectives of a single project under conventional institutional Reducing or deteriorating Project structure factor Increasing factor Flood Lower probability of Forest, agricultural field, Urbanization, non-permeable control flooding arrival time land, peak discharge Water Larger reservoir Water quality Eutrophication (retarding resources capacity time), affected area Safe and Larger gross Natural resources, Impacts on prosperous life domestic product Biological diversity environment in river basins discussed in this section. Therefore, a manager of a river basin needs to consider not only conditions of a river channel (a thin solid line in Figure 4) but also nonlinear social responses (triangle and square symbols in Figure 4) at the same time. If adverse effects by other factors on flooding in a river basin as a whole become very large, basin-wide utility or safety begins to reduce with normal river improvement works

as shown by a solid bold line in Figure 4. We are facing with such situations in many countries, regardless of developed and developing countries. I want to show that similar discussion can be applied to discussion in water resources and river environment later. Therefore, let me suggest you to pay attention to the point that general terms are used in Figure 4 to explain essential factors in the problem instead of specific terms in flood control. Feedback loops in basin development projects in river engineering and their social influences are summarized in Table 3. Impact and response by projects for flood control, water resources development, and natural environment in a river basin are listed up in the table and the similar discussion and categorization can be applied to all of them. Figure 4 shows a dilemma that the optimum condition for a part of a system is not the optimum for the whole system. We understand that flood control projects are not the optimum solution to secure comprehensive utility or safety of a whole basin and the mechanism of interaction of major components in a river basin is described in Figure 4. When we recognize that pressure of urbanization is difficult to suppress and in urbanized area it is very difficult to raise safety level only by conventional means. We need to resort to non-structural means for flood mitigation in parallel with structural means. This phase corresponds to the peak in basin-wide utility in Figure 4. Through structural means for flood control we constructed many structures in a river basin and consequently altered natural conditions of a river basin. Therefore, structural means of flood control stands for alteration of a river channel and a basin.

3.2 Toward basin-wide consensus – farewell to dualism

Non-structural means include floodplain manage

ment. For floodplain management we need a council

that is composed of all stakeholders, typically, man

agers of governments, water users, residents, and

audits or experts. In floodplain management final

conclusion may require conservation of hydrological

mechanism, conservation of wetlands, conservation of

agricultural fields, etc. Conservation can be said a core

part of river restoration. Therefore, river restoration is re-presented by conservation of natural conditions. Conservation principles introduce certain constraints to land developers, farmers, recreational activities and so on. In other words floodplain management is demand control in land use. In this sense river restoration is a synonym of floodplain management. Demand control in water resources and human activities are easily understood using Table 3. Demand control is not to maximize objectives of each single project in the first column of Table 3. In other words demand control is required to derive balance between increasing factor (human needs) and reducing factor (natural assets).

There is delicate difference in terminology. “Flood plain management” was conventionally used in the area of non-structural means of flood mitigation. In this paper the conventional concept is called as “floodplain management conventional”. “Floodplain management conventional” was introduced only for flood damage mitigation and considered quantity of water only. But floodplain management in this paper includes wider aspects. This is called as “floodplain management new”. “Floodplain management new” includes management of all water related systems in

a river basin, for instance, quantity, quality, riparian ecosystems, aquatic recreation, water ethics, local traditions of water related events and so on. River restoration in a broader sense means restoration of all aspects in water related systems. Frequently river restoration is used for enhancement of natural components for ecosystems in a river basin. But natural components are used symbolically for easy understanding of new aspects. It is emphasized that “river restoration” is a synonym of “floodplain management new”.

Flood mitigation and river restoration are not conflicting two factors in “floodplain management new”. Let me give two examples to explain one project can contribute both to river restoration and flood mitigation. Example 1 is re-meandering of a straightened channel. Re-meandering is a symbolic project in restoration works. A meandering river channel provides less water surface gradient and reduces flow velocity. At downstream of re-meandering reach concentration of river water is avoided and consequently we can deduce flood peak. Example 2 is conservation and restoration of wetlands. Wetlands serve as retarding basins for flood mitigation, provide various habitats to ecosystems, and can contribute to natural conservation in a river basin. We need to deepen the concept of “floodplain management new” and basic principles to guide actual projects in a river basin under “floodplain management new”. In order to reach to consensus among all stakeholders we need to apart from dualism. Furthermore, we

need to develop a decision support system that is able to evaluate ecosystems and value of environmental assets quantitatively. 4 A NEW HORIZON FOR ECO-COMPATIBLE BASIN MANAGEMENT 4.1 What is eco-compatibility? It is difficult to give a rigorous definition to ecocompatibility in one sentence like “turbulence”. Therefore, examples are introduced in the following paragraphs, in which eco-compatibility is satisfied. In this paper we saw several cases that a single purpose project tends to confront with conservation of natural environment. Then we consider that a multiple stakeholder approach is necessary. In this multiple stakeholder approach ecosystems or nature restoration takes part in the discussion as one of players. A multiple stakeholder approach is one of examples of eco-compatible way in river basin management. We already discussed tensions between flood control or flood mitigation and nature restoration, and water resources development and nature restoration in previous chapters. It is shown that merging of flood mitigation with nature restoration is possible and balance between water resources and nature restoration brings about comprehensive optimum condition in a river basin. These are examples of eco-compatible basin management. 4.2 Economic aspects in eco-compatible basin management From Figure 4 we can obtain an important result on a basic economic aspect in “river basin management new”. The peak in utility curve in Figure 4 appears in a middle level of investment for flood control project (The abscissa corresponds to investment to a flood control project.). This means that a single-purpose flood control project cannot attain a bigger utility even though we increase the amount of investment after the investment level reaches to this optimum point. This means safety level of a conventional flood control project need not to be very high. It should be reasonably high by a plan, say, FC. Let us denote the safety level of this FC is FC-year flood. In order to obtain higher safety level than FC-year flood we need to adopt combination with flood mitigation by non-structural

means. The additional cost for higher safety than FC

year flood should be used not for structural means

but for non-structural means. Usually a cost curve

for flood control facilities increases nonlinearly with

increase of safety level. Adoption of eco-compatible

techniques has ample room to seek for less costly flood

mitigation.

4.3 Examples of eco-compatible basin management

How can we cope with or live with floods? In order to accomplish this goal we need to change the principle of our activities from “flood control” to “eco-compatible basin management”. Examples are recent projects in the Mississippi and the Yangtze. After the great floods in 1993 and 1998, respectively, we understood that human beings could not control big floods with man made facilities and we need to give more space for rivers. Under natural conditions whole alluvial plain is space for rivers and swollen water during floods can move into floodplain freely. But recently rivers are confined into very narrow space between flood lev ees. Consequently, water stage during flood becomes higher and higher in a river channel as we want rain water to disappear around us as fast as possible.

In the Mississippi basin after the great flood of 1993 major emphasis is laid on flood mitigation or floodplain management. In this new plan buy out, restoration of wetlands, set back of flood levees, and others are core programs for flood mitigation. “Buy out” means a program to stimulate residents in flood plain in danger of inundation to buy alternate land in a higher location out of floodplain for movement.

In the Yangtze basin similar principles were intro

duced after the great flood of 1998. Major projects are

re-forestation in mountains, removal of farmers' dikes

in reclaimed land along Dong Ting Lake, move of

people in floodplain or islands in the river course to

higher location and so on.

In these two biggest class river basins in the world

amalgamation of nature restoration and flood mitiga

tion takes real form in many actual projects. They are

Floods management in Uruguay. The case study of Tacuarembó city

A. Capeluto, L. Teixeira & G. López

Instituto de Mecánica de los Fluidos e Ingeniería Ambiental (IMFIA). Facultad de Ingeniería. Universidad

de la República, Montevideo, Uruguay

ABSTRACT: Tacuarembó city may serve as a paradigm for several province capital cities of Uruguay with

respect to floods. As a consequence of this, the presented method of analysis as well as the developed solutions

can be used for many other cases. This paper summarizes the results of the work developed at the IMFIA in order

to diagnose and evaluate alternatives of flood management in the city of Tacuarembó. The problem approach

is based on an integrated watershed management scope, considering different dimensions of present problems.

Hydrologic and hydrodynamic models of the river basin were implemented, which allowed the analysis of different

alternatives of flood management. A multi-objective decision-making analysis was used as a complementary

tool for the determination of the most suitable solution. Particularly the possibility of combining structural and nonstructural measures was analyzed. The reliability of proposed flood control structures was analyzed by techniques of probabilistic methods.

1 INTRODUCTION

For Uruguay, floods mean not only a very important economical problem (about two million dollars per year of losses as a direct consequence) but also a socio environmental one that hits mainly on lower socio economical layers and have several repercussions on cities' activities.

Almost every important city in our country has suf fered floods and assume them as one of their main structural problem.

Since its origins Uruguay has shown a typical urban population distribution, living nowadays in the cities about 90% of the total population in the country.

The rising number of people settling on risky areas is a consequence of a complex process mainly influ enced by the migratory country-city process as well as the expulsion of poorest people from consoli dated areas of the cities. These people settle down in a very precarious way, consolidating areas of great vulnerability when occupying floodplains.

Additionally, in recent years, particularly since 1990

this problem has become even more relevant as a result

of the detected increase of floods frequency and inten

sity, reaching even consolidated areas, what can be

related to the notorious increase of rainfall frequency

and intensity. The last could be probably connected

with climate changes or climatic variability cycles

longer than a year.

Given the explained situation, as well as the lack

of specific studies for this kind of problem, and the scarcity of specific management and protection initiatives, it has become evident the need of developing a local analysis methodology that should fit local tools and resources in order to control or reduce impacts produced by this kind of events. This article summarizes the obtained experience in the case study of Tacuarembó city floods. As a riverside city, and because of its topographic and population characteristics, Tacuarembó turns to be a paradigmatic case of many other important cities in our country. In this way, a methodological approach is presented here, to analyze floods problem in Uruguay.The results point out the importance several tools like hydrodynamic models, multi-objective decision-making analyses and probabilistic reliability analyses. The applied approach provides a better understanding of the problem, what gives the chance to find the most suitable solution. 2 METHODOLOGY The basic analysis tool used in the present study were the hydrologic and hydrodynamic models of the case study system. In this way, a diagnosis of the present situation as well as the analysis of several flood protection and control alternatives were possible, considering both structural and non-structural measures. By implementing a multi-objective decisionmaking analysis, a systemic approach was intended in order to select an optimal alternative, considering not

only the classic technical and economical dimensions

of the problem, but also its environmental dimension.

Finally, reliability of the selected flood control

measures was estimated by probabilistic analysis tech

niques, using level II methods. These methods make it possible to analyze the failure of a work as a system by considering the uncertainties of every involved variable, as well as compare their respective incidence on reliability results.

2.1 Diagnosis tools

First, a diagnosis of the present situation was done, considering on one side the territorial occupation reality, and on the other a statistical analysis of rainfall data in order to detect a possible raising tendency of extreme events parameters related to climate changes or hyper-annual climatic cycles. This analysis was performed over existing data series of Tacuarembó city. As it is well known, annual accumulated rainfall records have been increasing in recent years in Uruguay. This accumulated rainfall increase does not necessarily implies an increase of potential flood cases, because these ones depend on maximum rainfall records whose durations are similar to the basin's concentration time. Consequently, it becomes particularly interesting to observe what happens to annual maximum daily rainfall, discharge, and stages records (behavior and evolution), what results to be representative information of extreme events in this case. Statistical information of rainfall data of

Tacuarembó city was also compared with similar statistical information of Artigas city, being able in this way to determine if the observed phenomena at Tacuarembó was just a particular case or we could find a larger area with similar behavior.

2.2 Hydrologic and hydrodynamic modeling

For this case study, hydrologic and hydrodynamic models were implemented for the analyzed basin, whose scheme is presented in figure 1.

The topographic information employed in this study was based, on one hand, on existing information (basi cally 1/50 000 topographic maps with level curves each 10 m), and on the other hand on a specially car ried out survey. The last involved a special flight, and several field measurements including 21 flood plain cross sections, 9 of the riverbed, and the bridges geom etry, gathering enough information so as to generate a digital terrain model.

Daily rainfall data was available for the period 1940–2001 at Tacuarembó, having also available sta tistical rainfall information of Artigas city, Genta (2003).

Hydrometric and gauge information as well as the estimated discharge – stage curves were supplied by Figure 1. Sub-basins of the modeled stretch. the national office of river management (DNH). From available information

(previous inspection), only the 1986-2001 period stage data and its corresponding gauged discharge were taken into account. The hydrological model of the upstream border subbasin as well as those of tributary sub-basins allowed to define the border conditions of the hydrodynamic model except for the downstream border. Hydrological modeling would finally supply the corresponding hydrographs at each border point. Hydrographs were obtained by applying the Triangular Unit Hydrograph method on the synthetically generated storm. The storm was configured by following theAlternate Block method which uses the IDF curves information. With respect to the hydrodynamic model, it can be outlined that a 49 km stretch was represented, taking also into account the hydrologic modeling of 36 tributaries. The involved catchment area is 1378 km 2 , being 663 km 2 of them situated downstream Tacuarembó city. The downstream border condition that best fitted the gauged data turned out to be a Q-h relationship given by Manning's equation, considering the last cross section geometry and a hydraulic slope equal to the riverbed slope (So= 0.0003). It was demonstrated by this model that flow conditions in this border section does not affect flow characteristics in the area of interest, what leads to conclude that the model was large enough to study this area. Part of model results, obtained after calibration and validation are presented in figure 2. Looking at model outputs of maximum river stages at those cross sections associated to the city's stretch, encroached areas of the city were identified for several return period floods. Superimposing the identified areas over the streets and estates plans of the city, damaged families and blocks were quantified for each return period event.

Figure 2. Comparison between modeled and measured

stages at Parque Batlle station.

Based on this information and the statistical study

results, present situation was described and evaluated.

2.3 The alternatives

Several flood control alternatives were also studied

by representing different structural measures in the

model. Effects of each alternative on floods was deter

mined by noticing the stage decreasing at "Paso del

Bote" cross section with respect to the present situa
tion. Damages were quantified in the same way it was
done for the present case, counting affected estates and
blocks and finally identifying the relieved cases.
The evaluated structural alternatives arise not only
from the working group, but also from interaction of
this group with local people, turning it necessary to
evaluate some alternatives that even being technically
unsuitable, they were present in the collective thought.
In this way, it was possible to quantify the negligible
relevance of these structural solutions and show them
to local people so that they could finally approve the
resulting alternative. This interaction experience can
be outlined itself as a relevant aspect.
The evaluated alternatives were the following:

- Dredging of the riverbed along a 6.5 km stretch
downstream the city.
- Removal of two existing bridges at the city.
- Construction of riverside levees
- Construction of regulating dam upstream
Tacuarembó city.

2.4 Multi-objective decision-making analysis

Aiming to select an optimal solution among the stud
ied group of alternatives, a special approach would
be necessary in order to methodically evaluate each

alternative from different points of view in accor

dance to several dimensions, and mark them to allow

a comparison. Technical, economical and environmental aspects where considered as the relevant criteria or analysis dimensions in order to value the different alternatives. To compare every alternative, valuation scales were established for each dimension, depending on the fulfillment of certain requisites inherent to the considered dimension, the mark assigned to the alternative.Taking an example, from the technical point of view a solution would be valued depending on the offered protection (temporally and spatially), if it tends to a definitive solution (as it could be land use regulation), or if it protects in a transitory way, etc. In a similar way, certain requirements were established for the economical (costs and financial feasibility) and the environmental (different kinds of impacts and degrees of incidence). Every alternative was marked in a range from 1 to 10 according to each criteria. Weighting coefficients were assigned to each dimension in order to outline their relative importance. A calibration process was required to establish the weight coefficients in order to properly reflect the assumed relevance order. This methodology allowed to order the alternatives in a systematic way, taking simultaneously into account several analysis dimensions and their relative importance. 2.5 Reliability calculations methodology Goodness of design as well as suitability of the proposed flood control measures will depend on how well predicted the behavior of these structures is in occasion of flood events along their service period. In a traditional analysis uncertainty is just attributed to rainfall. This information is represented in the way of IDF curves or probability density functions for each rainfall duration. By considering this information, service life and admissible risk criteria, the control structure is traditionally designed. It must be outlined that in this approach, reliability is just estimated as the probability of rainfall records of exceeding certain value. However, random character can also be attributed to many other design variables. Probabilistic methods of reliability calculation, particularly level II methods, Nowak (2000), Thoft-Christensen (1982), consider these other uncertainties. They work with the probability density functions associated to the respective variables and a mathematical expression of the studied failure mechanism, the so called failure function. Level II methods operate assuming every variable as normally distributed and

doing some approximations when estimating their associated probability. Among their advantages, it must be outlined that they allow to evaluate the relevance of each variable on reliability results. In this way it is possible to obtain a more balanced design by pointing out which are the critical variables with reference to reliability.

Table 1. Considered cases in reliability analysis. P 3,Tr N r N A T c

Case A X X X

Case B X X X

Case C X X

Case D X X

Case E X X X

Case 0 X

In the case study a regulating earth dam was selected

as a flood control measure. Its reliability with respect

to the overtopping failure mechanism was calculated

by means of level II methods, considering several

design variables as probabilistic and comparing results

to those calculated by the traditional analysis.

Overtopping failure mechanism can be represented

by the following reliability function:

where failure domain is defined as that which leads

to negative values of g, being H C the height of the

dam embankment and H máx the maximum height of

the reservoir water raised by an occurrence of a flood.

The variables considered with an associated ran

dom character were: rainfall intensity (3 hours, T r

years) P 3,Tr , roughness coefficient of the riverbed Nr, roughness coefficient of the culverts N A , and one of the dam's upstream sub-basin's concentration time Tc. These variables were not all simultaneously consid ered as probabilistic, proposing different case studies depending on which variable was considered in a prob abilistic way. In Table 1 the studied cases are defined, marking with a cross when the variable was considered in a probabilistic manner.

3 RESULTS

3.1 Diagnosis

This case study may serve as a paradigm for many of most important cities in Uruguay, that similarly to Tacuarembó, have historically developed beside rivers. Land use pattern and its evolution have been related to the migratory and urban expansion processes, which have given as a notorious result the occupation of Tacuarembó Chico's and some of its tributaries' flood plains all over the city. This people settle down in a very precarious way converting the riversides in really vulnerable areas to recurrent floods.

In conclusion, flood plains occupation turn to be one of the obvious causes of flood related damages that Tacuarembó city has historically endured.

On the other hand, as a result of the statistical

study, a notorious increase of the maximum rainfall Table 2. Results for 10, 25, 50, and 100 years return period. Affected Event Stage (m) Affected blocks properties T r = 10 yrs 128.63 55 326 T r = 25 yrs 128.96 86 613 T r = 50 yrs 129.30 107 871 T r = 100 yrs 129.62 123 1133 intensities as well as of the accumulated rainfall depth in the last 30 years must be pointed out. A concomitant variation was also observed when analyzing maximum river stages. Concentration time of Tacuarembó Chico river's basin at Tacuarembó city is about 24 hours. On the other hand the used accumulated rainfall depth data are daily. Consequently the detected increasing tendency of the daily maximum registries is coherent with the increasing tendency of the annual maximum discharges. 3.2 Hydrodynamic model. Present situation and analyzed measures Present situation is described in a precise manner by analyzing the following results of the hydrodynamic model. Table 3 summarizes relevant information and behavior of present situation and the analyzed alternatives for a 10 year return period event. The alternatives are compared in terms of the maximum stage at Paso del Bote, quantity of affected properties, consequences, quantity of alleviated properties, economical cost, environmental cost and how the measure protects for larger return period events. The multi-objective decision-making analysis is summarized in Table 4. Punctuation assigned to each alternative according to different analysis dimensions, weight coefficients (first column) as well as total punctuation per alternative, all of them are presented in this table. In spite of the fact that weight coefficients, scales and marks are established in a quite subjective way, this method helps to set up the implicit designer's criteria in a clear manner by quantifying them, and so making it possible to compare different alternatives. Furthermore, it also helps to re-evaluate the relative relevance attributed to each dimension. This method does not bring new results that were no implicit in designer's or decider's mind, but will help to present and see them in a clear way. From multi-objective decision-making analysis it was clearly set that a regulating earth dam would be the most adequate alternative as a flood control measure for Tacuarembó. Dam's location is shown in figure 3. In addition to this measure, non-structural Table 3. Summary of results for present situation and different flood control alternatives. Present Bridge Riverside Regulating situation Dredging opening levee dam Stage (m) 128.63 128.58 128.28 127.18 127.22 Affected properties 326 326 248 89 89 Consequences – – – – Urban drainage Bridge affection Relieved properties – 0 78 237 237 Cost (million dollars) – 4.5 12 3 1.75 Environmental cost – Very high Medium High Medium Degree of

Figure 3. Location of the regulating dam.

measures should also be implemented, being of prior

consideration land use policies and regulations. Other

non-structural measures were also evaluated, being

worth pointing out that of people transfer away from

risk areas.

The recommended measure consists on a regulat

ing earth filled dam 15 meters high, with an estimated retaining capacity of 85 000 000 m 3 , and a maximum pool area of about 1800 hectares. The discharge is automatic, by means of rectangular culverts. The proposed structural measure must necessarily be complemented and coordinated with land use regulations that would gradually tend to remove the established housings from the flood plain. Particular emphasis is required to control indiscriminate land occupation on protected areas. The accomplished damage reduction that results from floods frequency reduction can eventually be equaled or reversed as a result of an increased investment on protected areas. Structures are designed to endure up to specific return period events. Being these surpassed, works will not cope with them, leaving then protected areas again exposed to damage. The larger is the allowed investment, the larger is the potential damage. Civil works inspire false confidence feelings, and planners must be aware of this. 3.3 Reliability of the proposed dam Reliability results can be summarized by the following tables. Table 5. Reliability of dam for different cases and different service periods. Service period (years) Case 0 Case A Case B Case C Case D Case E 1 0,9999305 0,9999302 0,9999082 0,9999254 0,9999028 0,9998728 10 0,9993052 0,9993022 0,9990824 0,9992543 0,9990284 0,9987287 30 0,9979171 0,9979081 0,9972497 0,9977644 0,9970881 0,9961910 50 0,9965309 0,9965160 0,9954203 0,9962768 0,9951516 0,9936598 Table 6. Return period of the event that leads to failure (annual reliability). Return Period (years) Case 0 14 388 Case A 13 693 Case B 8715 Case C 12 256 Case D 7736 Case E 5000

On Table 5, variation on reliability results can be noticed for annual values as well as for different service periods when considering different combinations of variables with probabilistic behavior.

On Table 6 annual reliability results are shown in a more familiar way by showing the return period associated to that event that will induce to failure of the dam for each case. Special attention must be paid to the fact that, while according to the traditional analysis failure could be expected for a 14 000 years return period event, probabilistic methods would demonstrate that the dam will fail just for a 5000 years return period event when considering the larger number of probabilistic variables.

In order to apply these methods, it becomes a basic requirement to gather statistical information of design variables. In this way, a better representation of the corresponding uncertainties can be achieved by fitting probability density functions to finally obtain more certain reliability results.

4 CONCLUSIONS

A diagnosis of urban floods problem in Uruguay is presented, concluding that the notorious raise in frequency as well as in intensity of these kind of events in the last decades, is clearly associated with two rea

sons. On one hand, changes in land use occupation

New trends in flood risk analysis: working with 2D flow models,

laser DEM and a GIS environment

Laboratory of Applied Hydrodynamics and Hydraulic Constructions, University of Liege,

Belgium Second author: Research Fellow of the National Fund for Scientific Research (Belgium)

ABSTRACT: This paper outlines the integration of new and accurate laser DEM into the determination of

floodplains. Global and robust GIS environment is absolutely necessary to manage this very large amounts of

topographic data. The development and interaction of 2D flow models, simplified or not, ensures to offer more

accurate and flexible physically based tools to the decision-makers.

1 INTRODUCTION

Floods control, risk mapping and more generally

river management are topics on which a wide range

of decision-makers focus a permanently increasing

attention. The first step in flood hazard analysis and

management, prior to any mitigation policy, is a thor

ough understanding and assessing of the level of risk.

Though lots of work has been carried out for decades

in the field, a genuinely reliable and efficient mod

elling of the corresponding flows remains a challenge.

In spite of improved computation capacities, collect

ing, handling and validating large sets of topographic data as well as simulation results are still challenging tasks for hydro-modellers and practitioners.

The present paper covers a description and a detailed comparison of two state-of-the-art numerical models to be used as strategic tools in the process of flood risk assessment and mitigation. The first one is a 2D model for hydrodynamics, simplified according to the diffusive assumption (DM), quickly generating initial flow fields for the second one, a complete model based on the shallow water equations (SWE).

Those two models are integrated in the software package WOLF, which has been developed for almost ten years at the University of Liege. WOLF includes a complete set of numerical models for simulating free surface flows (process-oriented and spatially dis tributed hydrology [1], 1D and 2D hydrodynamics [2, 3], sediment transport [4, 5], air entrainment [6] …) as well as optimisation algorithms. This optimi sation tool, based on the innovative Genetic Algo rithms, allows an objective calibration of friction coefficients [7].

A user-friendly GIS interface, entirely designed and implemented by the authors, makes the preand post-processing operations very convenient. Import and export operations are easily feasible from and to various

classical GIS tools. Different layers of maps can be handled to analyse information related to topography, ground characteristics, vegetation density and hydrodynamic fields. The validation of the model has been performed continuously for many years and is still running. Two cases studies on Belgian rivers are presented to illustrate inundation applications in a urban area. 2 MATHEMATICAL MODEL DESCRIPTION The SWE model simulates any steady or unsteady situation, possibly taking into consideration air transport or sediment-laden flows, in Cartesian or curvilinear coordinates. It is in addition coupled to a turbulence model based on the Prandtl mixing length concept.The DM model is restricted to a specific range of Froude and kinematic numbers, but requires significantly less CPU resources. In the shallow-water approach (SWE) the only assumption states that velocities normal to a main flow direction are smaller than those in the main flow direction.As a consequence the pressure field is found to be almost hydrostatic everywhere. In the diffusive model (DM) a similar depth-averaging operation is combined to the following hypothesis: the purely advective terms can be neglected. As a consequence the free surface slope is simply balanced by the friction term. The divergence form of the SWE include the mass balance:

and the momentum balance:

where Einstein’s convention of summation over

repeated subscripts has been used. H represents the

free surface elevation, h is the water height, q i desig

nates the specific discharge in direction i and S fi is the

friction slope.

The diffusive assumption leads to a considerable

simplification of the momentum equations:

A friction law is needed for closure of both the SWE

and the DM models. Its general formulation can be

stated as a relation between the discharge, the water

height and the slope:

where α, γ and χ are coefficients suitable for the

description of floodplain flows.

A more detailed description of the mathematical formulation can be found in the recent paper by Archambeau et al [3].

3 NUMERICAL IMPLEMENTATION

A finite volume scheme is used in all models to ensure exact mass conservativity. An upwind scheme is exploited for space discretization of the SWE model and extended to the DM.

An implicit pseudo-time integration scheme, suitable for solving non-transient problems, is implemented in the SWE model. In the DM model the GMRES or Conjugate Gradients (CG) algorithms are used for evaluating iteratively the solution of the symmetric linearized system.

3.1 Space discretization and boundary conditions

An original upwind scheme is applied for space discretization of the complete set of equations. The stability of this second order upwind scheme has been demonstrated through a theoretical study of the mathematical system as well as a von Neumann stability analysis. Much care has been taken to handle correctly the source terms representing topography gradients. A fitted spatial upwinded scheme is developed similarly to the previously described DM.

The models allow the user to specify any inflow

discharge as an upstream boundary condition (BC). The downstream boundary condition can be a free surface elevation, a water height, a Froude number or even no specified condition if the outflow regime is supercritical (SWE only). 3.2 Resolution of the DM model The primary goal of the diffusive formulation is the quick computation of steady-state approximate solutions. Those first estimations of the final solution are intended to serve as fairly good initial condition for the complete SWE model. A first approach for solving the DM might be a pseudo-time evolution, starting from a user-defined initial condition. In order to prevail the possibility of using large time steps, this pseudo-time integration would need to be performed in an implicit way. A second approach is to disregard the time derivative term and to solve a non-linear system of time independent equations. Both methods are obviously very similar if the time step becomes very large. Various iterative techniques are available for solving such very large linear systems. Among them are the methods “by point”, such as Jacobi, Gaus-Seidel,…[8, 9] or full implicit such as ADI [10–14], GMRES [15], CG [16–19]. 3.3 Time integration for the SWE model An implicit pseudo-time integration scheme, suitable for solving steady-state problems, is implemented in the SWE model. This technique allows much larger time steps than those acceptable for an explicit time integration. On the other hand the resolution procedure is more intricate. A Newton method is exploited to solve the large non-linear system. The successive linearized systems are solved with the powerful GMRES algorithm, which is advantageously coupled to a preconditioner. For this purpose an incomplete LU decomposition is applied. The Switched EvolutionRelaxation technique by Van Leer has been used to continuously optimise the time step. In the DM model the GMRES or CG algorithms are also used for evaluating iteratively the solution of the symmetric linearized system. In both cases the resolution procedure represents a very challenging step because of the complexity of a cost-effective evaluation of the Jaobian matrix. WOLF performs this job effectively, by storing only non-zero elements and their location in the large sparse matrix. 3.4 Friction modelling River and floodplain flows are mainly driven by topography gradients and by friction effects. The total friction includes three components: bottom friction (drag and roughness), wall friction and internal friction.

The bottom friction is classically modelled thanks

to an empirical law, such as the Manning formula.

The DM and SWE models allow the definition of a spatially non uniform roughness coefficient. This parameter can thus easily be distributed as a function of soil properties, vegetation and sub-grid bed forms.

The friction along vertical boundaries, such as bank walls, is introduced thanks to a physically based model developed by the authors. This modification of the classical friction law presents the advantage of leading to a correct hydraulic radius of the 2D cross-section in case of sufficiently shallow flows.

The internal friction is properly reproduced by the turbulence model.

3.5 More features of the numerical codes

In addition an automatic mesh refinement is used to enhance the convergence rate towards accurate steady state solutions [3]. The computations are performed on several successive grids, first very coarse and then gradually refined. The hydrodynamic fields are almost stabilized when the computer code automatically jumps onto the next grid. This fully automatic method considerably reduces the number of cells in the first grids. Then, the successive so-called initial solutions are interpolated from the coarser towards

the finer grid in terms of both water heights and discharges.

In case of an explicit pseudo-time evolution: the stable time step is significantly larger since it depends linearly on the size of the mesh. For an implicit evo lution, the benefits of the quadratic convergence are reached since the initial solution is sufficiently close to the steady state solution. In spite of extra com putation time to re-mesh and linearly interpolate the initial solution the overall CPU time saving is clearly appealing.

4 LASER DEM

Very recently, the Belgian Ministry of Facilities and Transport (MET) and most particularly the Service of Hydrology Studies (SETHY) acquired a very accurate DEM on the floodplains in the whole Walloon Region. A method of airborne laser was used for the prox imity inundation zones of the entire rivers network. An echo-sonar was applied for measuring the bathymetry of the main channel, exclusively on navigable rivers (Fig. 1).

Consequently, the poor and inaccurate 3D informa tion that has been available for many years, 30 m square and an error of several meters in altitude, is replaced by an exceptional DEM since the precision in altitude

is 15 cm and, on top of that, the information density is

one point per square meter. Figure 1. Principle of the DEM acquisition by airborne laser and echo-sonar ship. Figure 2a. Bëthane: IGN topography (digitalized contour line map). Figure 2b. Béthane: laser data including buildings. To illustrate the accuracy of the DEM, (Figs. 2 and 3) two comparisons of data on the same regions are presented, the towns of Bethane and Eupen (Belgium). Generally, specific features of flows in urban area (such as blockage by buildings, slowing down of the wave front propagation, etc) were taken into account by a local modification of the roughness coefficient. While, with this new set of topographic data, irregularities of the topography influence directly the inundation flows. This permits to refocus the roughness coefficient to more proper physical values.

Figure 3a. Eupen: IGN topography (digitalized contour line

map).

Figure 3b. Eupen: laser data including buildings.

5 GIS ENVIRONMENT

Management and operations on such a large set of

data requires a robust and efficient preand postpro

cessing. A GIS environment, entirely designed and

implemented by the authors, performs this tools. Sev

eral databases containing topographic data, pictures of

historic floods, characteristics of structures along the

rivers (dams, bridges, weirs, …) are stored on a sin

gle data server with their geographic coordinates to be

easily downloaded by any modeller.

A difficult task for the preprocessing is the inter

polation of the minor river bed when no distributed

data are available. It’s the case on the non-navigable

rivers where the airborne laser is the only source of the DEM. In fact, the laser beam doesn't cross the water surface. Therefore, the only available information are based on cross-sections and thus must be interpolated in 3D to recompose a global DEM. Original methods were developed by Detrembleur [20] to fulfil this job and are implemented in the WOLF package.

6 CASES STUDIES

6.1 Flood induced inundation on the river Ourthe

The first case proposed is a flood event on the river Ourthe that occurs 14 February 2002 (study commissioned by the MET-SETHY). Figure 4. Example of DEM interpolation of the river bed and aggregation with the airborne laser data (river Ourthe, Tilff; Belgium). Figure 5. Comparison between water heights and aerial picture of the flood event (football field). Characteristics of the simulation are: • Discharge: 570 m 3 /s • Length of the real computed river: 7.35 km • Total number of computations cells: 300.000 • Uniform size of the cells: 2× 2 m • Two hydraulic structures: a mobile dam and a fixed sill.

Figure 6. Comparison between water heights and aerial picture of the flood event (water-pool of the "Prés de Tilff").

In this case, there were discrepancies between the first simulation and the real observations. Actually, the interpolation of the main river bed was computed based on cross sections taken in '70 years. Actually, major modifications of this bed were realized to mit igate floods in the town of Tilff. The right bank was

newly designed to a vertical wall when it was com

puted with a slope of 4 : 4. A complete dredging was

performed too.

After the introduction of the different modifications

in the topography, the results improved significantly

as demonstrate the comparisons between numeri

cal water heights and aerial pictures of the floods

(Figs. 5-6).

6.2 Flood inundation on the river Lesse

The second case presented in this paper consists in

the verification of the works protecting from floods

in Han-sur-Lesse on the river Lesse, Belgium (study

commissioned by DGRNE, Walloon Region).

This town, which attracts tourists, is located at

the downstream of geological caves that divert the

free surface flow of the Lesse trough underground

flow. A maximum discharge of about 25 m 3 /s can Downstream Upstream Outflow from the caves Diversion channel Figure 7. General topography of Han-sur-Lesse. Figure 8. Enlargement of the downstream topography. pass by this way. The rest is forced to return to the historical bed. A first stage was the building of a diversion channel to increase the natural discharge capacity of the river. A side-weir creates a separation between the two channels. Thus, the normal discharge only flows in the natural river. In addition, a second stage consists in the building of walls and small dyke to prohibit the overflow in the urban zone. Figures 8 and 9 illustrate the precision of the laser DEM. The drainage channels of farm fields, residual erosion of historical floodings, current small dyke and the interpolated topography of the main river bed can be observed. Characteristics of the simulations are: • Discharge: 150 m 3 /s • Length of the real computed river: 4 km • Total number of computations cells: 450.000 •

Variable size of cells (Fig. 10) • Hydraulic structures: a mobile dam and several fixed sills. A multibloc discretization is used in this problem to limit the total computation time. The finest information is conserved along the river trough the town but a progressive increase in the cells size is performed towards the extremities of the computation domain to ensure evanescent boundary conditions. Small dykes

Figure 10. Multiblocs discretization.

Figure 11. Free surface elevation for the flood of January

2003.

The reference event dates from Jannuary 2003

because it’s the only flood after the building of the

diversion channel. Figures 11 and 12 illustrate the

results in terms of free surface elevation and water

heights. A good concordance is obtained between

computed results and field observations, and thus both

in extension of the flood and in water heights.

An observation of the results in terms of Froude

numbers (Fig. 13) permits to indentify a critical Figure 12. Water heights for the flood of January 2003. Table 1. Comparison of water height for the flood of January 2003. Observation (cm) Computed (cm) 82 86 5 15-30 center of street 25 5 along the houses 20 30 94 95 113 117 100 100 Figure 13. Froude number for the flood of January 2003. section, just before the side-weir, in an obvious place. The real nature of the problem consists in a rise of the bottom topography due to an outcrop. This critical section reduces significantly the favourable effect of the stage 1 on the upstream. Furthermore, stage 2 doesn’t modify this place bacause the buildings just stop at the upstream. Thus, recommendations were made to

Figure 14. Free surface elevation after the building of

stage 2 (m).

the manager to extent the works to redraw this portion

of river.

The check of the stage 2 consists in a simulation

where the town is untouchable by the floods. Thus,

impermeable boundary conditions are applied on the

outline of the town. A comparison of the final water

heights with the heights of walls and dykes concludes

to a good design of the works.

7 CONCLUSION

The present paper offers a comprehensive compari

son between both numerical models (DM and SWE)

for very practical applications such as floodplains

modelling and inundation maps plotting. The key

advantages brought by the GIS environment are

also illustrated, focusing on the major contemporary

requirements of decision-makers in the field of flood

control.

Further research is currently undertaken for investi

gating sediment transport effects and their simulation.

Floods control in Argentina: learning from the experience

R.A. Lopardo & R. Seoane

INA (National Water Institute), Ezeiza, Argentina

ABSTRACT: This paper deals with flood control and mitigation in large flatland valleys in Argentina and

describes the advances, mistakes and omissions over the last twenty years. The authors analyse the advances

made and the problems encountered when developing a hydrological measurement network for planning and

designing hydraulic structures and a hydrological early warning system. The paper focuses on flood problems

along the Paraná River, which affected urban areas, the Southern Salado River, which inundated rich lands

in the flatland region of the Province of Buenos Aires, and the Northern Salado River, that caused a severe

flood event in 2003. Historically, Argentina has sought to tame floods through the construction of infrastructure

works to protect the people of the floodplains. Recent disasters and the need to protect the environment call for

non-structural measures, such as floodplain zoning, development control, flood warning and disaster mitigation

planning.

1 INTRODUCTION

Flood disasters are a major issue in the life of soci

eties.The objective of this paper is to describe different

aspects of flood-related problems, to stress the impor

tance of warning systems, to assess the impact of

climate change in Argentina, and to perform a hydro

logical analysis of the significant rise in the Salado River basin that affected the city of Santa Fe.

Integrated water resources planning, through a basin level Master Plan for flood protection that links and binds structures and protection works with non structural solutions to control and mitigate emergencies, is a critical and urgent task not only in Argentina and other Latin American countries but also in other parts of the world. Such a plan must be designed when waters are still. Even if the population “forgets about the water problem” because there are no floods, local authorities must take basic needs into account and implement a flood control and disaster prevention policy.

Located in the southern region of the Americas, Argentina has a population of 37 million and a total area of 2,500,000 km 2 . Because of their uneven distribution, water resources in Argentina cause both floods and droughts.

Humid regions represent 24% of the country’s total area and account for 68% of the total population. On the other hand, arid regions represent 61% of the country’s total area but account for only 6% of the population. Mean discharge in Argentina is 25,836 m 3 /s (22,000 m 3 per inhabitant per year), i.e., 22 times higher

than the “water stress level” adopted by the United Nations. The Plata River Basin, including the lowland “Pampas” region, accounts for 86% of the total discharge in Argentina. This basin is the most important in terms of human concentration, urban development and economic activity in the country. The waters of the Bermejo, Paraná, Paraguay and Uruguay rivers, which are part of the Plata system, are shared with Bolivia, Brazil, Paraguay and Uruguay. The Northern Salado River rises in the northwestern region of Argentina and is a tributary of the Paraná River. The Southern Salado River Basin, in the heart of the agricultural and cattle region of the “Pampas” region, forms the southern border of the Plata River Basin. Heavy convective rains in the “Pampas” Central Region are expected to aggravate actual physical conditions (reservoirs that are already full and groundwater levels that are already high). Floods are likely to cause damages, particularly in areas with vertical drainage processes, as is the case of the sandy soils in the NW region of the Province of Buenos Aires. This situation may seriously affect sowing and harvesting activities that are intensively carried out in the region. 2 THE LOWLAND “SOUTHERN” SALADO RIVER REGION The Central “Pampas” (Area Pampeana Central) comprises part of the provinces of San Luis, La Pampa,

BuenosAires, Santa Fe and Córdoba.The Salado River

Basin extends over an area of 168,100 km 2 compris

ing 58 districts of the Province of Buenos Aires with

a population of 1.3 million. The area’s main economic

activity is agriculture, accounting for 25% of the coun

try’s total farm crops, 30% of total beef production, and

18% of dairy produce.

Irregular rains and summer rainfall deficit are some

of the climate conditions prevailing in the basin. In the

last 25 years there have been periods of very heavy

rainfall resulting in extensive floods, such as those

which affected the north-eastern sub-region in 1986,

1987, 1993, and the recent floods in Lake La Picasa's command area, among others.

There is neither natural drainage nor important waterways. The region's average slope is 3.5 cm/km; it lacks a systematized drainage network; and floods are caused by excessive rainfall. Unplanned construction of canals has transferred the problem from upstream to downstream areas.

In the last few years the area has been subject to an intensive agricultural development process whereby it shifted from cattle raising to grain and crop farming activities.

Water management is crucial for the region's devel opment. Lack of a sustained policy to manage flood problems is one of the main obstacles to their solu tion. It should be noted that each province in the basin has embarked upon solving their own flood prob lems. Only two studies (1985, 1999) have attempted a comprehensive diagnosis of the region as a whole.

In order to provide a general view of the case under analysis, we may break down the system into three layers: the natural system, the socio-economic system, both of them interacting and generating mutual actions and reactions, and an institutional subsystem or layer which is closely linked to the other two.

Physically, the NW region of the Province of Buenos Aires is not a standard river basin. Since 1900, when records began to be kept, annual evaporation exceeded rainfall. Downstream from the Salado River, trib utaries and other rivers flowing into the sea were channelized (1920) to flush water out and render the land suitable for human occupation.

The natural system is described using the concep tual hydrological model for flatland areas which refers to a landscape with low energy to drain water flows and to the lack of defined basin limits and of major drainage structures or waterways. Consequently, there is a strong predominance of vertical variables, such as infiltration and evaporation, over horizontal vari ables, which relate to drainage. Surplus rainfall water is stored in shallow surface areas and drainage is gen erated by accumulation of water and the creation of a hydraulic gradient.

Environmentally, the rainfall regime has great space and time variability and an uneven seasonal distribution though the amount of rain has increased since 1971. The socio-economic subsystem is characterized by low population density, extensive grain and crop farming and cattle raising activities – depending on the suitability of the soils – little infrastructure – both in terms of road and canal networks – and unplanned land use. Flood problems have increased due to inadequate agricultural practices and poorly designed canals and embankments which sometimes affect downstream areas. As regards the political-institutional subsystem, Argentina has adopted a federal system for administering its natural resources.

According to the National Constitution, natural resources are owned by the provinces and it is them who manage and supervise their water resources without the participation of the national government. Lack of a long-term active policy for flood management is another issue affecting the region. In the absence of a policy for the entire hydrological system, each province in the basin seeks to find its own solutions to their water problems. 3 THE SALADO RIVER MASTER PLAN To mitigate the damages caused by torrential floods and severe droughts, the Integrated Master Plan for the Salado River Basin seeks to promote sustainable use of water resources, improve economic conditions, and preserve environmental parameters in the Salado River. Local roads as well as provincial and national highways have been flooded causing serious economic restrictions that had a strong impact on the transportation of agricultural and dairy products. Not only fields that were not flooded but also important urban and rural areas experienced production losses for they were isolated from the rest. Estimates show that the value of agricultural production will rise by 10% as a result of drainage works and reservoir construction. The area protected by the Plan represents almost 35% of the basin's total area (6 million hectares). Maximum annual benefits to be derived directly from the construction of works for the whole basin are estimated to be in the order of U$55 million for grain and crop farming; U$93 million for cattle raising; U$19 million for dairy products; U$10 million for land-holding infrastructure; U$60 million from changes in land use; and U$9 million for public rural infrastructure. This makes up an annual total of mean direct benefits of almost U$250 million once the whole hydraulic infrastructure included in the Plan has been executed.

The total cost of investments in hydraulic drainage

and storage works, rural roads and environmental mit

igation measures is in the order of U$1.5 to U$1.8

billion. Investment in the said works is planned to take

place over a fifteen to eighteen year period, i.e., an

annual investment of around U$100 million per year.

The Net Present Value of the investment at a 10% rate

is U$193 million and the Economic Internal Rate of

Return for the whole project is 14.3%.

Finally, it is important to note that the Province of BuenosAires has enacted Law No. 11257 fostering the creation of Basin Committees and Management Consortia to manage resources and monitor infrastructure construction. The Provincial Government, together with the respective districts, has started outreach and consultation tasks in the belief that dissemination and consultation of the Plan among farmers and potential beneficiaries is a key factor for its success.

From a technical point of view, the Integrated Master Plan is based on analytical tools that facilitate the understanding of the basin's operation and make it possible to predict how it will react to planned interventions. The plan will provide a well-balanced social and environmental development framework by implementing a range of different measures that supplement one another and are coordinated by a flexible execution scheme. Non-structural measures in the Master Plan are:

(a) An Institutional Program that includes institutional restructuring, legal and fiscal measures, capacity building, transparent management tools, and public education and awareness.

(b) An Environmental Program that includes management of wet and inundated areas, environmental analysis and monitoring, regulation of fishing, integrated natural resources management, and wildlife and habitat management.

(c) A Sustainable Economic Development Program that includes soil conservation, improvement of natural pastures, intensive cattle breeding activities, promotion and development of smalland medium-sized tourism businesses, and rural employment opportunities.

4 FLOODS IN THE DOWNSTREAM AREA OF

THE PLATA RIVER BASIN

The Plata River Basin comprises an area of some

3,150,000 km 2 over the territories of Bolivia, Paraguay,

Brazil, Uruguay and Argentina. It is made up of the

following river basins: Alto Paraná, Paraná, Paraguay,

Uruguay, Iguazú, Pilcomayo and Bermejo (Figure 1).

The total population in the basin is over 80 mil

lion that contribute 70% of the gross domestic product of these five countries. More than forty hydroelectric dams, that produce 60% of the region's total energy, have been built on the rivers flowing in the basin (the well-known Itaipú Dam among them). Some rivers are navigable, and implementation of the "ParanáParaguay Hidrovía" navigation scheme is under way. The Paraná River Basin, between 16 ∘ and 34 ∘ of southern latitude, covers an important part of Brazil, the entire territory of Paraguay, part of Bolivia, and an important part of Argentina. The catchment area in the Delta upstream from the Plata River is 2,600,000 km 2 . The Paraná River Basin comprises four distinct rivers: the Paraguay River, the Iguazú River, the Upper Paraná River and the Paraná River (downstream from the confluence with the Paraguay River). The present analysis focuses on that final stretch of the Paraná River. The town of Paso de la Patria (Argentina) is on the confluence of the Upper Paraná and Paraguay rivers, 687 km downstream from the left bank of the Iguazú River. The Paraná River section at Paso de la Patria is 3,500 m wide, with plenty of islands and sandy banks. This section is 1,240 km from the city of Buenos Aires, where the river rises (Soldano, 1947). Downstream from the confluence with the Paraguay River, the Paraná River turns into a typical "flatland river with movable bed": permanent discharges and low slopes, dune translation on a fine sand bed, and a big floodplain that is inundated only during copious discharges, with the exception of some islands. Downstream from the city of Corrientes, the river

slope decreases gradually reaching some 0.01 m/km. Systematic water level measurements in the Paraná River started in 1901. As noted by Aisiks (1984), if the Paraná River does not reach the 5.5 m level mark in the city of Corrientes (discharging some 25,000 m 3 /s), there will be no flood damages in the valley upstream and downstream from that section. An analysis of historical data shows that the Paraná River floods every three or four years and although floods can occur in any season, they are more likely to take place in February and March with a secondary rise in June. The most severe floods occurred in 1905, 1966, 1982-1983, 1992 and 1998. A discharge was gauged in June 1905 (Q= 43,000 m 3 /s); in March 1966 the discharge was 41,000 m 3 /s. The 1983 flood had special characteristics because it had started in 1982 after heavy rainfall saturated the soil in the basin. A high discharge was recorded at the Corrientes section (Q= 51,300 m 3 /s) on May 30th, there was a second peak on July 12th (Q= 45,000 m 3 /s), and the maximum discharge took place on July 18th (Q= 61,000 m 3 /s). A large-scale coupled ocean-atmosphere oscillation in the Pacific Ocean, known as the El Niño-Southern Oscillation (ENSO), is related to interannual variations in precipitation and streamflow in several region of the world. Sea Surface Temperature index (SST) and the Southern Oscillation Index (SOI) are used to

Figure 1. La Plata river basin.

quantify ENSO. SST anomaly is the sea surface tem

perature departure from the long term mean, averaged

over a eastern and central equatorial Pacific Ocean.

The warm El Niño phase is associated with high SST

anomalies and the higher annual discharge in River

Paraná at Corrientes and Posadas (Amarasekera et al.,

1997). Floods related with warm phase of El Niño

observed during 1982/83, 1992/93 and 1997/98 and

the median of daily discharges are shown at the figure 2

for the period 1884/2002.

In 1992 a devastating flood in the city of Santa Fe

reached a discharge of Q= 54,000 m 3 /s. The water

level was higher than the one measured during the

large flood of 1982-1983 due to excessive anthropic

pressure on the floodplains (Paoli, 1997).

The increase in mean discharges and water levels

since 1970 shows that the volume of water over the

last three decades has increased with respect to sim

ilar periods in the past. Even if this condition is not

permanent, it can be associated to the global climate

change.

Statistical data on monthly minimum mean lev

els (month of September) and on the usual monthly

maximum mean level (month of April) for the period

1970-1992 show a seasonal variation amplitude that

decreases through time because flows have been 0 10000 20000 30000 40000 50000 60000 70000 1 3 1 6 1 9 1 1 2 1 1 5 1 1 8 1 2 1 1 2 4 1 2 7 1 3 0 1 3 3 1 3 6 1 3 9 1 4 2 1 4 5 1 4 8 1 5 1 1 5 4 1 5 7 1 6 0 1 6 3 1 6 6 1 6 9 1 7 2 1 Time (days) D i s c h a r g e (m 3 / s) Median 1884/2002 Observed 1982/1983 Observed 1991/1992 Observed 1997/1998 Figure 2. Discharges at Corrientes. Median and discharges associates with ENSO events. regulated by many Brazilian hydroelectric dams in the upstream basin. The said amplitude reduction exerts a greater impact on low water levels than on high water levels. During severe floods the system’s regulation capacity is negligible.

In the case of large rivers flowing in flatland val

leys with low slopes, extreme floods can be predicted

and forecasted by means of rainfall data in the basin’s

upstream and middle regions. It must be pointed that

even if storm characteristics and conditions are criti

cal, the magnitude of the flood will strongly depend on the previous humidity content in the basin. If the basin's soil is saturated, if the floodplains are water logged, and if the reservoirs are full, a storm with heavy rainfall will trigger a flooding disaster.

5 THE HYDROLOGICAL EARLY WARNING SYSTEM

A hydrological warning system provides the Civil Defence and Disaster Control authorities with antici pated information on exceptional hydrological events. Forecasts must be precise. If floods are not accurately predicted credibility is lost and the cost of emergency measures increases. If the flooding event is not pre dicted, disaster occurs. Precision and regularity of the forecasting system is of the utmost importance for the preservation of life and minimisation of material losses in affected areas.

As a result of the 1982/83 floods, the National Sec retariat of Water Resources created a Hydrological Warning System for Plata River Basin, which is oper ated by the National Water Institute (Goniadzki, 1997). The severe flood of 1992 caused serious damages in the northeastern provinces of Argentina. The Inter American Bank for Reconstruction and Promotion (BIRF) has granted a loan for the flooding restora

tion program that is administered by the Ministry of the Interior. This agency has signed an agreement with the National Water Institute to improve the technological capacity of the Hydrological Warning System for the Plata River Basin.

The Hydrological Warning System must operate on a continuous basis because it forecasts not only floods but also low water levels strongly required for navigation purposes. In the cities of Rosario and Santa Fe the Paraná River's water level can be predicted more than twenty days in advance while in other cities (Formosa, Corrientes, Goya) prediction levels are different.

The flood of 1992, when INA's early warning system was already in operation, caused physical damages that amounted to approximately U$500 million. Water levels were considerably higher than in 1966; however, in spite of the fact that there was a remarkable increase in investments and in population density, there were less physical damages.

The Plata River Basin System comprises simulation and forecasting models for different real-time hydrological variables. A probabilistic focus is represented by multiple lineal regression models using a recursive estimation algorithm for the parameters with the Kalman filter. Deterministic hydrological models

are represented by the Sacramento Model of the National Weather Service, calibrated for the downstream basin of the Iguazú River (24,000 km 2), Chavasse and Seoane (1997). The HEC-HMS precipitation-discharge transformation model developed by the U.S. Corps of Engineers has been calibrated and is used for the Uruguay River Basin. For floods along the Paraná River, a hydrodynamic translation model (Ezeiza V) has been developed by the National Water Institute (Menéndez, 1998). The early warning system includes a series of tasks which range from rainfall monitoring (in different time scales) to short-and long-term rainfall forecasting in selected catchments. Main field tasks are: (a) estimation of rainfall areal distribution by means of satellite images combined with field data (real precipitation in the catchment); (b) areal distribution calculation with the “Hydroestimator” model; (c) assessment of different rainfall estimation techniques for use in several hydrological and neuronal models; (d) convective systems monitoring through satellite images (use of the FORTACC algorithm-FORecasting and Tracking for Active Cloud Clusters); and e) mean areal precipitation forecasting (72 hours) at catchment level. The catchment areas of the Southern Salado River (2001) and of the Salado River (2003) are examples of rainfall estimated with satellite images in cooperation with the National Environmental Data and Information Service (NESDIS/NOAA) from USA. 6 RECENT FLOODING OF THE CITY OF SANTA FE During the last days of April and early in May 2003 the city of Santa Fe, subject to periodic flooding of the Paraná River, experienced a most devastating flood induced by a tributary of the Paraná River, called Salado River (which is not the Salado River that flows in the “Pampas” region of Buenos Aires, some 1,000 km south). The loss of more than twenty human lives, the large number of people evacuated, and the huge economic damages characterize this event as a disaster of catastrophic proportions. More than one third of the city’s area, including strategic buildings such as schools, hospitals and an electric power plant, was suddenly inundated. The downstream basin of the Salado River a typical flatland river is in the Province of Santa Fe. The upstream basin flow has little influence on maximum downstream flow discharges. The Salado River flows into the Paraná River between the cities of Santa Fe and Santo Tome. The Salado River mean discharge in the downstream region is 145,6 m 3 /s. Mean annual precipitation in the area ranged from 1,100 mm in the east to 800 mm

in the west during the 1941/1970 period, and from

1,200 mm to 900 mm during the 1971/2000 period.

The natural flatland landscape has been modified by anthropogenic activities (construction of roads, canals and land works). In the 1990s the Province of Santa Fe implemented diverse structural and non-structural measures such as Argentina's flood program, which was launched with World Bank financing after the big flood of 1992.

The 2003 flood was caused by heavy rains that fell within the southern basin and which lasted from April 22 to April 24 (saturation of the basin had been detected in January 2003). Most of the rainfall turned into surface flow.

The discharge measured at the railway bridge near the city of Santa Fe was Q= 3,100 m 3 /s. Previous hydrological analyses (INA, 1998) estimated a dis charge of 3,010 m 3 /s (some kilometres upstream from that section) for a recurrence period T= 100 years.

Fortunately, the mighty Salado River flood did not occur simultaneously with the Paraná River flood since the backwater effect would have further raised the Salado River water levels.

Some of the anthropogenic activities that con tributed to the disaster were:

- A small part of the western protection, erected between 1994 and 1998, was not finished. It seems

that this disaster could have been prevented if construction of the structure had been completed.

- The Santa Fe-Rosario highway bridge is narrow (155 m) representing only 8% of the total valley's width (2,000 m) in this section. During the flood the backwater effect raised the water level more than 80 cm and overflowed the western protection 1,800 m upstream from the bridge.
- Since March 2003 the Hydrological Warning System of the Plata River Basin had been reporting that the basin was saturated and that the region was being affected by severe storms. The flood wave translation was already known to the authorities because of the floods that affected small villages and caused bridge damages in the upstream region.
- Land use in the floodplains is not adequately regulated. Construction of permanent strategic buildings in floodplains should not be authorized.
- The city lacked a flood contingency plan for evacuation and social assistance during and after the event.

In conclusion, the vulnerability (from a physical point of view) of the city of Santa Fe is the result of the following major factors:

- Its geographical location: it is located between two

big uncontrolled rivers and its large floodplains have

been occupied due to urban expansion.

• Its flat topography: inadequate rainfall runoff, low

lands close to the rivers, and high groundwater table

levels. • It lacks comprehensive and consistent urban planning. • Its roads and protection works: inadequate for the increasing severe water scenarios and poor operation and maintenance plans. • People should be made aware of the fact that a protected area is still a risk area. The province failed to implement non-structural measures to supplement infra-structure works and to devise an explicit contingency plan. The damages caused by the extraordinary rise of the Salado River are the result of both natural and anthropogenic vulnerability. 7 RESEARCH PRIORITIES There are no infallible flood protection structures. A flood protection structure may overflow during its life cycle or have construction problems or be poorly maintained. Therefore, non-structural measures are a must. It is worth pointing out that flood risk assessment and formulation of emergency plans are tasks involving many disciplines in which professionals in water sciences must participate using a holistic approach. It should be borne in mind that integrated water resources management related to floods and rising water levels calls for the need to investigate the means to improve administrative and economic management. Some lines of research and development to be considered in the near future, always aiming at diminishing risks and economic losses during critical water events, are: • Research to improve hydrological modelling in order to gain a better understanding of the selection criteria and of statistic function parameters required to define the flow-return period relationship. This must be supplemented with enhanced knowledge of mathematical modelling of rain-flow transformation processes in order to safely predict possible rated flows for protection works. • Research to improve hydrodynamic flood modelling in watercourses. It is particularly important to obtain accurate basic data on floodplain topography in areas of low slope, bathymetries, gauging and water quality monitoring. • Research to use at – a local scale – the results derived from climate prediction models (such as those used for the El Niño-Southern Oscillation phenomenon). • Comprehensive water resources management studies related to rising water levels and to jurisdictional, economic and legal problems derived from

flood protection structural and non-structural measures. • Research to optimise hydraulic design of infrastructure waterworks.

• Specific research to solve water-related problems in urban areas (floods, waterlogging, and pollution).

• Research on sustainable water resources use to prevent future water disasters.

• Development of techniques that combine satel lite information with forecasting and monitoring activities.

“Science and Technology must be useful to soci ety”. This means that there must be an interaction between knowledge expansion and the society that will benefit from it, that boundary conditions must be taken into account so that society can profit from scientific production. The services rendered by a hydrological warning system is only one part of an overall process which should be fully operational to be meaningful.

8 CONCLUSIONS

The academic community, specialized agencies and decision-making bodies must interact in order to opti mise human and material resources and generate greater benefits to society.

It is then crucial to develop, adapt and promote the use of modern hydro-meteorological technologies and to establish hydrological measurement networks. This

can be achieved through the joint action of specialized state agencies that have shown an interest in working together. Cooperation links should be cemented, both formally and informally, across the institutions engaged in emergency response and mitigation activities. This is the only way to promote adequate and timely actions to withstand adversity.

One major problem specialists in this field currently face relates to dissemination of technological advances. Engineers, in particular, have always been and are still considered by the media as some sort of mercenaries reporting to a powerful client who puts the rest of the population at risk. Their voice and opinions are always questioned by professionals from other disciplines, by the journalists themselves, and by people that lack technological knowledge.

Moreover, decision-making bodies usually get conflicting messages about the benefits of some measures

Flood management and control in an urban environment – Diakoniaris case study

E.I. Daniil, S. Michas, G. Bouklis, P.L. Lazaridou & L.S. Lazarides

HYDROEXIGIANTIKI, L. S. Lazarides & Co. Consulting Engineers, Marousi, Greece

ABSTRACT: In this paper the implementation of general design considerations for flood management and control in an urban environment and their application to

Diakoniaris project is presented. Diakoniaris river is

located near Patra city, Peloponnese, Greece. It has ephemeral flow, flows from south to north and for the last

5 km before its outlet to the sea flows through the west suburbs of the city of Patra. Presently only 1 km, just before

the outlet, is trained with a closed section, running under the main avenue of the area. According to city planning

this avenue is proposed to be extended to the north to meet the highway circumventing Patra city, currently under

construction. The design was based on an integrated watershed management approach, including works in the

upstream mountainous area and consideration of the impact of proposed diversions on adjacent basins. Sediment

control dams upstream and a sedimentation basin downstream of the new highway are proposed. Parallel to the

closed concrete section, which will have to be extended upstream under the new part of the road, additional

culverts running parallel to the existing one will be constructed.

1 INTRODUCTION

Integrated decision making for watershed manage

ment is not a simple task. Currently, different tools and

approaches are proposed by researchers, and a trend

for public involvement is evident in many countries.As

the state of the art is far from complete understanding

of the processes involved, many times, custom solu

tions, taking into consideration cultural and other local

features, should be preferred.

Diplas (2002) notes that although significant atten

tion has been paid recently on the impact that man induced changes have on the environment, this has been a well known fact for a very long time, dating back to Plato. While the concept of land use change is not new, the rate, scale, and kind of changes that have been taking place over the last hundred years or so have been unprecedented. Real progress in predicting the modifi cations caused by human activities within a watershed will require further disciplinary work, research at the interface between disciplines, and improved dynamic interaction of the processes occurring in the abiotic and biotic systems.

General design considerations and principles for flood protection and related stormwater drainage sys tem design, based on an integrated environmental approach, involving less technical works and preser vation of the physical condition of streams and creeks in urbanized areas have been presented (Daniil et al. 2000, Lazaridou et al. 2002). Special topics to be taken into consideration include sediment control through check dams and selection of design return period. The design period should be selected depending on the specific location, the associated design of the receiving stream or water body, and considering the consequences of a bigger flood than the one used for the design. It should always be kept in mind that the selected design should be implemented starting from the downstream end and special care should be used in main road crossings. 1.1 General design principles For flood protection design, regulation and management of streams passing through urban areas, an integrated environmental approach should be implemented and many factors taken into account (Daniil et al. 2000). Design considerations to be used as guidelines for practical use

are mentioned below. • Streams should remain in their physical condition, wherever possible. Channelization gains effectiveness by increasing channel slope and reducing bed resistance. This augments the velocity of flow and enables a channel to capacitate greater discharges without overbank flow and consequent flooding. However, rivers are not passive and their morphological structure responds to channelisation by

changing configuration, with undesirable and even

detrimental effects (Parker & Andres 1976).

• Technical works should be designed with environ

ment friendly materials and adapted to the natural

architecture.

• The design return period should be selected depend

ing on the specific location, the associated design

of the receiving stream or water body, and consider

ing the consequences of a bigger flood than the one

used for the design. Designing upstream reaches for

higher return periods than the downstream reaches

may have disastrous effects due to intense flooding.

• Special effort should be made to locate possible

sites for the construction of dams or reservoirs for

upstream flood control in order to avoid designing

a more costly stormwater drainage system.

• Alternative solutions should be evaluated to exam

ine if existing insufficient storm sewers can be used

as part of the new design system in their whole or

even partly instead of being destroyed and rebuilt.

• Sediment transport calculations and measures for

its control in populated areas are necessary.

• Geological mapping and assessment of possible hydrological flushing is also indispensable.

2 HYDROLOGY CONSIDERATIONS

Singh & Woolhiser (2002) in the 150 year anniversary hydrology paper discuss many aspects of mathemati cal modeling in watershed hydrology, illustrating the complexity of the problems involved.

In the case of complex basins and drainage systems, the use of hydrographs should be preferred over the rational method, that is widely used, but cannot easily give the spatial distribution of discharges over time. Design for a given return period is not uniquely defined and may vary considerably depending on the selection of the parameters and methodologies involved: choice of appropriate intensity-duration frequency (idf) curve, rainfall distribution, rainfall height and duration, unit hydrograph type. Implement ing the worst profile distribution may result in twice the design discharge, compared to the one result ing from rainfall heights computed by the idf curve without redistribution (Daniil & Lazaridis 2003). Yen (2000) notes that part of the misunderstanding comes from inadequate appreciation of probability and that the more serious problem is that the X-year return

period of what is not clearly specified.

2.1 Rainfall duration

A common recommendation is that the storm duration

should be sufficiently long so that the entire drainage

area is contributing to runoff, as a result it should

exceed the time of concentration and it is suggested

that it should be 3 to 4 times the concentration time. Concentration time can be severely shortened due to urbanization and river training works. In the USA the National Weather Service reports that the most frequent duration of runoff-producing rainfall is about 12 hours. Levy & McCuen (1999), based on observed data in Maryland, show that 24 hr is a good hypothetical storm. Storm types provided by the Soil Conservation Service (SCS) for different areas in the US have a 24 hr duration. The choice of rainfall duration, as a result, depends largely on the designer's interpretation of the data and the significance of the project. 2.2 Rainfall distribution Alternating block method distribution and Worst profile distribution tend to become popular in recent years. The alternating block method distribution produces a center-loaded storm, while the worst profile distribution produces the highest peak discharge for a given total rainfall height and unit hydrograph. Levy & McCuen (1999) report that actual data from six Maryland watersheds (5<A< 135 km 2) suggest that center-loaded design storms are appropriate. Packman & Kidd (1980) also reported that center-loaded hyetograph was most appropriate based on the analysis of data from the United Kingdom. The concern on the effect of rainfall distribution is also reflected in recent editions of commercially available software packages. HEC-HMS (USACE 2000) for example provides the user in the case of the frequency storm with the choice of placing the hydrograph peak at 25-33-50-67-75% of the storm duration. In every case the user has to give rainfall heights at predetermined times according to the idf curve and the program performs the redistribution. No option for the worst profile scenario is given and the 50% is usually considered the standard. Although the above choices do not give exactly the worst profile scenario, the user can determine the one that gives the highest peak. Eventually, a frequency or return period should be associated with rainfall distribution patterns, or alternatively certain patterns should be adopted for

given return periods of rainfall. 2.3 Unit hydrograph selection Determining an appropriate design hydrograph in ungaged basins becomes almost an art and depends largely on the experience of the design engineer. It involves choices of many parameters including rainfall distribution, once a type of unit hydrograph is selected. In the third edition of Design of Small Dams (US Dept. of the Interior, Bureau of Reclamation 1987) six types of dimensionless hydrographs are presented based on 162 reconstructed flood hydrographs. The Sierra Nevada type and the Rocky Mountain Thunderstorms seem applicable to some Greek mountainous

basins and have been used by the authors in recent

studies.

In order to apply these dimensionless hydrographs,

lag time has to be determined, based on the geomet

ric characteristics of the basin and a parameter, Kn.

Kn is an average Manning's n value representing the

hydraulic characteristics of the drainage network. For

Kn higher values are considered appropriate for devel

oping flood hydrographs of more common frequency

than, say the 100 yr event.

Lag time was originally defined by Horner & Flynt

as the ". . . time difference between . . . center of mass

of rainfall and center of mass of runoff. . .". Bureau of

Reclamation uses the following definition in conjunc

tion with the dimensionless hydrograph technique:

Lag time is the time from the midpoint of the unit

rainfall excess to the time that 50% of the volume

of unit runoff from the drainage basin has passed the

concentration point.

Lg is the unit hydrograph time in hours, C, N are constants N= 0.33, C= 26 Kn, L is the longest water course from the point of concentration to the boundary of the drainage basin in miles. The point of con centration is the location on the watercourse where a hydrograph is desired, Lca is the length along the longest watercourse from the point of concentration to a point opposite the centroid of the drainage basin in miles, and S is the overall slope of the longest watercourse (along L) in feet per mile.

Unit hydrographs by the Soil Conservation Service (SCS) can also be used and they are offered as an option in mathematical modeling programs (e.g. HEC-HMS), contrary to the aforementioned hydrographs given in the Design of Small Dams. A critical parameter again is the time to peak.

2.4 Design discharge – return period

Design for a given return period is not uniquely defined and may vary considerably depending on the selection of the parameters and methodologies involved: choice of appropriate idf curve, rainfall distribution, rainfall height and duration and unit hydrograph type.

Idf curves derived from a limited time series can not usually be extrapolated to predict rainfall depth at very high return periods. Koutsoyiannis & Baloutsos

(2000) have demonstrated that the General Extreme Value (GEV) distribution appears to be suitable for the analysis of annual maximum rainfall, its predictions for large return periods agree with the probable maximum precipitation estimated by the statistical method (Hershfield 1961, 1965) and an idf curve with a wide range of applicability can be derived. Koutsoyiannis' (1999) methodology provides at the same time a rainfall distribution even at those high return periods and no additional assumptions are needed. Equations of this type should be used wherever possible. The scale of the catchment area is also important in determining peak discharge, which is not directly proportional to the catchment area. Odgen & Dawdy (2003) based on data from an experimental watershed, 21.2 km 2 , report that on the average, individual runoff event peak discharges are described by a power law function of a catchment area. They also found that flood quantiles in nearly all subbasin are self-similar as described by a simple scaling theory. Finally, another consideration is the impact of stormwater on the water quality of the receiving water body. In some countries, environmental regulations exist that impose strict standards for water quality and measures preventing pollution due to stormwater inflow have to be taken. Calabro (2004) presents an interesting study and shows that design storms with triangular or Chicago shape and duration similar to the time of concentration of the catchment are in most case the worst regarding the water quality impact and can be used in the design. For complex drainage systems, computational platforms, such as HEC-HMS should be used, as they facilitate determination of time and spatial distribution of discharges. 3 DIAKONIARIS PROJECT Diakoniaris river is located near Patra city, Peloponnese, Greece (Fig. 1). It has ephemeral flow and flows from south to north. For the last 5 km before its outlet in the sea flows through the west suburbs of the city of Patra. Presently only 1 km, just before the outlet to the sea is trained with a closed section, running under the main avenue of the area. According to city planning this avenue is proposed to be extended to the north to meet the highway circumventing Patra city (PCH), currently under construction. 3.1 Background Diakoniaris river (Fig. 2) and its tributaries, Malamamoutis, Panagitsa, Romanos etc, used to have a total drainage area upstream of the new highway

of ~19.5 km 2 in the 70's, when part of Elekystra's (~9.6 km 2) basin was diverted through an open diversion channel to Glaykos river. The remaining basin ~9.8 km 2 develops on the west side of Panachaikos mountain from elevation +150 to +1150 m along a 5.2 km. In December 2001 a flood resulted in human losses, drawing public awareness to the problem and a new

Figure 1. Location of the project.

study of the project. The project in its introductory and preliminary stage was assigned to Hydroexigiantiki by the Ministry of the Environment, Planning and Public Works. Hydrology of the area, including idf relations and design discharges, was reevaluated.

In the mountainous area geological instabilities and erosion are observed in the area of neogenic formations. This is considered the main source for sediment production. Main sediment producing areas are located within Diakoniaris and Panagitsa catch ment areas. Sediment transport rate has not been determined from systematic measurements. However, based on field reconnaissance and on site obser vations after the December 2001 flood, it can be concluded that sediment yield is high, possibly more than 1000 m 3 /km 2 /yr. This value may be more than doubled for certain years. The river bed upstream of the city limits is wide and flows through a forested area. Within the city limits urban development has limited the width of the river bed and the floodplain has been

inhabited.

Sediment control upstream from PCH (Patra Cir

cumventing Highway) is crucial for the design of

Diakoniaris training works. Based on this realization

a final design study was performed for Diakoniaris

and downstream drainage network covering ~11 km 2

drainage area, under the assumption that the area

upstream of PCH will be diverted to Glaykos river.

Implementing this design the existing close section

was constructed with a 2× 6× 2 closed conduit sec

tion running for 400 m from the outlet to the sea and

upstream simple box culvert 6.0× 2.6 and 7.5× 2.6

up to station 1+ 100. Assuming that no significant sediment depositions reducing the conveyance of the system will take place, the existing structure can convey ~90 m 3 /s. The proposed Diakoniaris diversion to Glaykos was never constructed, with the exception of small area ~1 km 2 between Elekystra diversion and PCH. The rest of the watercourses continued to follow their natural course. 3.2 Intensity – duration – frequency curves The following idf curve determined in the old study (1984) and adopted with a fit for return period term in the hydraulic design of the new highway (PCH) where i intensity in mm/hr, t rainfall duration in hrs, T return period in years. The idf curve was compared to the one used in Xerias River Corinth, also in northern Peloponnese (Lazaridou et al., 2003). The idf curve adopted for Xerias river, constructed based on Koutsoyiannis methodology, was: where d is the rainfall duration in hours, i the rainfall intensity in mm/h and T the return period in years. The comparison of the two curves is given in graphical form in figure 3. Comparison of hydrographs for the return periods considered gave no significant difference in peak discharge between the two idf curves and consequently eq. (2), used for the design of other works in the area was used in modeling of Diakoniaris basin. The rainfall distribution resulting from the idf curve was also compared to the SCS synthetic storm hyetographs proposed for use in the USA for storms of 6 and

24 hours duration (Chow et al. 1988). Types I, IA are for the Pacific maritime climate with wet winters and dry summers. Type I is quite close to the alternating block method distribution applied to eq. (2) as shown in figure 4. 3.3 Design discharge – return period A return period of 50 years was specified as the lower acceptable return period in the environmental permit relating to the extension of Diakoniaris Avenue. Due to the complexity of the system it was deemed appropriate to model it in a HEC-HMS environment. Diakoniaris basin was modeled in great detail. Elekystra basin and part of Glaykos basin were also included F i g u r e 2 . G e n e r a l l a y o u t o f D i a k o n i a r i s b a s i n a n d d r a i n a g e s y s t e m . 0 50

in the model, but not with the same detail, in order to determine the impact of the proposed diversions.

Information from geologic and land resource maps was used for the determination of CN to appropriately include infiltration losses. In the upstream area there

is a small part of pseudoalpine zone and fir zone. The

largest part of the area just upstream of the city lim

its is covered by the broadleaved evergreen zone and

cultivated land and near the city limits there is a decid

uous oak zone. Near the sea we encounter alluvium

and tertiary deposits.

In their majority the soils can be considered to be in

category C with the exception of the area downstream

of Elekystra diversion channel that falls in category B.

Finally, for the modeling three CN curve numbers

were implemented: CN= 80 for the upstream Diako

niaris basin, CN= 75 for the areas outside the city

limits and CN= 85 for the areas within the city limits. 3.4 Hydrologic modeling For the Diakoniaris project the drainage area (~20 km 2) was modeled with HEC-HMS software. For the mountain area of the basin, hydrographs were also developed according to the design of Small Dams and compared to the SCS hydrographs obtained within the HEC-HMS environment. Many scenarios were run with different idf relations, return periods of 10, 20, 50 and 100 years and different rainfall distributions. Using the developed model many alternatives were examined: diversions both in the mountainous area, involving tunnels and open channels, and closed conduits in the urbanized area. The whole drainage system was modeled using HEC-HMS (Hydrologic Engineering Center – Hydrologic Modeling System). Modeling in the HEC-HMS environment includes three components. The basin model where the watersheds or basins are represented and hydrologic elements connected in a dendritic network to simulate runoff process. In this part losses, runoff transformations and open channel routing are selected. The meteorological model where precipitation to be used is given and the method for its distribution selected. The control specifications, where the duration and time step of the modeling is defined. 3.5 Hydrologic modeling parameters The whole drainage system was modeled using HECHMS with the following parameter selection: • Hydrographs according to SCS • SCS curve number loss model • Lag time was determined

using data from hydrographs given in Design of Small Dams and estimated flow velocities in concrete culverts in the order of 6 m/s • Flood routing through trained sections with the Muskingam – Cunge standard method. The final design discharges were determined for a 12-hour – center-loaded storm. For the Sierra Nevada type hydrograph, that is considered applicable to Diakoniaris area, where tp is the time to peak, D is the unit rainfall duration and Lg is the lag time. For a small unit duration, as assumed in HEC-HMS simulations This value was used as time to peak for the SCS hydrographs. 0

proposed diversions is presented.

4 SEDIMENT TRANSPORT

Geological and land resource maps along with new

geological studies performed for the study area and

especially the upstream sediment producing area, were

used for estimating sediment transport conditions in

the area.

Sediment production is high in the area causing

depositions in the closed sections and the outlet. Figure 7. Existing sediment control drop structures in the mountainous area filled with sediment. Figure 8. Existing sediment control structure upstream of the highway crossing. Average sediment transport in the area is estimated at 2200 m 3 /km 2 /yr while there is an very active area upstream where 23,000 m 3 /km 2 /yr sediment production rate is reported in the literature. Therefore, sediment control structures are absolutely necessary. Sediment control drop structures have been constructed in the past in the mountainous area, but the have been filled with sediment (Fig. 7). A newer sediment control structure exists upstream of the highway crossing (Fig. 8). This structure was filled with sediment during the December 2001 flood and subsequently cleared out. A sedimentation basin in the natural confluence of Diakoniaris and Panagitsa tributary was designed.This involved a special design. In the main conduit under the road, a spillway was placed so that for discharges up to the design discharge is routed through the sedimentation basin, while for higher discharges it acts as emergency spillway. This special structure will be studied in a model before construction. Check dams to

Figure 9. Existing Diakoniaris outlet structure to the sea.

be used for sediment control, combined with upstream

diversions were also proposed.

Additionally two sediment control dams were pro

posed. The upstream one can be combined with

the diversion of the upstream Diakoniaris basin to Elekystra Diversion Channel.

5 DIAKONIARIS TRAINING WORKS

The training works and diversion were designed for the 50-year flood according to the environmental permit. The existing closed section can only convey about 90 m 3 /s and possible additional culverts running parallel to the existing one, due to space limitations, can handle only a maximum additional 60 m 3 /s.

The downstream closed sections were checked for higher discharges in order to locate critical points. The estimated discharge without any diversions is 215 m 3 /s, while with a combination of diversions upstream and in the city area, the discharge at the outlet can be limited to 150 m 3 /s.

Higher discharges were assumed to be combined with unfavorable conditions at the outlet, thus creating pressurized flow towards the outlet and the pressure gradient was determined. It was desired that the pressure grade line remains below the ground, so that manhole covers are not affected.

The following possibilities were examined:

- Diversion of the upstream Diakoniaris basin, A= 3.89 km 2 .
- Diversion of sewer basins S9 and S10 to

“Perimetriki”, i.e. a sewer running under the new

road running around Patra suburbs.

- Diversion of sewer basins S2 and S3 to Papanasta

siou, a road running parallel to Diakoniaris axis and

reaching the harbor area. In the harbor area (under

construction) a channel running parallel to the sea

front and receiving all sewers flowing towards that Figure 10. View of the river bed and pedestrian crossings within the city limits, to be trained. area will be constructed. The proposed Papanastasiou diversion will also flow in this channel, close to the outlet, with appropriate outlet modification. - Diversions of local creeks R2 and R3 to Glaykos through the storm sewer system of the new highway. Various combinations of all the above were simulated with the HEC-HMS model and results for the discharge at the outlet are presented in Table 1. It should be noted that in modeling the future conditions, with full development of the city and the drainage system, were represented. With the existing conditions, with minimal development of the drainage system, concentration times are expected to be longer and consequently peak discharges lower. This was taken into account in scheduling the construction of the proposed works. As a result construction of the closed conduit upstream of the existing closed section can start before the addition of parallel conduits to the existing structure. Provision is made in the design for big surface openings (~2-3× 6-8 m), appropriately fenced, that would facilitate aeration and cleaning by mechanical means of the closed section. Additionally, holes in the bottom of the conduit are provided for water table recharge. Proposed training works for Diakoniaris main course are summarized in Table 2.

Flood mitigation planning related to land use

Y. Takeuchi

Kawasaki Geological Engineering Co., Ltd, Tokyo, Japan

M. Takezawa

Nihon University, Tokyo, Japan

ABSTRACT: The present study proposes a new comprehensive flood mitigation system that considers the

current stage of land development. The proposal includes the distribution of a flood mitigation guidebook

to affected residents, followed by a medium-scale implementation of measures involving the construction of

readily achievable structures such as one-sided dikes or unenclosed ring dikes. The project would then extend

to a large-scale consultation and the implementation of comprehensive flood mitigation measures.

The present study also presents a unique economic analysis method to increase the relative economic value

of a flood migration project by combining previously independent structures like river, highway and railroad

dikes and eliminating unnecessary construction. The concept of “time and regional extended effects” is also

introduced as an assessment technique for determining the economic value of flood mitigation projects.

1 INTRODUCTION

Many flood mitigation plans for alluvial basins around

the world have not been implemented because of prob

lems associated with the economic analyses or the

measures themselves. In many cases, failure to imple

ment the flood mitigation measures has lead to an area

being under-utilized. In some instances, mitigation

projects are not followed through due to plan imple

mentation difficulties, which have often been drawn up

without consideration of current levels of development

and land usage or the financial capacity of the con

cerned countries or regions. In other cases, the projects

have not been started because the estimated economic

value of flood mitigation is insufficient, when imple

mentation of the measures may in fact increase the

economic efficiency significantly.

Flood mitigation projects should be designed so as

to correspond with target area conditions. The present

study proposes a new comprehensive flood mitigation

system that considers the current stage of land develop

ment. The proposal includes the distribution of a flood

mitigation guidebook to the residents concerned, fol

lowed by medium-scale implementation involving the

construction of readily achievable structures, such as

one-side dikes or unenclosed ring dikes. The project

would subsequently extend to large-scale consulta

tion and the implementation of comprehensive flood

mitigation measures. The present study also presents a unique economic analysis method that increases the relative economic value of a flood migration project by combining structures, such as previously independent structures like rivers, highways and railroad dikes and eliminating unnecessary construction. The concept of “time and regional extended effects” is also introduced as an economic value assessment of flood mitigation projects, which also ensures that the scope and efficiency of the project is optimized. This measure is calculated based on an existing standard method employed in feasibility studies. The “time extended effect” concept identifies how flood mitigation infrastructures allow the development of property and capital, with accumulated benefits over long periods.Thus, when properties are protected against floods, new properties and capital will accumulate without destruction and confidence will increase. The “regional extended effect” of flood mitigation projects refers to the influence on increased economic activity of a region, locally, nationally and throughout the world. 2 COMPREHENSIVE FLOOD DAMAGE MITIGATION SYSTEM A comprehensive flood damage mitigation system consists of three main sub-systems that simultaneously F i g u r e 1 . C o m p r e h e n s i v e f l o o d d a m a g e m i t i g a t i o n s y s t e m .

monitor hydrology and land use information, warning

and evacuation systems and defense systems, as shown

in Figure 1. The warning and evacuation sub-system

consists of a flood disaster measures manual, a flood

measures guidebook, a flood measures information network and hazard map. The defense sub-system consists of individual defense and group defense. Individual defense consists of waterproofed buildings, flood insurance, land choice and refuge availability. Group defense consists of flood mitigation infrastructures, flood fighting activities, building restrictions and zoning.

A comprehensive flood damage mitigation system is based on the assumption that flood damage inevitably happens, regardless of the strength of flood mitigation measures. To minimize flood damage, which includes restoration costs, flood mitigation measures should always be systematically combined with the development stage of engineering, economics and regional land use.

A comprehensive flood damage mitigation system should give priority to the development of linked soft wares of flood mitigation related to land use as a first step in land development. These soft wares include flood disaster measures manuals, flood measures guidebooks, flood measures information networks, hazard maps and flood forecasting and warning systems, which give the highest priority to saving human life with evacuation instructions and evacua

tion indicators as guidance.

In an intensive stage of land development, hard wares of flood measures, such as high water measures, landside water measures, sediment transportation measures and runoff measures become necessary. 3 ECONOMIC ESTIMATION OF DIKE CONSTRUCTION WORKS JOINTED PROJECTS Some projects were judged infeasible due to low economic effect. If the construction costs of dike combined with flood mitigation and highway infrastructure costs are distributed across each project, higher accuracy economic estimations become feasible. In this case study, the Apure River Flood Mitigation Project is presented. The flood mitigation project in the Apure River Basin, Venezuela, was subdivided into the following three projects, shown in Figure 2. Project A: construction of a 187 km-long dike on the right bank of the Portuguese River Project B: construction of a 145 km-long dike on the right bank of the Guanare River Project C: construction of a 155 km-long dike on the left bank of the Apure River. Table 1 shows the dike length, project costs and benefit-cost ratio of these projects. The design life of each dike is 50 years. The benefit-cost ratio of Project A, Project B, Project C and total projects are 1.39, 1.45, 0.82,

1.15, respectively. The total project was economi

cally judged feasible because its benefit-cost ratio was

above 1.The tops of the project dikes were designed for

use as gravel-paved roads, however, the benefit-cost

ratios did not include the road construction benefits.

If these were counted in the benefit-cost ratios, the

benefits of dike construction would have increased.

Figure 3. River improvement works from El Vijia to Lake Maracaibo. the Lower Basin Project to protect the alluvial fan region from El Vijia to the Lake Maracaibo and the Upper Basin Project from El Vijia to the mountain regions. The Lower Basin Project was subdivided into river improvement works on the lower reaches from El Vijia and sediment control works on the upper reaches from El Vijia to the mountain regions. The main sediment control works in the Lower Basin Project, which aim to control sediment load, consisted of 3 high dams, 18 low dams and 340 retaining walls. The river improvement works of the action plan from El Vijia to Lake Maracaibo are the same as those of Master Plan, which consist of the construction of a 24.7 km-long one-sided dike, a 10.4 km-long dike on the right side bank and a 10.3 km-long dike on the left side bank, and the strengthening of a 12 km long of existing one-side

dikes on the left bank, as shown in Figure 3. Consequently, if the Action Plan were implemented, 36.7 km of one-sided dikes would be installed in the 53.4 km between ElVijia to the Lake of Maracaibo. The costs of the Action Plan are shown in Table 2. The project costs and the benefit-cost ratio of the Action Plan were estimated in 2000 to be US $27.58 million and 1.58, respectively. The economic benefits of executing the Action Plan Project were considerable. If only 24.7 km of one-sided dikes and 12 km of strengthening works were executed, the project would

be more profitable with US $12.93 million in project

costs and a 2.65 benefit-cost ratio.

5 “TIME EXTENDED EFFECT”

The “time extended effect” is the effect of flood mit

igation infrastructures that allow the development of

properties and capital with benefits accumulated over

long periods. Thus, economic development, in the

form of property and capital accumulation, is impos

sible in an area submerged by flood every year and

the “effect” is the benefits accrued from the enabled

development.

Conventional economic assessments of flood miti

gation projects have counted direct and indirect dam age to inhabited properties. The deprived potential for new property development due to flooding was not counted with the losses of old properties and capital in the flooded areas. In other words, if properties are pro tected from flooding, new properties are produced and capital is accumulated without potential for destruc tion. The effect of producing new properties and capital is defined here as the “time extended effect” of flood mitigation infrastructures over long periods. It is currently difficult to quantitatively calculate the “time extended effect”. However, the “time extended effect” of constructing the Okakoi Dike, Japan, in the early 17th century was studied as follows. A 50 km long of dike was constructed on the left bank of the Kiso River from Inuyama to Yatomi in 1610 as shown in Figure 4. As a result, the height of the left bank was 0.9 m higher than that of the right for approximately 280 years, until 1887. In the 400 years since 1610, there has not been a flood on the left-side plain of the Kiso River, while many floods have occurred on the right-side plain.

Before 1610, both plains were closely connected with the river and their natural, social and economic conditions were almost identical. Economic capital

formation in the side plains has been different since the

construction of the left-side dike. In the Bisai District

ofAichi Prefecture on the left-side plain, from the early
Figure 4. Location of Okakoi Dike. 17th to the early 19th,
cotton textiles were produced, in addition to the existing
silk textiles. Textile industries developed, which
encouraged engineering and capital accumulation, and
enabled the production of high quality wool textiles,
creating the industrial infrastructure to produce weapons,
cars and aircrafts in the whole of Aichi Prefecture until
the 1920s. In 1999, industrial production per person in
Aichi Prefecture, on the left-side plain, was 1,960
thousand yen and that in Gifu Prefecture, on the right-side
plain, was 96 thousand yen. This difference in industrial
production per person between the two prefectures is
thought to be influenced by the difference in bank height
between both sides due to the dike construction. The
difference in flood damage between Aichi Prefecture on the
left-side plain and Gifu Prefecture on the right-side plain
in the probable flood area of the Kiso River was analyzed
in 1953, as shown in Table 1. The inhabitants ofAichi
Prefecture were richer in domestic property than those in
Giju Prefecture. If the indicators included the industrial
and agricultural properties and products, the difference in
economic power between the two prefectures would be even
more evident. The “time extended effect” from the flood
mitigation project was qualitatively proven through the
case study of the Okakoi Dike on the left bank of the Kiso
River, in which the capital accumulated properties were
protected against floods and produced new capital, as
listed in Table 3. If this case study were surveyed in
detail over several historical stages, a qualitative study
of the “time extended effect” would be possible. 6
“REGIONAL EXTENDED EFFECT” The “regional extended effect”
of flood mitigation projects is the influence on economic
activities not

only in the region adjacent to the flooded area, but also in the country and in the world. For example, if the center of Manila is flooded, indirect damage is caused not only in Manila City, but also on the whole Luzon Island, in all of the Philippines and in the world. On September 12, 2000 the Shinkawa River, Japan, was flooded because of a dike failure. Several car fac tories in Toyota City, 30 km south-east of the river, stopped working due to the resulting insufficient supply of parts. However, the determination of the “regional extended effect” and the “time extended effect” has not been an objective of the economic

evaluations for flood mitigation projects.

We propose to measure the decreases in land prices due to floods, instead of measuring indirect damage from the “regional extended effect” of floods, because the indirect damage is very difficult to measure. If the “regional extended effect” was assessed in the Flood Control and Drainage Project in metropolitan Manila, the Philippines, as an example, the priority between the following two subprojects would be reversed.

The Japan International Cooperation Agency (JICA) study selected the Mangahan Drainage Improvement Project as more feasible than the Pasig River Improve ment Project, with a higher economic efficiency, as summarized in Table 4.

The SM-2 district of the Pasig River Improvement Project is the center core area in metropolitan Manila, as in shown Figure 5. Land use in the SM-2 district was developed in 1986 and if the Pasig River Improve ment Project were executed, a high dense commercial and residential area would be developed in 4.4 km 2 by 2020, as in shown Table 5.

The WM-1 district was planned as the development

of 2.86 km 2 of the largest high-density commercial Table 4. Economic efficiency. High dense commercial and house areas A.D. 1986 2020 SM-2 District in the Pasig River Improvement Project 3.97 km 2 4.41 km 2 WM-1 District in the Mangahan Drainage Project 0.00 km 2 2.86 km 2 Figure 5.

Location of SM-2 district and WM-1 district. Table 5. Land use conditions. Mangahan drainage Pasig river improvement improvement project project Total project 132.0 million 65.8 million cost US$ US$ Mean annual 20.2 million 9.3 million decreased US$ US$ damage B/C: benefit- 1.11 1.07 cost ratio Internal rate 16.80% 16.10% of return and residential area in the Mangahan Drainage area (as shown in Figure 5 and Table 5). Each district in the Flood Control and Drainage Project in metropolitan Manila was at a different landdevelopment stage. The capacity for land development in the underdeveloped areas of the Mangahan Drainage Project area was larger than that in the developed area of the Pasig River Improvement Project. As a consequence of these capacities, the Pasig River Improvement Project, in the center of metropolitan Manila, was determined to have less economic efficiency than the Mangahan Drainage Project in the

marshland suburbs of Manila. The “regional extended

effect” was taken into account when planning the eco

nomic evaluation, and the economic efficiencies of

developing the projects were reversed.

Through the metropolitan Manila Flood Control

and Drainage Project case study, issues such as the

“regional extended effect” were studied qualitatively.

If land prices decreased by actual flood damage were

measured over time and in several districts, it would be

possible to quantitatively study the regional extended

effects.

The integrated efficiency of the total project was

increased by making the area with the higher regional

extended effect safer from floods than the lower effect

area. The area with a high regional extended effect

is the district that would sustain greater indirect flood

damage per unit squared than the other area, the highly developed land use area, with high land prices, and the central core cites in the basin with the collective transportation areas such as highways, railways, ports and airports.

The success of a flood mitigation project in regional development depends on the cooperation of social, economic and cultural infrastructures, which are essential in attracting able inhabitants.

7 CONCLUSIONS

The process of executing a flood mitigation project should be related to the stage of land development in the study area. The new basic concept explained in the present paper clarified problems with existing plans. Flood mitigation projects should be designed so as to relate to the land use conditions of the target area. A comprehensive flood damage mitigation system that considers the current stages of land development should initiate the distribution of flood mitigation guidebooks to the residents concerned, followed by the medium-scale implementation of mitigation mea sures, involving the construction of readily achievable structures, such as one-sided dikes or unenclosed ring dikes. Subsequently, a large-scale consultation and implementation of comprehensive flood mitigation

measures would be implemented.

Depending on the potential for flood and the need

for flood mitigation in the area, some flood mitigation

projects could not be easily executed without invest

ment, approval of residents and their government. In

these areas, the economic effects were often assessed

lower than the actual costs. Consequently, it is very

important to show the true economic effects. If a river

dike is constructed as part of a highway or railway

infrastructure, and the inestimable construction works

are separated from the flood mitigation project, the

economic effects increase and the project would be

Modeling floodplain flow on lower Deer Creek, CA

M.L. MacWilliams, Jr., R.L. Street & P.K. Kitanidis

Environmental Fluid Mechanics Laboratory, Department of Civil and Environmental Engineering, Stanford

University, Stanford, CA

ABSTRACT: Three-dimensional hydrodynamic modeling of flow in complex river-floodplain systems offers

the potential to increase the current understanding of stream stability, channel morphology, and flood conveyance

in natural channels. A three-dimensional hydrodynamic model is applied to lower Deer Creek, CA to simulate

a large flood event that resulted in levee failure. A description of the numerical model and the development of

the model grid and boundary conditions are presented. Simulation results show good agreement with high water

surveys and demonstrate the important features influencing flow on the lower Deer Creek floodplain. Simulation

results provide detailed information about the capacity of floodplain pathways and demonstrate the value of

detailed hydrodynamic modeling as a tool to understand and quantify flow on complex floodplain systems.

These results will be used to help guide the planning and implementation of future flood management strategies

on lower Deer Creek.

1 INTRODUCTION

Deer Creek is one of the last drainages in the

Sacramento River system that supports spring-run

Chinook salmon, which have recently been added to

the federal list of endangered species. As a result,

Deer Creek has been recognized as a priority for habi

tat restoration by the CALFED Bay-Delta Program

(CALFED 2000). A geomorphic study (DCWC 1998)

concluded that habitat in Deer Creek is limited mostly

because of effects of the existing flood control project.

These effects include a lack of habitat diversity and

riparian vegetation due to channel maintenance and

clearing, and a lack of suitable spawning material due

to the high shear stresses which occur in the channel

when high flows are constrained within the existing

levees.

Various proposals have been put forth to enhance

salmon habitat and passage on Deer Creek, including

maintaining minimum base flows, artificial addition of

smaller gravel for spawning, and planting of riparian trees to address the relative lack of vegetation on the banks of most of lower Deer Creek (CALFED 2000).

The CALFED Strategic Plan for Ecosystem Restoration (2000) notes that many of the restoration efforts planned for Deer Creek are treatments of the symptoms of the current flood management strategy and do not address the underlying problems. Their proposed management alternative suggests that if the style of flood management were changed to set levees back, permit overbank flooding, and eliminate channel clearing, Deer Creek would, in the course of one or more floods, reestablish a more natural channel form with better habitat. The California Department of Water Resources (DWR) is currently considering flood management alternatives for lower Deer Creek which would incorporate the proposed CALFED management strategies. As noted in the Lower Deer Creek Flood Management Study Draft Scope of Work (Cepello 2000): "The opportunity exists through a combination of redesigning existing flood control features and encouraging appropriate land use to restore the reliability of the flood control project, reclaim a large portion of the historic floodplain, and incorporate natural distributary channels into an overflow bypass system for lower Deer Creek. These actions would also help natural stream processes occur and would be the most effective ecological strategy to restoring the terrestrial and aquatic habitats of lower Deer Creek." A detailed understanding of river stage, flow velocities, bed shear stresses, inundation areas, levy capacity and floodplain storage will be essential to understand the response of the system to various flood discharges and provide information necessary for developing further project objectives. Commonly used one-dimensional hydraulic models are not suitable for assessing complex flow systems that will result from the proposed flood management strategy, which includes reclamation of the historic floodplain and the incorporation of historic distributary channels. This

study utilizes a robust and efficient three-dimensional hydrodynamic model, UnTRIM, to simulate a large flood event which occurred on lower Deer Creek in January, 1997. This modeling effort provides much more detailed information about channel conveyance, flow variability within the river channel, floodplain storage, the capacity of the natural distributary chan nels and existing culverts for overflow bypass, and the effects of potential levee modifications on the flow system than could be obtained from existing one-dimensional models. Through collaboration with California DWR and the Deer Creek Watershed Con servancy, this information will be used to help guide the implementation of the proposed flood management strategy on lower Deer Creek.

1.1 Site description

Deer Creek originates on the west slope of Mount Lassen and ultimately flows into the Sacramento River near Vina, CA. The watershed encompasses approxi mately 590 km 2 and ranges in elevation from 2400 m to less than 100 m above mean sea level. Historical aerial photographs taken in 1939 show that the lower portion of Deer Creek was highly sinuous, with small-scale bends, point bars, and alternating pools and riffles (CALFED 2000). During floods, Deer Creek would

regularly overflow its banks and inundate adjacent floodplains, providing water and nutrients to adjacent riparian zones. Under natural conditions, lower Deer Creek exhibited the multiple channels characteristic of alluvial fans. During floods, water flowed across the floodplain and into some of the multiple distributary channels on the alluvial fan.

The Deer Creek Flood Control Project, authorized by the 1944 Flood Control Act, was completed by the U.S. Army Corps of Engineers in 1953 and transferred to the jurisdiction of the State Reclamation Board in 1956 (Cepello 2000).About 16 km of levees were built along lower Deer Creek by the U.S. Army Corps of Engineers to control flooding, and the channel was straightened and cleared (CALFED 2000). As a result of this work, the role of the natural distributary chan nels was disrupted and the riparian zone was limited to a small band within the constructed levees.

Although the average flow rate on Deer Creek is only about 9 m 3 /s, Deer Creek experiences a high snowmelt flow virtually every year, and large floods often result from warm winter rains on snow. Large floods have occurred in January 1997 (680 m 3 /s), 1970 (530 m 3 /s), December 1964 (570 m 3 /s), 1940 (610 m 3 /s), and 1937 (675 m 3 /s) (CALFED 2000).

Although the 1997 flood experienced flows greater

than 7500% of the average flow rate, frequency analysis indicates that this is only considered a 25-year recurrence interval flow event (CALFED 2000). Under the pressure of such floods, maintenance of the stream channel and levee system has been an expensive undertaking. Major levee repair work was undertaken by the Corps of Engineers following the flood of February 1986 and by the National Resources Conservation Service and Tehama County after the January 1997 flood (Cepello 2000). During the January 1997 flood, Deer Creek breached its levee and flowed across the floodplain for several kilometers. The areas which were flooded during the 1997 flood were predominantly agricultural land, including orchards, grazing land, and farms. Based on field observations following the flood and eyewitness accounts, a conceptual model of the January 1997 flood on lower Deer Creek has been developed by the California DWR. This conceptual model, shown in Figure 1, demonstrates the importance of the role of the floodplain for providing flood storage and the importance of the natural distributary channels in influencing the flow of water on the floodplain. In particular, Delaney Slough (top right) and China Slough (bottom center) play an important role in the natural hydrology of Deer Creek and served as conduits for water on the floodplain during the 1997 flood. The conceptual model of the 1997 flood on lower Deer Creek provides a valuable resource for identifying the features on the floodplain which had a significant effect on floodplain hydrodynamics; however the conceptual model does not provide any quantifiable information about flow on the lower Deer Creek floodplain. The collection of data during large flood events is not practical, and thus limited quantifiable information is available to help guide efforts to redesign the flood management strategy. The application of a threedimensional hydrodynamic model to lower Deer Creek provides an opportunity to quantify floodplain storage and the capacity of specific pathways on the floodplain to convey bypass flow. 2 METHODS 2.1 Model description This study applies the three-dimensional nonhydrostatic hydrodynamic model for free-surface flows on unstructured grids, UnTRIM, described in Casulli and Zanolli (2002).The model solves the threedimensional Navier-Stokes equations on an unstructured grid in the horizontal plane. A structured grid is used in the vertical direction, such that the domain is divided into vertical layers of uniform, but not necessarily equal, thickness. Volume conservation is expressed by the incompressible continuity equation, and the free-surface is calculated by integrating the continuity equation over the depth and

using a Deer Creek Levee Breach Levee Breaches

Figure 1. DWR conceptual model of the January 1997 flood. The Sacramento River flows from top left to bottom left, and

Deer Creek flows from top right to lower left. The levee breach occurred on the upper right portion of the figure. The breaches

shown in the center served to allow water back into the main channel. Note the influence of Delaney Slough and China Slough

in influencing the flow of water on the floodplain (Source: California DWR).

kinematic condition at the free-surface as described

in Casulli and Cheng (1992). The governing equations

are discretized using a finite difference – finite volume

algorithm. The numerical model accounts for bottom

friction, wind stress, convective and viscous accel

eration, gravitational acceleration, and vertical eddy

viscosity. For the work presented in this study, sev

eral additional enhancements were added to the model

presented by Casulli and Zanolli (2002). An inflow

boundary condition for volume and momentum, a

radiation outflow boundary condition, a modified for

mulation of bed drag and vertical eddy viscosity, and a

method for modeling hydraulic structures were added,

as described in MacWilliams (2004). The modified

UnTRIM code was applied to simulate flow on lower

Deer Creek.

2.2 Grid development

One of the limitations of using three-dimensional

models is the capacity to accurately specify complex

topography (Lane et al. 1999). At the Deer Creek site, high resolution photogrammetric data had already been collected, and this photogrammetric topography was available in digital form. Photogrammetry was completed as part of the Lower Deer Creek Flood Management Study and includes detailed (0.6 m contours) topography for the lower Deer Creek study area (approximately 75 km 2) based on photography and ground control data provided by the Department of Water Resources. Processing of aerial photography and terrestrial and bathymetric surveys into detailed topography was completed by the U.S. Army Corps of Engineers and the California DWR under the Sacramento and San Joaquin River Basins Comprehensive Study. This terrain and bathymetric data was obtained from California DWR and used in the development of the grids used in UnTRIM. Using this detailed topography it was possible to minimize the difficulties associated with specifying channel geometry and generate a high resolution grid consistent with the actual topography at the site. An orthogonal unstructured grid was generated over the horizontal domain for use with the UnTRIM

Figure 2. Model grid for lower Deer Creek (black). The grid for the channel of lower Deer Creek is bounded by the levees

or high topography (shown as two “parallel” white dotted lines from top right to bottom left). The floodplain grid is bounded

predominantly by bordering roads (solid white). The top inset shows a portion of the grid with the low flow channel and the

South-Main Canal highlighted. The lower inset shows a close-up view of the area identified in the top inset, again showing

a portion of the low flow channel and the South-Main Canal (bottom right). The model grid extends approximately 5 km

upstream of the area shown.

model. The grid was generated in two sections

using the mesh generation program TRIANGLE

(Shewchuck 1996). The first section of the grid was

generated for the portion of lower Deer Creek which

is bounded by the levees on each side of the channel,

shown in Figure 2. In this portion of the grid, the grid

was constrained such that the levees and the low water

waterlines were aligned with cell edges in the grid

mesh. Where no distinct levees were present, the grid

is bounded by the local topographic break along the

edge of the floodplain. This was done to ensure that

the topographic high associated with the levees was

captured in the grid, and to delineate the area within

the low flow channel as a distinct portion within the

grid. Because the topography for lower Deer Creek

was obtained through photogrammetric mapping, the

topographic data extend only to the edge of the wetted channel on the date which the photogrammetry was collected. No bathymetric data were available for the low water channel. The bathymetry of the low water channel was estimated through a series of model calibrations. The aerial photogrammetry for lower Deer Creek was completed on May 11, 1999. On this day, the average daily flow in Deer Creek was measured to be 11 m 3 /s. A series of UnTRIM simulations was made by assuming an initial bathymetry where the bed was set to be 1 m below the observed water surface in the low flow channel. A constant flow rate of 11 m 3 /s was applied and the downstream water surface elevation was set to be 51.5 m, which is the water surface elevation observed in the photogrammetric data at the mouth of Deer Creek on May 11, 1999. By comparing the predicted water surface throughout the low flow channel

to the water surface observed in the photogrammetric

survey, the low flow channel bathymetry was adjusted

and the procedure was iteratively repeated. Although this method is not expected to provide a highly accurate estimate of low flow bathymetry, visual comparison of calibration results and channel morphology visible on the aerial photographs suggests that this calibration procedure produced a reasonable bathymetric profile for the low flow channel. Because the flow capac ity of the low flow channel is only 11 m 3 /s, it is not expected that errors associated with this bathymetric calibration will introduce significant effects on model ing flood flows on the order of 500 m 3 /s. Additionally, it is believed that this approach is more consistent with the other available topographic data than conducting a present-day bathymetric survey on the low flow chan nel, which has been altered since 1999 and since the pre-flood 1997 bathymetry.

A grid of the upper portion of the lower Deer Creek floodplain was also developed using TRIANGLE. The western boundary of the floodplain grid was con strained so that the grid sides aligned with the edge of the levee-bounded grid. Additionally, the edges of the South-Main Canal, which flows across the floodplain, were identified and preserved in the floodplain grid. The floodplain grid is bounded by a series of roads which are topographic highs and serve as hydraulic

barriers. Highway CA-99 runs along the southwestern edge of the floodplain grid. The merged grid consisting of the levee-bounded grid and the upper floodplain grid, shown in Figure 2, contains 45,668 triangular elements in the horizontal grid and over two and a half million computational cells. As seen in Figure 2, the model grid follows the topography such that the levees, low flow channel, and South-Main Canal are all aligned with grid cell faces. This ensures that the elevations associated with these features are captured in the model grid, because grid elevations are located on the center of each cell side. The resolution of the model grid surrounding the South-Main canal, as seen in the lower offset is on the order of 5 m. The grid spacing on the majority of the floodplain is typically on the order of 25 m, and a slightly finer resolution of approximately 20 m is typically used between the levees and in the low flow channel. A uniform vertical grid spacing of 1 m was used.

2.3 Boundary conditions

The simulation of the 1997 flood on lower Deer Creek requires the specification of an inflow hydrograph and a downstream water surface elevation. Additional boundary conditions are applied to model hydraulic structures on the floodplain.

A USGS gauging station is located on Deer Creek,

approximately 14.5 km upstream of its confluence

with the Sacramento River, and approximately 2.5 km upstream of the upstream end of the model domain. This gauge reports river stage, and a stage-discharge relationship exists for this station. Using the USGS stage-discharge relationship with the measured stage data predicts two flood peaks of 564 and 680 m 3 /s. It is known that the second peak resulted in levy failure on Deer Creek and that the first peak did not exceed the capacity of the levees. Preliminary simulations, an analysis of previous levee failures, and a one-dimensional model indicate that the magnitude of both of these flood peaks exceeds the capacity of the levee system. Annual peak discharge data are available for lower Dear Creek from 1912 through 1997. Comparing the yearly peak discharge with the years in which levee failure occurred indicates that flows greater than 450 m 3 /s consistently resulted in levee failure. This suggests that the two peaks predicted by the USGS rating curve are not accurate because if the first flood peak was actually more than 560 m 3 /s, as predicted by the measured stage data and the USGS rating curve, levee failure almost certainly would have occurred. The measured stage for the second flood peak is only 0.33 m greater than the stage measured for the first peak. This small difference in measured stage is inconsistent with eyewitness accounts of river stage near the breach location. Additionally, the measured stage for the second flood peak varies by less than 0.06 m during the seven hours surrounding the peak. This flat stage measurement at the flood peak suggests that the stage for the flood peak has exceeded the height which can be measured at the gauge and that the actual stage at the gauge was greater during the peak than was reported at the station. By assuming that the actual stage for the second flood peak exhibited a similar shape to the stage measured for the first peak, the flat stage data for the second peak were augmented by an appropriate filter. Using this filter, the difference in stage between the first and second flood peaks was increased from 0.33 to 0.91 m.A new stage-discharge relationship was developed, as shown in Figure 3, which maintained the discharge at the augmented peak stage to be identical to the discharge at the original peak stage for the second flood peak. However, the discharge associated with the first peak in flood stage is reduced relative to the original rating curve. Using the modified stage data and the new stage-discharge relationship, the discharge associated with the second

flood peak remained at 680 m 3 /s, while the first flood peak was calculated to be 450 m 3 /s, which is within the capacity of the levee system. This hydrograph is shown in Figure 4 and was used as the inflow boundary condition. Based on observational information about stage and breach timing, an analysis of past levee failures, onedimensional simulations and preliminary simulations using the three-dimensional model, this hydrograph

is a more appropriate estimate of the hydrograph

for the January 1997 flood than the hydrograph cal

culated from the raw stage data using the USGS

stage-discharge relationship (MacWilliams 2004).

The downstream boundary is specified using the

river stage on the Sacramento River measured at DWR

Woodson-Vina gauging station at Woodson Bridge,

shown in Figure 4. The Woodson Bridge gauge is

approximately 1.7 km downstream of the mouth of

Deer Creek. Based on the photogrammetric data and

the DWR stage data atWoodson Bridge, the stage at the

mouth of Deer Creek is estimated to be 0.3 m above

the stage observed at the Woodson-Vina Bridge gauge.

This estimate is used to calculate the downstream

boundary stage and is based on the assumption that the

water surface slope on this reach of the Sacramento

elevation (bottom) used as downstream boundary condition.

River does not change significantly during higher flows. In addition to the upstream and downstream boundary conditions, culvert rating curves were developed for three hydraulic structures that are important conduits for flow on the lower Deer Creek floodplain. The rating curves were developed using HEC-RAS based on field measurements of the culvert dimensions for each of the three culverts. The rating curves used assume free-flow conditions at the outlet, which provides the largest possible flow through the culvert based on the set of rating curves developed. Using these boundary conditions and rating curves, UnTRIM was used to simulate the 1997 flood on lower Deer Creek. A period of six days was simulated using a time step of 1 second. The bottom roughness was specified over the domain using a roughness height of 1× 10 −3 m in the channel and on the floodplain values of 1× 10 −2 and 1× 10 −1 m were specified for areas delineated as grazing lands and orchards, respectively. The roughness parameters on the floodplain were calculated from the tables of Chow (1959) by converting the appropriate roughness coefficient to a roughness height using the approach described in MacWilliams (2004). The levee failure resulted in a significant change in local geometry at the location of the levee breach and a section of levee was washed out. To capture this effect in the flood simulations, a similar adjustment is made to the model grid by removing a section of levee at the breach location at the time in the simulation when significant levee topping occurs. 3 RESULTS Because no data were collected during the 1997 flood, there is only a limited capacity to quantitatively validate the model results. However, efforts have been made to gather as much quantitative or qualitative information as possible about the 1997 flood to perform an assessment of model performance. Following the 1997 flood, high water mark surveys were conducted on January 13–16, 1997. The data from these surveys were obtained through the California Department of Water Resources Northern District Office. Eighteen high water marks were surveyed on the east levee of Deer Creek and twenty high water marks were surveyed on the west levee of Deer Creek. At each survey point, the high water mark (HWM) was photographed, sketched relative to surrounding features, and surveyed. Using the information available in the survey notes, each of the HWM survey stations within the study area was identified and located on the model grid. The predicted HWM was calculated to be the maximum water surface at the survey location during the flood simulation. The differences between predicted and

measured HWM along the Deer Creek levees for the

January 1997 flood are shown in Figure 5. All of the predicted HWM elevations are higher than the observed HWM elevations, which suggests that the modeled peak discharge may exceed the actual peak flood discharge. The average difference between the predicted and observed HWM is 0.36 m. This difference can also be attributed to error associated with the field HWM survey elevations, error in the photogrammetric topography, error in the simulated hydrograph, and model accuracy. The error associated with the topographic data are on the order of 0.15 m; a slightly higher error is associated with the HWM surveys. Based on this, the model results show good agreement with the surveyed HWM elevations within the accuracy of the available data.

In addition to the high water mark surveys, the other primary sources for model validation come from the

Figure 5. Difference between predicted and observed high water marks at stations surveyed by DWR following the January 1997 flood.

Figure 6. DWR conceptual model of January 1997 flood (left) shown with UnTRIM model predictions during maximum floodplain inundation (right). Lightly hatched area on conceptual model indicates flooded areas; flooded area on the model results shown as light-colored area overlaid by velocity vectors. Arrows on the conceptual model show flow pathways

but are

not scaled to flow magnitude or velocity. Arrows on the model predictions show surface velocity vectors for a subset of the

computational cells. DWR conceptual model of lower Deer Creek flood actions, shown in Figure 1, and from post-flood aerial photographs. The post-flood aerial photographs give a good indication of flooded areas and flow direction based on disruption of floodplain vegetation and deposition sediment on the floodplain. A comparison between the inundation area predicted by UnTRIM at the time of maximum floodplain inundation and the inundation area incorporated in the DWR conceptual model is shown in Figure 6. As seen in this figure, the results from the UnTRIM simulation show good agreement with the conceptual model both in terms of inundation areas and flow direction on the floodplain. Figure 7 shows a comparison between post-flood aerial photographs, the DWR conceptual model and the UnTRIM predictions in the section of the floodplain containing the South-Main Canal. The orientation of the conceptual model and the UnTRIM results have been rotated to match the boundaries of the aerial photographs. As seen in this figure, there is good agreement between the inundation areas predicted by UnTRIM and the flooded areas shown by the conceptual model. The grey areas in the UnTRIM model (top left of the right panel) which designate portions of the model grid which remain dry agree well with the areas in the aerial photograph which show no evidence of sediment deposition and thus are assumed to have been above the elevation of the flood waters. One of the major flow pathways back into the main channel is shown crossing the irrigation canal in the top center of each panel on Figure 7 and then entering the main

of January 1997 (center) and UnTRIM model predictions during maximum floodplain inundation (right). Arrows on the

conceptual model show flow pathways. Arrows on the model predictions show surface velocity vectors for a subset of the

computational cells.

channel in the bottom half of each panel. On the aerial

photograph, the sediment deposition pattern between the South-Main Canal and the main channel of Deer Creek indicate the significance of this flow pathway. A similar pathway is observed in the UnTRIM results and is shown in the conceptual model. In the aerial photograph, a significant amount of headcut erosion into the floodplain is visible at the location where flow re-enters the main channel. This is consistent with model results which indicate a large fraction of the flow on the floodplain re-enters the main channel in this reach. Overall these comparisons suggest the UnTRIM model is providing a reasonable estimate of flow on the floodplain for the January 1997 flood.

A schematic of the primary flow pathways on the Deer Creek floodplain for the January 1997 flood is shown in Figure 8. The primary levee breach on lower Deer Creek occurred approximately 0.5 km down stream of Leininger Bridge. The majority of the water traveling across the floodplain re-entered the main channel at two locations, downstream of the Stanford Vina diversion dam, and immediately upstream of highway CA-99. Figure 9 shows the hydrographs for the flow contained between the levees at Leininger Bridge, the Stanford-Vina diversion dam, and at the highway CA-99 Bridge. These hydrographs are Figure 8.

Schematic of primary flood pathways on lower Deer Creek during January 1997 flood. The boundaries of the main channel (white dashed lines) and the boundaries of the floodplain grid (white solid line) are indicated for reference. The dark arrows show primary flow pathways. Text boxes and white arrows identify the locations corresponding to the channel and hydraulic structure hydrographs shown in Figures 9–10.

Figure 9. Predicted hydrographs in the main channel of

lower Deer Creek at three locations identified on figure 8.

obtained by calculating the total flow through each of

these channel cross-sections during each time step dur

ing the simulation.As seen in Figure 9, the levee breach

truncates the second flood peak at the Stanford-Vina

diversion dam due to the flow across the floodplain.

The peak discharge predicted at the Stanford-Vina

diversion during the first flood peak was 450 m 3 /s.

The discharge predicted at the Stanford-Vina diver

sion at the time of the levee breach was approximately

475 m 3 /s and following the levee breach the maxi

mum discharge predicted was 450 m 3 /s.This reduction

in maximum discharge results because, following the

breach, a larger amount of water is diverted onto the

floodplain and the effective downstream conveyance

capacity of the main channel at the breach is trun

cated. Downstream of Stanford-Vina diversion dam,

the floodplain elevation is sufficiently above the main

channel that no significant levees were constructed.

As a result, water from the floodplain can freely flow

back into the main channel of lower Deer Creek. A significant fraction of the flow on the floodplain during the 1997 flood re-entered the main channel at this location (as seen in Figure 7). The remaining water flowed down the floodplain until it reached highway CA-99.At the highway, which is elevated significantly above the surrounding floodplain, the water backed up until the levees were breached to allow the water to flow back into the main channel immediately above the CA-99 highway bridge. As seen in Figure 9, the hydrograph at the CA-99 Bridge shows a flood peak similar to the hydrograph at Leininger Bridge, which indicates that the majority of water has re-entered the main channel by the time Deer Creek flows under CA 99. The simulation results predict a peak discharge of 670 m 3 /s at Leininger Bridge and a peak discharge of 620 m 3 /s at CA-99.

The balance of water which does not re-enter the main channel upstream of CA-99 flows under the highway at overpasses located on Delaney Slough and Figure 10. Predicted hydrographs through the hydraulic structures at the locations identified on figure 8. China Slough. The flow hydrographs for these two structures, and the hydrograph for the culvert under Vina Road which connects the main area of the floodplain with China Slough, are shown in Figure 10. The culvert under Vina Road is quite small and based on the large discharge predicted through the end of the simulation it is evident that this culvert is limiting flow into China Slough. The culvert on China Slough under CA-99 provides a larger conveyance capacity

but also shows a significant flow rate following the initial flood pulses. If a substantial flow is to be routed through China Slough as is suggested in the Lower Deer Creek Flood Management Study, this culvert would also need to be resized to increase its capacity. 4 DISCUSSION The three-dimensional simulation of the January 1997 flood on lower Deer Creek provides valuable quantifiable information about water levels, flow velocities, inundation areas, flow pathways on the floodplain, and the performance of existing floodplain hydraulic structures. Coupled with the knowledge provided by the DWR conceptual model of the 1997 flood on lower Deer Creek, this information can serve as a valuable tool in planning future restoration strategies on lower Deer Creek. The implementation of flood management alternatives that will change the style of flood management to set levees back, permit overbank flooding, and incorporate natural distributary channels back into the floodplain system depends on an adequate understanding of hydrodynamics on the floodplain during large flood events. This understanding is necessary in order to help improve the reliability of the existing flood management system and to help foster the restoration of the terrestrial and aquatic habitats of lower Deer Creek by allowing natural stream processes to occur.

Kondolf (2000) argues that “aquatic and riparian

habitat for salmon and other organisms is, in effect,

a by-product of the channel geomorphology, which,

in alluvial reaches, largely reflects the prevailing flow

and sediment regimes, as well as effects of riparian

vegetation and human modifications.” As a result, a

detailed understanding of the flow regime on lower

Deer Creek during floods is necessary for the proper

evaluation of future restoration efforts on Deer Creek.

Restoration projects, such as that on the Cosumnes

River, CA, have demonstrated the benefit of breaching

and setting back levees. Based on the result of a levee

breach on the Cosumnes River it was concluded that “if

the natural process of flooding is allowed to take place, the river can reforest its old flood plain and restore fish and wildlife habitat quickly and effectively. When nat ural processes are allowed to shape the landscape on a large scale, the habitat becomes very diverse, enabling many species to live together in a balanced ecosys tem" (Cosumnes 2003). A similar opportunity exists on lower Deer Creek to setback levees and reclaim a large portion of the historic floodplain. Deer Creek remains one of the least altered streams in the Cen tral Valley and still supports all four runs of Chinook salmon, as well as runs of steelhead. As a result, the preservation of this resource is a high priority.

Using the model developed in this study as a start ing point, it is possible to simulate the potential effects of various structural modifications to the floodplain using UnTRIM. Information about flood inundation and frequency under the proposed management plan can be used to recommend sensitive areas that should be obtained through purchase or land-easements to ensure the reliability of the proposed flood manage ment strategy. An analysis of the hydraulic effects of levee setbacks, allowing inundation of the natural floodplain, and the incorporation of natural distribu tary channels into the flood management strategy, can

be used to recommend appropriate modifications to the levee system that will allow natural channel and floodplain processes to occur while still providing adequate protection to existing structures. As a result, the extension of this modeling study can be used to provide information that will help to maximize the effectiveness of the proposed management strategy. Funds spent on this type of planning study can help prevent much larger expenditures on projects that would prove to be ineffective or unnecessary (Kondolf 2000).

5 CONCLUSIONS

These results demonstrate the ability of detailed hydrodynamic modeling to simulate flooding on a large-scale complex river floodplain. Through the application of a newly-developed three-dimensional

Estimating hydraulic parameters and geometric characteristics of a river

from remote sensing data using optimization methods

H. Roux & D. Dartus

Institut de Mécanique des Fluides, Toulouse, France

ABSTRACT: The necessity of an improvement of flood risk management has been emphasized by the impor

tance of the damages caused by several disastrous floods in recent years. An obligatory way to better understand

and forecast these events is to be able to accurately simulate the water transport in the river.Application of numer

ical models requires parameter calibration, even when in situ measurements are available. Here is presented an

exploration of the possibility of estimating these parameters from observations provided by telemetry imple

menting optimization techniques. The originality of this study is to reconstitute information about the geometry

of the river and the hydraulic characteristics of the considered event from top sights. Application examples on

two different rivers are presented.

1 INTRODUCTION

Recent floods in Europe have had catastrophic conse
quences from a human but also economic and historic
point of view. The total damages have emphasized
the need of an accurate prevision of these floods to
improve the risk management (Plate, 2002). Huge pro
gresses have been recently realized in the modelling of
the hydrodynamic of the flow in the river but also on
the floodplain areas (Bates & de Roo, 2000), (Stewart
et al., 1999), (Marks & Bates, 2000). However, hydro
logical modelling requires a thorough knowledge of
the river to be able to map flood extents for risk analysis
purpose. Some models contain conceptual parameters
that usually cannot be assessed by measurements in
the field; on the contrary, distributed, physically based
models use only parameters that can be assessed from
in-situ data. But it is often a long and expensive proce
dure, sometimes difficult to implement and in practice,
it is not possible to determine the parameters at each
computational point grid (Madsen, 2003). Therefore,
both type of models need calibration and the prob
lem is even more pronounced in the case of ungauged
rivers.

New generations of satellite are equipped with sen

sors of metric resolution, 1m in panchromatic for IKONOS-2, launched by the USA in 1999 and 2.5 m in panchromatic for SPOT-5, launched by France in 2002. Air photo techniques have also developed quickly and compared to the satellite telemetry, they offer a bet ter reactivity in front of the events. Indeed, satellite images taken during a flood remain rare as it needs the concomitancy of the event with the satellite track. This study starts from these two facts: the need of a thorough knowledge of the river for both model calibration and running and the increasing potential of telemetry as a source of information. Data assimilation methods allow to combine data provided by the model with data provided by space observation to identify information about the river. The formulation of flowstate equations to ascertain the value of the parameters embedded in the simulation process is referred to as an inverse problem (Khatibi et al., 2001).There is no exact solution but it is possible to estimate the best one in a mathematical sense using optimization techniques. This paper focuses on the identification of parameters necessary to simulate open-channel flows by resolution of the one-dimensional Saint-Venant equations. That is to say discharge, Manning roughness coefficient or geometric characteristics of the channel. A preliminary study (Roux et al., 2004) has shown that the minimization of an error criterion gives satisfactory results for this purpose. This method has then been implemented using two different approaches. Both estimate parameters such as discharge, Manning roughness coefficients and a downstream condition, but they differ in their way of identifying the geometry of the cross-section. The first approach consists in identifying an equivalent river: a hypothesis is made on the geometry of the cross-section and the characteristics of this geometry are then estimated. It has been implemented on the river Lèze (South-West of France). The second approach consists in taking into account the topography of the overbanks in the assimilation process. This topography may also be provided by telemetry. In the cross-section, only the geometry of the main channel is then identified. This method has been implemented on the river Aisne (North of

France).

2 METHODOLOGY

2.1 Optimization techniques

The scope of data assimilation is to make the best estimate of the model state using observations and a numerical model.

If X t is the true state of the system at a given time (Ide et al., 1997), an observation y o of X t can be written as (Hoteit, 2001):

where F is an operator linking state space with obser vation space, called observation operator. It allows to calculate the model equivalent F(X t) of the obser vations. ε is a random vector with zero mean and covariance matrix R, modelling an observation noise.

The best estimate X a of the model state X t can be obtained by minimization of the sum of a distance to an a priori estimate (often a prevision) of the model state X f and a distance to the observations y o .

P is the covariance matrix of the error made in estimating X t by X f .

The numerical calculus of the analysis state X a can be very expensive, in terms of computation time, if the size of the vector is big. Several methods have been developed, using simplification hypothesis. They can be divided into two categories: statistical meth

ods calculate X a directly using its analytic expression

and formulating statistical hypothesis on the form

of the matrix P (Kalman, 1960). Variational meth

ods minimize the cost function in an iterative

way, using minimization algorithms (PALM Team,

1998).

These techniques have very different numerical

properties. Their equivalence stops as soon as some

underlying hypotheses are not verified, like the lin

earization of the observation operator for instance

(Carlier, 1982).A preliminary study (Roux et al., 2004)

has shown that the minimization of an error crite

rion gives satisfactory results for the purpose of this

study.

In the case of hydraulic parameter identification,

there is no prevision of the model state and therefore

no a priori estimate X f . That's why the cost function

only takes into account the distance to gauged data. 2.2 Model description The model that has been developed solves the steady-state one-dimensional Saint-Venant equations (Horritt & Bates, 2002): where Q is the discharge, q L the lateral inflow, H the water depth, S 0 the bed slope, S f the friction slope: S f = n 2 Q 2 /R H 4/3 S 2 (Graf, 1996), n the Manning coefficient, R H the hydraulic radius, S the cross-sectional area, Fr the Froude number: Fr = (Q 2 B/gS 3) 1/2 , B the flow top width and x the distance along the channel. This study will only deal with subcritical flows (Fr< 1). Therefore only one downstream boundary condition on the water depth and one on the discharge are necessary to solve (3). The chosen compound channel modelling supposes the equality of the friction slopes as well as the equality of the velocities in all the

cross-sectional subdivisions (Carlier, 1982), (U.S.A.C.E., 1997). It allows to calculate a composite coefficient of roughness n comp , function of the water depth (4). where P w is the wetted perimeter of the entire channel, P w,i is the wetted perimeter of subdivision i and n i is the friction coefficient of subdivision i (Figure 1). Equations (3) are integrated by means of order four Runge-Kutta's method. The resolution requires: - The definition of the geometry of the cross-section - The determination of the Manning roughness coefficient for each subdivision of the cross-section - The determination of the boundary conditions. Subdivision n°1 n 1 Subdivision n°2 n 2 Subdivision n°3 n 3 Figure 1. Compound channel.

The purpose of this study is to explore the possibility

to determine these data using optimization techniques

and the information provided by telemetry. Such a

method would be useful for the determination of all

the parameters for ungauged or poorly gauged rivers

but also for the determination of non-directly measur

able parameters, such as the Manning coefficient for

instance.

3 IDENTIFICATION OF AN EQUIVALENT RIVER

A 4 km reach of the river Lèze, in the South of

France, between the cities of Lagardelle-sur-Lèze and

Labarthe-sur-Lèze was considered (Figure 2).

Data concerning this site have been provided by

the DIREN Midi-Pyrénées (DIREN Midi-Pyrénées,

2001). They consist in two synthetic flood events, one

15-year event and one exceptional event determined

by geomorphology (Figure 3), and two real floods,

one occurred in 1977 and the other one in June 2000.

Figure 4 shows the extent of the flooded area for each event. The two real floods can be considered as exceptional events, indeed their extents are larger than the one of the exceptional event in some places.

3.1 Identification from one flood event

Figure 5 represents the hypothesis made on the geometry of the cross-section. The identified parameters are: the discharge at the downstream boundary, a local inflow as there is a local stream draining into the river, the stage at the downstream boundary, two Manning roughness coefficients, one for the main channel and one for the overbanks, and the characteristics of the geometry of the cross-section (Figure 5), that is to say main channel depths, cross bank and overbank slopes. These geometric parameters are estimated for each side of the river and for each cross-section. Crosssections are distant of about 70 m. In addition to the width of the flooded area for each event, the main channel width, that is to say the river bed, was also available as it can be seen in Figure 4. The most known error criterion in hydrology is the sum of square of errors (Nash & Sutcliffe, 1970), the objective function to be minimized in the assimilation process is then chosen as the sum of square of

Figure 2. Location map of the test site (from Agence de l'eau Adour-Garonne, 1998/1999).

Figure 3. Cartography of the possible floodplains of the river Lèze provided by the DIREN Midi-Pyrénées (from DIREN Midi-Pyrénées, 2001).

Figure 4. Extent of the 4 studied flood events.

Figure 5. Geometric characteristics of the cross-section.

Figure 6. Comparison between gauged and identified flow top widths, 15-year event.

errors between the observed flow top width B Obs and the simulated one B Sim . In order to take into account the asymmetry of the flooded area, the minimised cost function (5) represents the distance between gauged flow top widths and simulated flow top widths for each bank (Roux et al., 2003b).

The minimization is carried out using traditional algorithms based on the non-linear least square tech nique (Madsen, 2003).

Figure 6 shows the flow top width simulated with the parameters identified from the 15-year event. The result is satisfactory, nevertheless this approach needs a validation: the equivalent geometry (Figure 7) has been identified with only one event, it is necessary to ascertain that it also suits for others events.

The parameters listed above have been identified for each available flood event. Table 1 gives the values found for the hydraulic parameters by minimization of the cost function (5) for each event.

Knowing these values and the geometry, it is then possible to simulate the flow top width for each event.

Figure 8 compares the flooded area of the event of Figure 7. Geometry identified from the 15-year event. Table 1. Identified value of the hydraulic parameters. 15-year Exceptional Flood of event event June 2000 Discharge at 122.5 m 3 /s 259.0 m 3 /s 285.8 m 3 /s the downstream boundary Lateral 9.43 m 3 /s 12.8 m 3 /s 17.3 m 3 /s inflow Stage at 5.86 m 6.39 m 6.64 m the downstream boundary Figure 8. Comparison between gauged and simulated flow top

widths for the flood of June 2000. June 2000 with the flooded area simulated using the geometry identified from the 15-year event. As these events have very different hydraulic characteristics, the flooded area of the exceptional event

Figure 9. Comparison between gauged and simulated flow top widths for the exceptional event.

obtained by resolution of the Saint-Venant equations with the geometry identified from the 15-year event doesn't correspond to the observed one: the average error on the flow top width is of ±170 m for the right bank and±580 m for the left bank which corresponds to a average relative error of 37%. But if the two events have closer hydraulic characteristics, like the excep tional event and the flood of June 2000 for instance, the result is better as it can be seen in Figure 9. Indeed, the average error on the flow top width is of ±70 m for the right bank and±200 m for the left bank, that is to say a relative error of 19%.

Moreover, it is reasonable to say that the relevance of the identification can be improved by introducing more sets of gauged data into the assimilation process (Werner, 2001).

3.2 Identification from several flood events

3.2.1 Simultaneous minimization

The methodology is the same as in the previous para graph 3.1 but the cost function (6) represents the

distance to several flood events:

with

Discharge, lateral inflow and stage at the down

stream boundary are supposed to be known (Table 1)

and only the geometric characteristics of the transver

sal bed profile (Figure 5) are estimated by minimiza

tion of the cost function (6).A comparison between the Figure 10. Gradual building of the cross-section bed profile. gauged flooded areas for the three events and the simulated ones shows that the average relative error on the flow top width is of 14% for the 15-year event, 9.7% for the flood of June 2000 and 7.4% for the exceptional event. Consequently, the use of several flood events to identify an equivalent river actually leads to an improvement of the results. Indeed, the identified geometry allows to simulate the flooded area of the three events with an average error of less than 14%, compare to up to 37% with a reconstitution using only one event. Moreover, it is also possible to add points in the cross-section in order to better adapt the shape to the magnitude of the considered event. 3.2.2 Gradual building of the cross-section The implemented method consists in a gradual building of the transversal bed profile (Figure 10). A first minimization considering an event of discharge Q 1 will estimate the characteristics of a transversal bed profile with four cross-sectional slopes (Figure 5). These points will then be considered as known. The introduction of another event of discharge Q 2 , greater than Q 1 will allow to determine a change in the slope of the overbanks. In the case of the river Lèze, the first minimization considers the 15-year event. The flood of June 2000 and the exceptional event are then introduced into the assimilation process in order to estimate the location of the change of slope and the second slope of the overbank, for each side of the river. Consequently, in this second step, there are 4 new parameters to estimate for each cross-section. Figure 11 compares the extent of the 1977 flood with the flooded area obtained by simulation of the Saint-Venant equations with the geometry identified using the method of gradual building. The average error on the flow top width is now of ±50 m for the right bank and ±30 m for the left bank, that is to say a relative error of about 4.9% against 19% using only one event as for Figure 9, or 7.4% using several events simultaneously. Hence, there is an important

improvement of the portability of the identified geometry.

Figure 11. Comparison between gauged and simulated flow top widths, flood of 1977.

Next step will be to compare the flooded area simulated using the equivalent geometry with the one simulated using transversal bed profiles from in situ measurements.

4 UTILISATION OF THE OVERBANK TOPOGRAPHY

A 5 km reach of the river Aisne, located in the north of France, between the cities of Soisson and Compiègne, was considered (Figure 12). Data concerning this event have been provided by the Cemagref of Montpellier.

Flow top widths have been extracted from several air photos taken during the flood of December 1993 (Raclot, 2003). Another set of air photos, taken in low water period, provides the main channel width and the flow axe.This additional information can be integrated with profit into the assimilation process. Except the bridges and the locks, the studied flood plain presents few structures that can influence the flow, therefore it suits well the one-dimensional choice for the resolution of the Saint-Venant equations. However, only one set of gauged data is available.

Overbanks topography information (Figure 13) has

been obtained by photogrammetry. The precision of this information is supposed to be sufficient for hydraulic simulation purpose (Raclot et al., 2000). However, measurement points are distant of fifty meters approximately in both horizontal directions.

The objective function to be minimized is the same as in the previous case (5). The identified parameters are: the discharge, which is taken constant along the channel reach, the stage at the downstream boundary, two Manning roughness coefficients, one for the main channel and one for the overbanks, and Figure 12. Location map of the river Aisne reach (from Conseil Régional de Picardie, 2003). Figure 13. Topography of the overbanks provided by photogrammetry. the characteristics of the geometry of the main channel (Figure 14), that is to say altitudes of the bottom of the main channel and cross bank slopes. The geometric parameters are estimated for each side of the river and for each cross-section. Cross-sections are distant of 100 m. Figure 15 compares the gauged flooded area and the simulated one. The result is satisfactory for the right bank, the lower one on the figure. The simulated flow top width of the other bank does not correspond to the gauged flooded area. This is probably due to the fact that, as it can be easily seen on Figure 15, the left overbank is uneven. As the hydraulic simulation of Saint-Venant equations used to obtain the flow top width is strictly onedimensional, there is no way for the flow to bypass the obstacles. The incapacity of the model to simulate flows around an elevated part of the floodplain and

Figure 15. Top sight of the overbanks topography with the limits of both gauged and identified flooded areas and the points which altitude corresponds to the identified stage.

therefore separated from the main channel, explains

the peaks of the identified flooded area: the water is stuck behind the topography obstacles (Roux et al., 2003a). Indeed, a bidimensional simulation imple mented with Telemac2D (developed by Electricité de France, (Galland et al., 1991)) using the identi fied parameters calculates a flooded area that doesn't present these peaks. Furthermore, this flooded area better corresponds to the observed one (Figure 16). Searching for the points beyond the topography obstacles, which altitude corresponds to the identi fied stage, gives a better approximation of the gauged flooded area (Figure 15), as the 2D simulation already did. This result obviously does not take into account flows around the obstacles of the floodplain. Neverthe less, it shows that the identified altitude is satisfactory (Figure 17). Even if the flow discharge in the areas separated from the main channel is low, this test has emphasizes the importance of introducing the possibility of bypassing the topography obstacles in the resolution of the Saint-Venant equations, which is now being implemented. Another observation that can be made from Figure 17 is that the difference of water surface elevation between the two banks can rise up to 5 m, which is obviously incompatible with hydraulic requirements. Therefore a more accurate topography is needed to proceed the study in this direction.

5 CONCLUSIONS

The first approach of hydraulic parameter identification using an equivalent river has given satisfactory results for one set of observation. Adding information by introducing more events in the

assimilation process allows to build gradually the transversal bed profile which increases the relevance of the estimated parameters. Indeed, geometric parameters identified from two or three events allow to simulate the flooded area of a third event with a satisfactory precision. Concerning the introduction of the overbank topography in the assimilation process, it has been shown that the results can be satisfactory provided that

the topography is known with a sufficient precision.

According to (Alquier et al., 2000), an horizontal accu

racy of 2 m and a vertical accuracy of 0.5 m are needed

to simulate correctly the hydrodynamics of the flow on

the overbanks and to determine the stage with a preci

sion sufficient for flood risk management. Concerning

the determination of the flooded areas, a very good

knowledge of the topography is necessary, as local

bumps or holes can radically modify the flood inun

dation conditions. Indeed, (Bates & Anderson, 1996)

has demonstrated that a small change in topography

(±10 cm) may have complex and non negligible influ

ence on the model prediction. The case of the river

Aisne has emphasised the necessity of the introduc

tion of the modelling of flows separated from the main

channel in the resolution of the Saint-Venant equations

(Roux et al., 2003a), even if in these areas, the dis

charge is relatively low because of their high roughness

and their low depth.

Moreover, the methodology of this study is easily

adaptable to the new sorts of data that the pro

gresses in telemetry are going to make available in a few years (Smith, 1997). Indeed, satellite altimetry (TOPEX/POSEIDON launched in August 1992, or ENVISAT launched in March 2002) has been able to measure time series of water levels on very large rivers, such as the Amazon (Koblinsky et al., 1993), (Birkett, 1998), the Paraná or the Gange. If water levels were also available, the assimilation problem could be for mulated in a multi-objective context in which different cost functions those measure different distances, one related to the water level and one related to the flow top width for instance, can be optimised simultaneously. In this framework, the calibration will be tailored to the specific model application being considered (Madsen, 2003).
