Preface

River Flow 2004 is the second International Conference on fluvial hydraulics and has established the periodicity of the series. Organized as specialty conferences under the auspices of the International Association of Hydraulic Engineering and Research (IAHR) with its Fluvial Hydraulics and Eco Hydraulics Sections, River Flow conferences seem to be an important moment of aggregation for many researchers involved in river modelling and observation.

The intense land use of the last century and the lack of adequate sustainable development policies are probably the most important reasons of river hazards. For the importance of water as a resource in the human well-being we need a better comprehension of river processes and an adequate management of fluvial areas.

Scientists are aware of this necessity and largely contribute with their researches toward this aim. This clearly appears in the number of papers presented at River Flow 2004 (174) and from the number of country represented (43). Papers in this volume are related to the following topics:

- **Fluvial processes** (Morphology and morphodynamics; Bed forms and flow resistance; Over-bank flow and vegetation; Interaction with structures; Sediment supply, entrainment and transport);
- **River hazards** (Dam break and fast transients; Bank failure; Flood propagation; Hyper-concentrated flows; Water pollution and contaminant transport);
- **Hydraulics for river management** (River training and restoration; Habitat management and maintenance flows; Flood management and control; Integration of telemetry and GIS).

As the editors of the Conference proceedings we acknowledge the members of the International Scientific Committee for the in-depth reviewing of the manuscripts. The 70% of the accepted papers have been selected for oral presentation (123), while the 30% have been evaluated as more appropriately presented in the poster session (49). All the accepted papers have been included in this volume.

A grateful acknowledgment is deserved to all the members of the Local Organizing Committee for the intense work related to Conference preparation. Finally we acknowledge the Federico II University of Naples that was strongly involved in the success of River Flow 2004 for hosting the Conference, and the various sponsors for their financial support.

ABSTRACT: Failure of hydraulic structures by scour is a recent research topic in hydraulics, following spectacular losses of hydraulic structures mainly during floods. The research addressed in this paper refers to two types of scour, namely plunge pool scour and scour related to bridge structures. Based on recent research, the main results are presented along with descriptions on the reasons for scour progress and the basic concepts in which the scour features are hydraulically described. All results were collected from systematic model observations given that numerical predictions are complicated by a highly three-dimensional two-phase flow in bridge scour, and even a three-phase flow in plunge pool scour. The current observations may aid to define the missing items needed for numerical scour analysis in the future. It is also stated that both experimental and numerical approaches will be required in the future to deal with complex problems of scour in general.

1 INTRODUCTION

What is scour? According to an Internet notice: 'Scour is the removal of sediment (soil and rock) from streambeds and streambanks caused by moving water. Although scour may occur at any time, it is usually more significant during high flows, when the water is swift and deep. Swiftly moving water has more energy to lift and transport sediment than slowly moving water'. Is this really correct? We do not think so because an important point related to scour is the *local* erosion of sediments. Sediment transport, in contrast is more extended where sediment is dislocated and possibly deposited again. The difference between (more gradual) erosion and (concentrated local) scour of sediment in fluvial hydraulics may be the principal reason for complication with scour descriptions.

Scour has not been a research topic in hydraulic engineering until the 1930s. Some isolated tests were then conducted because of the failure of various structures and the damages caused. Even in the 1950s small attention was paid to local erosion because hydraulic engineers felt that their structures would withstand all impacts by water flow. This attitude changed only after significant troubles had been observed, such as with plunging jets related to trajectory spillways. Kariba dam on the Zambezi River was a typical example where the scour set a limit to designers, and this site has until now been under significant control and maintenance. Other problems occurred with bridges of which both the piers and the abutments were often a matter of concern. Most of these damages were attributed to unexpected floods and their malicious pattern that results in flow conditions not accounted for in the bridge design. Few damages are known from steep and narrow rivers, whereas most bridge failures occurred in flood plains with relatively small sediment particles where the river usually looks peaceful but where extraordinary forces may be mobilized during floods.

In recent years, scour analysis has become a specialty of fluvial hydraulics, with various books published on this topic. Mention may be made of Breusers and Raudkivi (1991), Hoffmans and Verheij (1997), Melville and Coleman (2000), May et al (2002), and Schleiss and Bollaert (2002). When going through the actual literature, one may observe an almost exponential increase of papers related to scour. This may have several reasons, among which can be stated: (1) Scour

has for a long time not been physically understood, whereas the basic concepts have been formulated within the past decades, (2) Scour experiments are relatively easy to conduct, and many may profit from this ease, (3) Scour can at this time hardly be modeled numerically, or only based on detailed laboratory observations, (4) Instrumentation has been refined and allows actually detailed insight into the hydrodynamic structure of scour, and (5) Scour is still a concern for sites which do not follow the standard arrangement, such as bridges in curves or in braided river reaches, where the direction of the main flow may be subject to significant changes during a flood. This last item was mentioned at this place because the authors do not think that actual failures are the real reason for the increased research activity in scour. Research items undergo also a fashion, and one of the topics of the day is obviously scour related.

The following intends to summarize recent findings of the authors. These include work related to bridge piers and abutments, to groynes both for steady and unsteady flow conditions, and to steady plunge pool scour. In all these cases essentially cohesionless sediment will be considered which can be described as a granular material. Scour is by far more complex, and may relate to almost all fields of hydraulic engineering where sediment is involved. Mention might be made here to problems in estuaries and tidal river reaches, to shore erosion in river curves, to drop structures in smaller river reaches or to oil platforms in the oceans. Accordingly, the present paper covers only a limited number of problems related to the local erosion process.

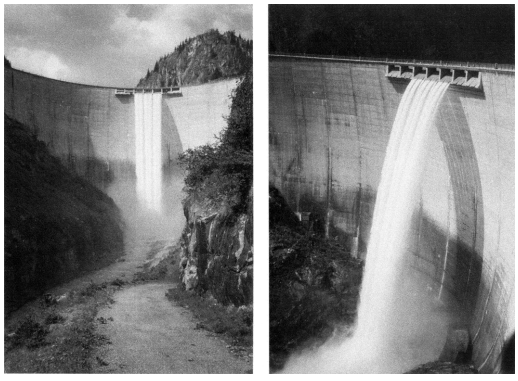

Figure 2. Free jet from crest overflow, general view (left), and side view (right).

2 PLUNGE POOL SCOURING

Scour resulting from plunging jets can be a significant concern both for structural foundation and backwater due to the ridge formation, where the scour material is deposited. Figure 1 shows a trajectory spillway in the French Alps that produces an air-water mixture flow in the atmosphere eventually impacting the downstream valley. Scour may be relatively small in such circumstances because the density of the impinging jet is relatively small, given the immense dispersion of the water flow and the production of spray. This may not be true for an almost vertically falling jet issued at the overfall crest shown in Figure 2, as compared to Figure 1, where the jet develops on a chute.

One reason that plunge pool scour by trajectory jets has received only limited attention until today is the complex experimental arrangement. In the past, thousands of plunge pools have been modeled yet the observations were practically all site related. Accordingly, limited information is presently available on the scour resulting from these jets (Canepa and Hager 2003). VAW has initiated a new research initiative some years ago, which was based on a simplified experimental arrangement: Instead of modeling the entire spillway with an overflow structure or a bottom outlet, the ski-jump structure and the entire trajectory reach, a pressurized jet configuration has been analyzed. Figure 3 shows the test scheme in which the main components are contained.

An air-water mixture jet composed of discharge Q_a and Q_w was supplied to a circular pipe of diameter D that varied between 0.040 and 0.10 m. The ratio of air to water discharges was denoted as $\beta = Q_a/Q_w \geq 0$. For some cases a base flow Q_m was added upstream from the pipe to investigate its effect on the scour. The pipe had an angle α relative to the originally horizontal sediment surface composed of grains with a median diameter d_{50} and a non-uniformity of $\sigma = (d_{84}/d_{16})^{1/2}$ of up to 2.67. The pipe could be submerged below the water surface of which the original flow depth was h_o, or discharge the mixture flow onto the water body. In the following, only the latter configuration will be considered.

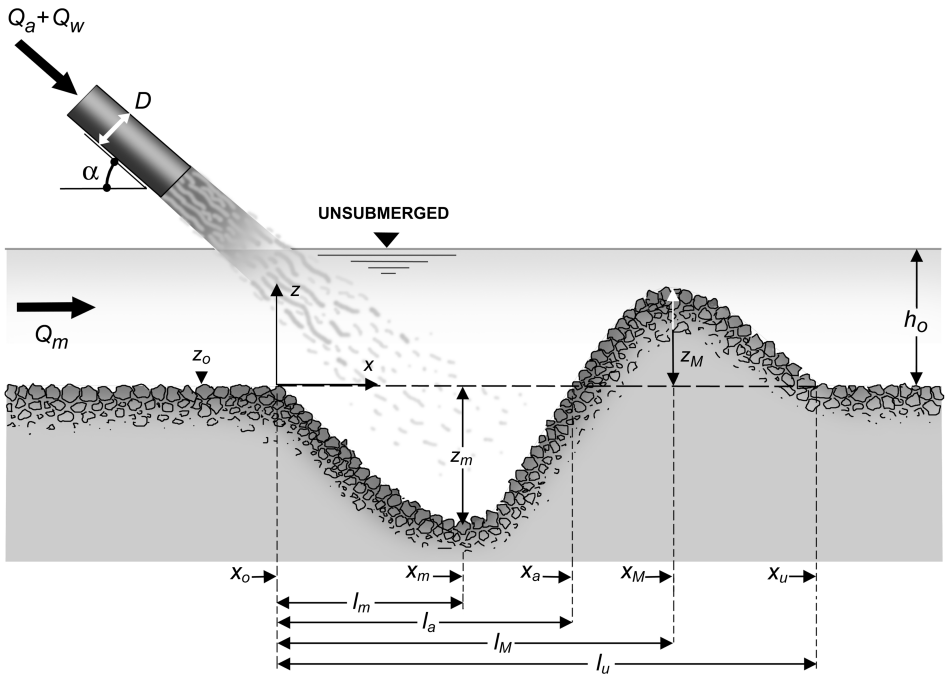

Figure 3. Test arrangement for laboratory investigation in plunge pool scour (Pagliara et al 2004b).

The scour hole resulting from the previous jet arrangement may be described with the maximum scour depth z_m, the maximum elevation of the ridge z_M and various streamwise distances that allow the full description of the scour geometry $z(x)$. It should be noted that there is a significant difference between the so called static and the dynamic scour. The latter occurs under water flow, whereas the static scour results when water flow has stopped. Static scour is usually much smaller than dynamic scour, depending mainly on the jet impact angle.

For incohesive sediment and relatively large jet velocity and jet diameter, it was demonstrated that the Froude similitude applies. Accordingly, because the flow in the vicinity of the scour hole has an almost horizontal surface, the densimetric Froude number $F_{d90} = V/(g' d_{90})^{1/2}$ had the main effect on all scour parameters, with $V = Q_w/(\pi D^2/4)$ as water velocity, $g' = [(\rho_s \rho)/\rho]g$ as reduced gravitational acceleration where ρ_s and ρ are the densities of sediment and fluid, respectively, and d_{90} corresponds to approximately the largest members of the granulate mixture. In prototypes, one may admit typically a $d_{90} = 0.20$ m for a fully developed scour hole in rock.

Based on more than 500 experimental tests, the main features of plunge pool scour have been determined experimentally for an almost two-dimensional arrangement (Canepa and Hager 2003, Pagliara et al 2004a, 2004b). In all the research, the relative maximum scour depth $Z_m = z_m/D$ was of particular interest. The results relating to Z_m may be summarized as follows:

(1) The densimetric particle Froude number F_d is linearly related to Z_m
(2) The effect of the jet impact angle α is small for $45° < \alpha < 90°$ and Z_m for $\alpha = 30°$ is about 80% of the absolute maximum
(3) The more air the jet contains, the less becomes the scour depth (Minor et al 2002)
(4) The tailwater effect as expressed with $T = h_o/D$ is relatively large; scour depths are deeper for small T than for large, because of the jet diffusion in the water body
(5) Sediment non-uniformity σ has no effect when the densimetric particle Froude number F_{d50} is considered using the median grain size d_{50}
(6) The upstream discharge Q_m may be accounted for by the Froude number $F_u = V_u/(gh_o)^{1/2}$ where V_u is upstream average velocity and h_o stillwater depth; Increasing F_u may significantly deepen the scour hole because the suspended material is deposited on the ridge
(7) The jet shape has no significant effect on the scour depth and scour geometry, an important justification for the test arrangement adopted in this research

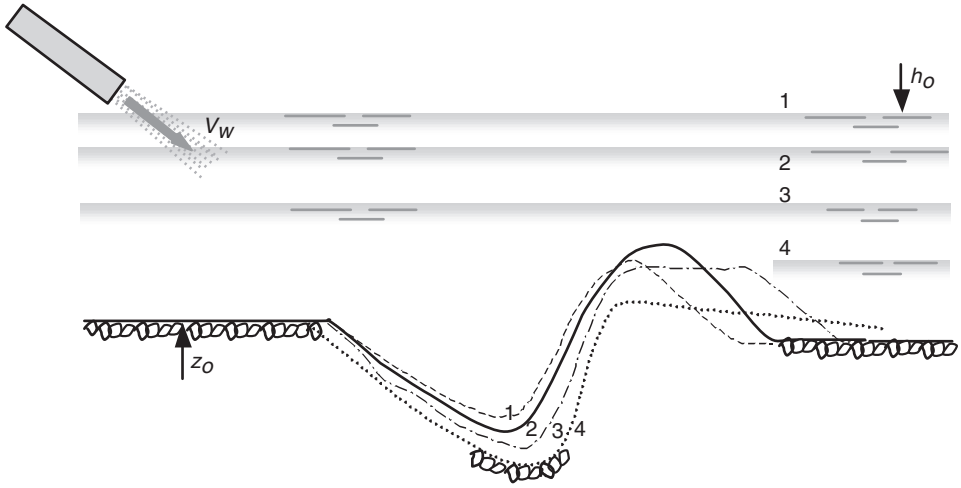

Figure 4. Effect of relative tailwater elevation T on scour geometry (Pagliara et al 2004b).

(8) A number of additional limitation govern the computational model, relating to minimum sediment size, minimum densimetric particle Froude number and the two materials sand and water involved to exclude scale effects.

Figure 4 shows a scheme where the tailwater effect is explained. For a large value of $T = h_o/D$ the scour hole is almost point-symmetrically distributed about the central point with $z = 0$ (case 1). As T decreases (case 2) both the scour depth and the deposition ridge increase. However, if T is further reduced the ridge reduces in height because its overflow has such a strong velocity that ridge erosion is initiated (case 3). By further reducing the relative tailwater to case 4 an even larger scour hole results, whereas the ridge may be completely eroded. This description points to the complexity of scour hole experimentation. This research pointed mainly to the definitions of both maximum scour depth and the scour profile, whereas the ridge characteristics were not fully explored, because of the combined scour and erosion involved by high velocities.

An equation for the maximum scour depth Z_m was presented in terms of the densimetric particle Froude number F_{d50}, the jet air content β, the relative tailwater depth T, the jet angle α relative to the horizontal, and the upstream Froude number F_u (Pagliara et al 2004b). The correlation with the present data was $R^2 = 0.94$. The authors were unable to locate other data series in which all the parameters are specified.

Figure 5 shows a photograph of the test arrangement used for this research. It must be stated that this problem would have hardly been solved without the experimental simplifications introduced as regards the air-water jet arrangement.

3 BRIDGE HYDRAULICS

3.1 *Introduction*

Bridges constitute a main infrastructure; their loss may have significant consequences particularly during

floods by cutting off adjacent transportation lines. From modern logistic considerations, the value of a bridge is thus high. Concerns for bridge structures became only a problem after the loss of some important structures. Today, not only the ways of how bridges may be protected against scour are of interest but also the causes of scour. Given that each obstacle placed in fluid flow results in a complex spatial and often highly-turbulent response by the fluid flow, the observation of bridge scour was for a long time obscure, although the main agent was attributed to the development of the horse-shoe vortex. The vortex structure as developed by a bridge pier, for example, is much more complicated as we presently regard the horse-shoe vortex. Due to the deflection of flow along the disturbing element, a strong vertical flow component is generated that may directly attack the sediment surface close to it. Novel instrumentation allows the visualization of these fascinating vortices, and these will be understood when the results are correctly analyzed.

Figure 6 relates to a typical plane velocity distribution upstream of a bridge pier. The flow is characterized by a densimetric particle Froude number $F_{d50} = 2.16$, the approach flow depth is $h_o = 0.13$ m, the approach velocity is $V_o = 0.62$ m/s, the sediment size is $d_{50} = 5.0$ mm, with a sediment non-uniformity parameter $\sigma = 2.13$ for a pier diameter $D = 0.26$ m. The (PIV) velocity field was taken once at the beginning of the experiment (Figure 6a), and after one day (Figure 6b).

Figure 6a shows the axial velocity distribution after 60s from initiation of the test, corresponding to the incipient entrainment of sediment. The approach flow is practically undisturbed up to close to the cylindrical pier and then deflected to either side of it. Note the relatively small surface recirculation zone and scour hole as compared to Figure 6b. The latter plot shows an advanced scour profile in the streamwise direction of some 0.09 m depth in front of the cylinder and a front wave height of some 0.02 m, corresponding to the approach velocity head $V_o^2/2g$. The velocity distribution in the approach region is almost uniform except for the bottom boundary layer and then slightly reduces when approaching the cylinder. More importantly is the deflection of flow, close to the free surface to form the surface recirculation zone, and at the lower flow portion to generate the bottom recirculation that creates the horse shoe vortex. The plot shows various distinct bottom recirculation zones that may be described with two essential vortices, and a small sediment rim between the two. The rim is a usual feature of pier scour, as also shown in Figures 7(a) and 8.

Figure 7 shows views of pier scour in fine sediment under a relatively small and large hydraulic load, including interesting structures of sediment deposition previously mentioned. For larger scour material the wavy deposition structure of the sediment disappears.

The following aims to describe both the overall effects of scour related to bridge structures, and more detailed results that were obtained by using modern instrumentation in scale models. It should be noted that numerical modeling of scour around bridge structures, or even in a general arrangement, is hardly possible these days, given the complex interactions between the fluid and the solid phases combined with a highly turbulent flow field. In contrast to a believe expressed some decades ago, most two- or even three-phase problems of the future will this involve a *combined* experimental and numerical approach. Figure 8 shows the complex scour surface at the end of an experiment, indicating a two-vortex structure close to the sediment surface.

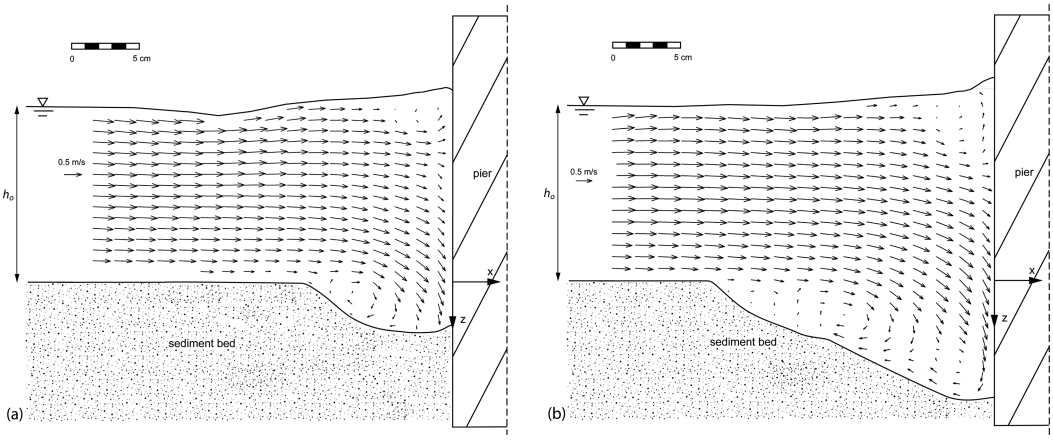

Figure 6. Plane velocity distribution in pier axis upstream of a bridge pier (a) shortly after the beginning of test and (b) after one day.

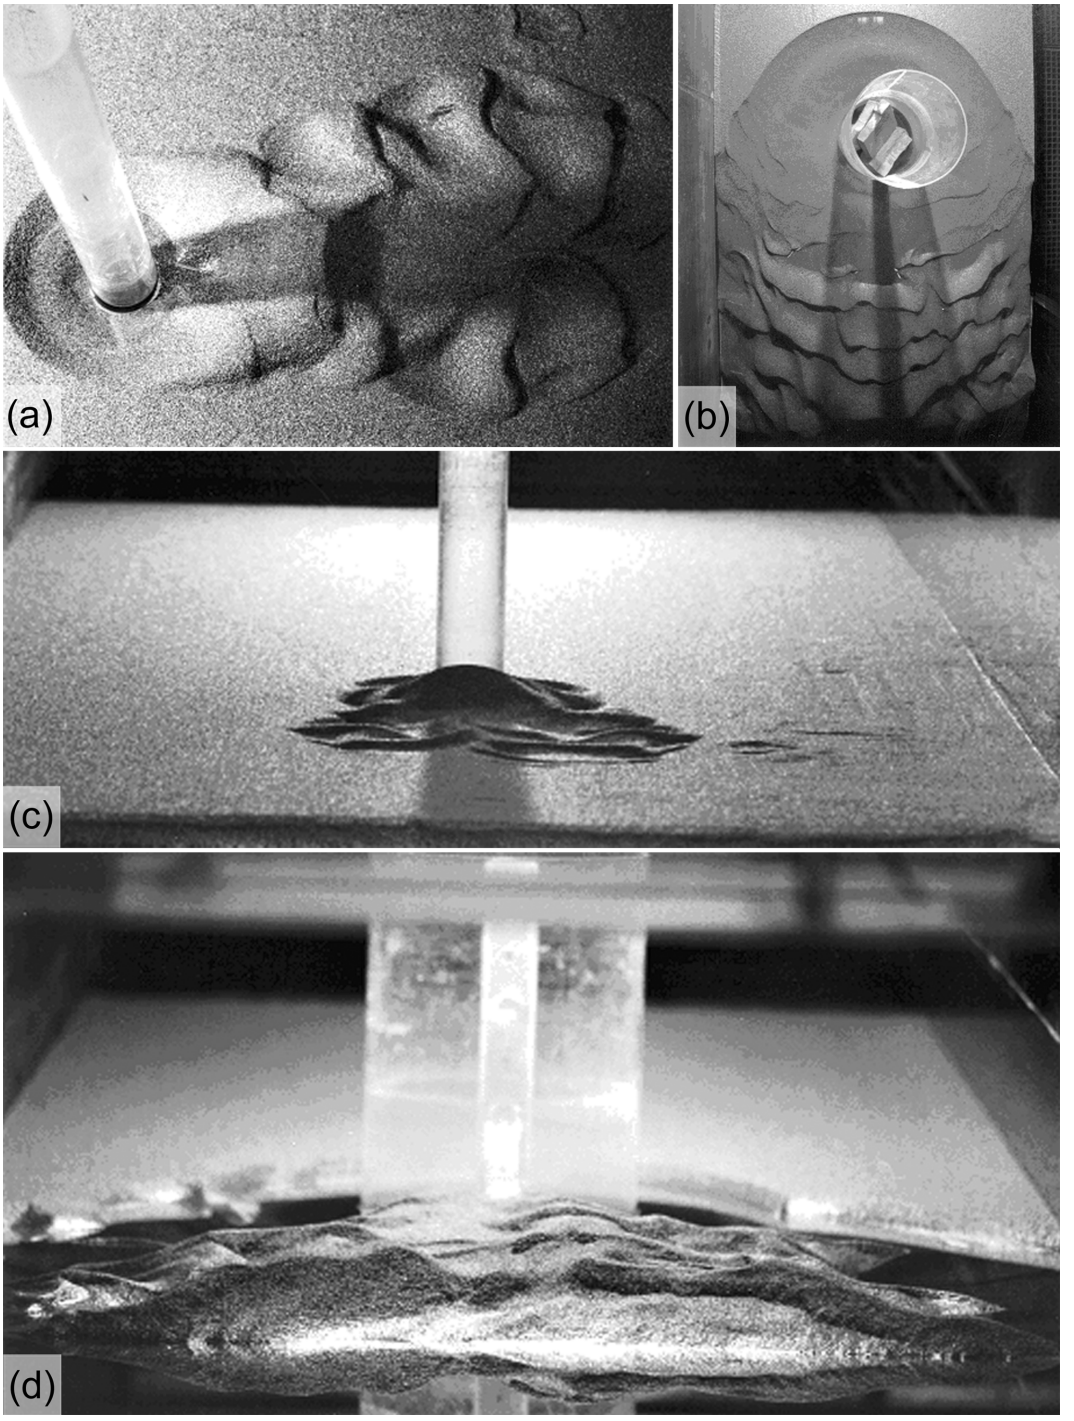

Figure 7. Pier scour (a–b) in plan and (c–d) downstream view (a and c) for small and (b and d) large hydraulic loads.

3.2 *General bridge scour equation*

Consider again cohesionless sediment that is subjected by turbulent fluid flow. As discussed by Oliveto and Hager (2002), the force F opposed by the element of surface A vertical to the direction of flow can be expressed simply by Newton's approach $F = \rho C_d A \bullet V_o^2/(2g)$ where ρ is fluid density, C_d drag coefficient and V_o the approach velocity. In engineering applications, the drag coefficient is often independent of viscous effects and varies exclusively with the element geometry. The extent of the scour hole and particularly the maximum (subscript M) scour depth z_M are assumed to depend directly on the force F, provided viscous effects are absent. Because the scour depth is a length, its determining length scale z_R is made up of relevant lengths that describe the problem. It was found that these are $z_R = (D^2 h_o)^{1/3}$ for a circular-shaped pier, and $(b^2 h_o)^{1/3}$ for a rectangular abutment, respectively. Here, D is the pier diameter, b the abutment width and h_o the approach flow depth (Figure 9).

Following the above approach the dimensionless scour depth $Z_M = z_M/z_R$ may thus be represented by a dimensionless velocity head times a function of time to account for scour progress. For flows with an almost horizontal surface across the element, i.e. for strongly subcritical flow, the so-called densimetric particle Froude number $F_d = V_o/(g' d)^{1/2}$ becomes relevant, because the approach Froude number $F_o = V_o/(g h_o)^{1/2}$ is practically zero. The scaling velocity $V_R = (g' d)^{1/2}$ replaces thus the shallow water celerity $(g h_o)^{1/2}$, where d is the relevant sediment size and $g' = [(\rho_s - \rho)/\rho]g$ is the reduced gravitational acceleration with subscript s relating to sediment.

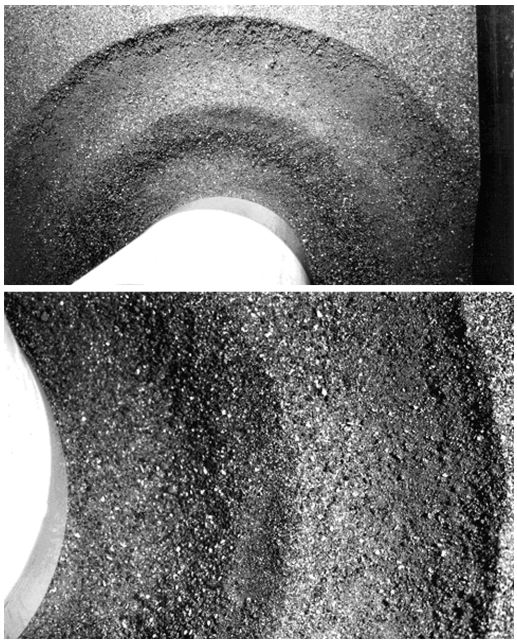

Figure 8. Structure of pier scour after scour hole was drained.

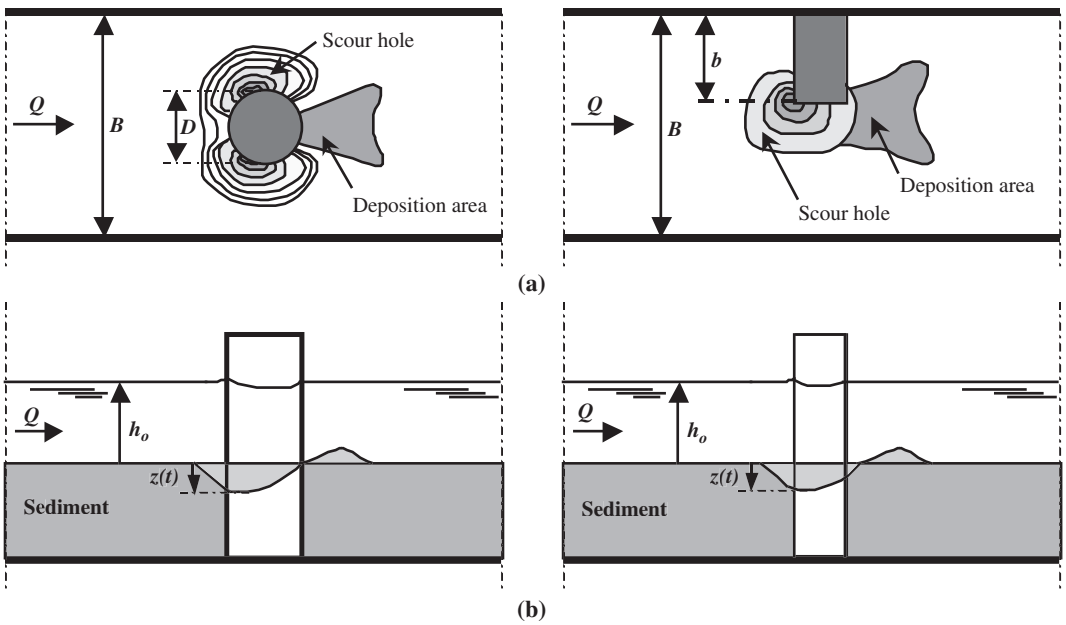

Figure 9. Definition plot for bridge pier (left) and bridge abutment (right), (a) plan, (b) section.

The previous considerations also allow the definition of the time scale, because $t_R = z_R/V_R$ such that the dimensionless time is $T = t/t_R$ simply. As an example, the reference time for bridge piers thus amounts to $t_R = (D^2 h_o)^{1/3}/(g'd)^{1/2}$ and involves parameters that are normally not considered with such processes, such as the relative density between the two phases considered.

The general form of the equation for maximum scour depth thus may be expressed, based on these considerations and detailed experimental observations as (Oliveto and Hager 2002)

$$Z_M = C \cdot N \cdot \sigma^{-1/2} \cdot F_d^{1.5} \cdot \log T \qquad (1)$$

Here, C is a constant, N is a coefficient in analogy to the drag coefficient, thus essentially variable with the scour element geometry, with $N = 1$ for circular-shaped piers and $N = 1.25$ for bluff abutments, and $\sigma = (d_{84}/d_{16})^{1/2}$ is the sediment non-uniformity parameter. The constant was found to be $C = 0.068$. Figure 10 shows scour around a rectangular-shaped abutment.

3.3 Extension of results

Oliveto and Hager (2004) considered additional scour elements, i.e. sloping abutments and spur dikes. The maximum scour depth resulting from these involve also (1). Figure 11 is a definition plot for the sloping abutment with b'' as its width at the original sediment surface and b' its width at the water depth h_o. Abutment angles $30° \le \alpha \le 60°$ were considered. Based on an extensive experimental approach, it was found that (1) may be applied provided the determining width of the element is $b = (b' + b'')/2$ and $N = 1$. The reduction of N from 1.25 to 1.00 is associated with the reduced resistance offered by the sloping as compared to the vertical abutment.

Spur dikes were then also investigated, based on the previous approach. Figure 12 shows an isolated spur whose length perpendicular to the flow direction is b_{eff} and whose average height is $s = (s' + s'')/2$. Note that it is assumed that the spur is fully submerged, i.e. $s < h_o$. Then, (1) may be assumed again provided the reference length is logically set to $z_R = (b_{eff}^2 s)^{1/3}$. Angles of α_s between 45° and 135° were considered, and reasonable agreement between (1) and observations was found, providing a spur factor $N_s = [\cos(\alpha_s/2)]^{1/3}$ was accounted for.

The typical spur effect, namely the flow concentration to the river axis associated with a generation of recirculation zones between two spurs may only be obtained with a series of spur elements. Oliveto and Hager (2004) thus investigated a sequence of three spur dikes and verified (1). It was found that the maximum scour depth is often located upstream of the first spur

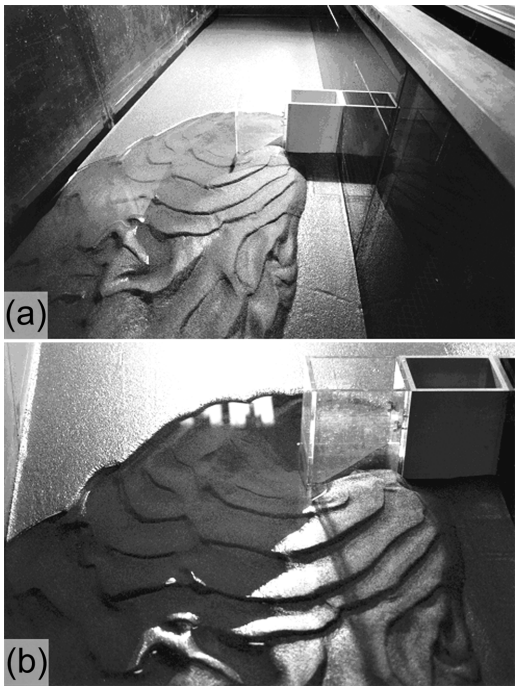

Figure 10. Scour around (a) relatively narrow and (b) wide abutments.

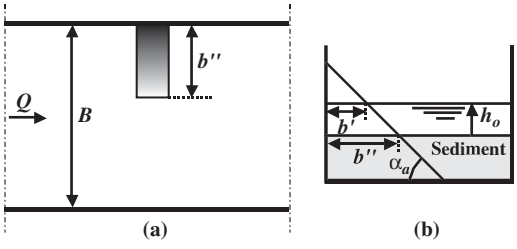

Figure 11. Sloping bridge abutment (a) plan, (b) section.

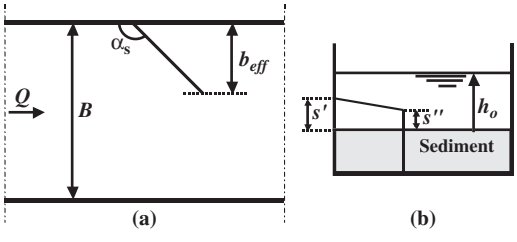

Figure 12. Isolated spur (a) plan, (b) section.

which may be described with the basic scour equation provided adequate coefficients are attributed to the various spur geometries. Until today, observations have not yet proceeded to a final equation involving

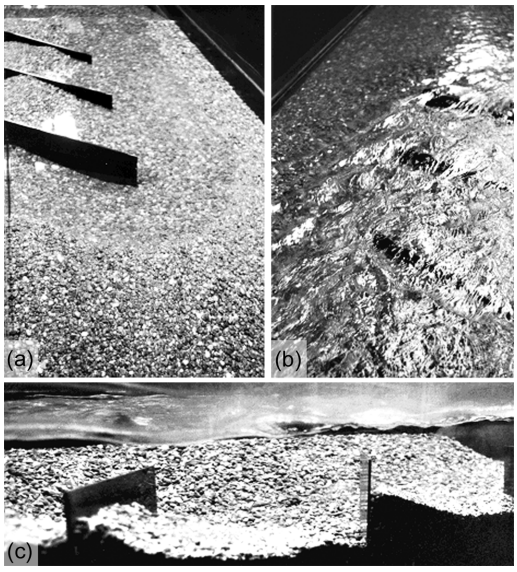

Figure 13. Spur experiments (a) at the end (view in flow direction) and (b) during water flow (view against flow direction); (c) side view.

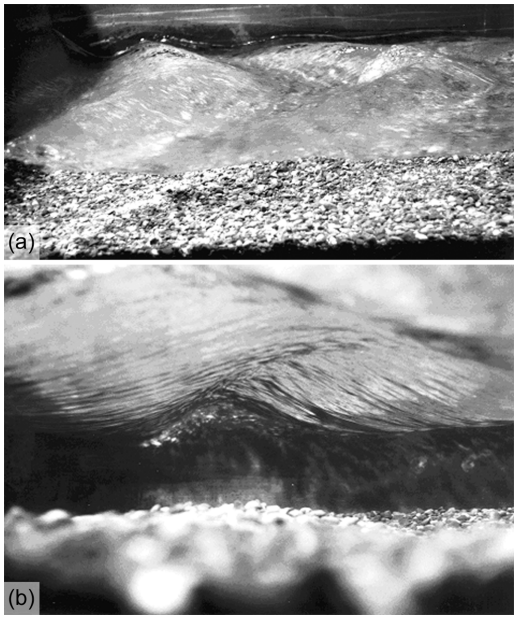

Figure 14. Scour below wave formation, (a) general arrangement and (b) detail of wave flow.

the spur angle α_s, the spur spacing and the spur slope. Figure 13 shows typical photos of spur experiments.

Figure 14 relates to scour below waves that were generated by removing the flow straightener at the channel inflow. Such poor flow conditions must be expected when the approach flow region is not correctly modeled. Here we show this flow because of its interest with the present discussion.

4 CONCLUSIONS

Scour related to hydraulic structures in rivers has many facets, involving the basic development of maximum scour depth and scour extension with time to the complex scour surface associated with the instantaneous velocity field that generates bottom currents responsible for scour advance. The present research intends to show some of the most striking features of scour in relation to plunge pools and to bridge structures. Both problems are characterized by a large number of parameters. Preliminary results were produced by suitably introducing simplifications that allow a straightforward approach to the problem.

For the plunge pool scour problem, the effective spillway was replaced with a pipe in which an arbitrary air-water mixture approach flow was generated. It was demonstrated that the shape of the approach flow on the scour advance has a negligible effect and that the substitute experimental setup suites for experimental observations. The effect of the main parameters mainly on the maximum scour depth was investigated. Results include in addition a generalized scour profile.

For bridge elements, and equation based on the resistance problem was employed and it was demonstrated that the data for various hydraulic elements such as piers or abutments, and spur dykes may be described with such a basic formula, provided the scaling parameters are carefully selected. In both and other research, the densimetric particle Froude number has the main effect on the scour characteristics, provided the sediment involved is sufficiently large that it may be considered incohesive, and the flow is in the turbulent rough regime such that viscosity effects remain insignificant. Problems to be considered in the future relate to both small hydraulic load and small sediment scale, where the viscous effects may not be negligible.

River Flow 2004 – Greco, Carravetta & Della Morte (eds.)

Mixing and dispersion in rivers

Gerhard H. Jirka
Institute for Hydromechanics, University of Karlsruhe, Karlsruhe, Germany

ABSTRACT: Water quality in rivers results from the physical, chemical and biological processes that take place due to multiple pollutant loadings along a river stretch. A sound understanding and description of these processes – usually encapsulated into predictive models – is needed so that design engineers and water authorities can develop appropriate discharge solutions and control strategies that meet applicable water quality laws and objectives. Continuous discharges from municipal, industrial or agricultural sources are subject to a permitting process by water authorities. The "combined approach" in the new EC-Water Framework Directive (WFD, 2000) consisting of environmental quality standards in addition to emission limit values promises improvements in the quality characteristics of surface waters. However, the specification of where in the water body the environmental quality standards do apply is missing in the WFD. This omission will limit its administrative implementation. A clear mixing zone regulation is needed so that the quality objectives of the WFD are not jeopardized. Instantaneous or accidental pollutant releases are another source of pollution loadings on rivers. Water authorities rely increasingly on "river alarm models" that predict the downriver propagation and dispersion of the pollutant mass as well as biochemical decay or adsorption processes. Currently, these models are fraught with considerable parameter uncertainties and an improved understanding of the transport mechanics in river systems with strong morphological variability is needed to minimize these. This is demonstrated for the case of rivers with a long sequence of groin fields that alternately retain and release the pollutant mass, greatly increasing the longitudinal dispersion.

1 INTRODUCTION

Rivers have always been the recipients of liquid water discharges from human activities, be it domestic sources, industrial or agricultural effluents, or mining process waters. Over the last two centuries, since the age of industrialization, the massive increase of industrial production accompanied by the growth of large urban populations has led to severe water pollution problems on many rivers, turning some of them into essentially open cloacae. In many of the developed countries, this adverse situation has fortunately been mitigated since stringent water quality protection laws were instituted in the period between the 1960s and 1980s so that modern pollution control schemes were implemented. Nevertheless, undesirable water quality conditions may persist and further improvements are needed even in these countries. Sadly, however, a rapidly worsening water situation takes place in many of the lesser developed countries, some of the urban megalopolises with unbridled population growth and uncontrolled industrial development being the worst examples.

Riverine water quality, with its spatial and temperoral distribution attributes, is the result of various physical, chemical and biological processes that occur due to the multiple pollutant loadings in a river stretch. A sound understanding and description of these processes – usually encapsulated into predictive models – is needed so that design engineers and water authorities can develop appropriate discharge solutions and control strategies that meet applicable water quality laws and objectives.

It is useful to distinguish two types of pollutant discharge problems as these have different physical response characteristics as well as different pollution control strategies that are used by water authorities. These are continuous discharge problems on one hand and instantaneous release problems on the other.

Continuous discharge problems are given by the more or less steady discharge of pollutants from "point sources" (e.g. effluents from treatment plants, from industries or from mining sources) and from "diffuse sources" (or "non-point sources", e.g. runoff from agricultural land or from urban drainage areas). These discharges occur continuously – even though they may undergo diurnal or seasonal variations – are somewhat controllable – especially so for the "point sources" – and are subject to water quality regulations. For the countries of the European Union the new EC-Water

Framework Directive (WFD, 2000) has the objective of an integrated catchment-oriented water quality protection for all European waters with the purpose of attaining a good quality status by the year 2015. The water quality evaluation for surface waters shall rely predominantly on biological parameters (such as flora and fauna) – however, aided by hydromorphological (such as flow and substrate conditions) and physico-chemical quality components (such as temperature, oxygen or nutrient conditions) – and on specific pollutants (such as metals or synthetic organic compounds). A good chemical quality status is provided when the environment quality standards (specified as concentration values) are met for all pollutants or pollutant groups.

Instantaneous release problems are given by the more or less sudden release of a pollutants mass into a river or adjacent to a river. These are mostly accidental releases or "spills", e.g. from industrial accidents, navigation mishaps, or failure of chemical holding tanks or ponds. The released pollutant mass propagates downstream in the river while gradually being dispersed and partially retained, due to various heterogeneities in the river channel. In order to plan short-term response measures for such accidental spills water authorities increasingly demand the establishment of co-called "river alarm models" that predict the propagation and dispersion of the pollutant mass in the river.

This article reviews the major physical, i.e. hydrodynamic, mechanisms that control these two types of pollutant discharge problems. It points out a major deficiency within the new WFD regulations, i.e. the absence of a clear "mixing zone" definition for continuous point sources, that is likely to limit its effectiveness in improving riverine water quality (see also Jirka et al., 2004). The article also indicates outstanding research needs in this area.

2 CONTINUOUS POINT SOURCE DISCHARGES IN RIVERS

2.1 *Regulatory mechanisms for water quality control*

The WFD defines new strategies against water pollution as a consequence of releases from point or diffuse sources. A new aspect of the EC water policy is the "combined approach", i.e. both limitations on pollutant releases at the source due to promulgation of emission limit values as well as the establishment of environmental quality standards. Releases of pollutants – especially from point sources – must meet both requirements. For most European member countries this new policy means a considerable deviation from current water quality management practice by which the releases of pollutants has been controlled by either one of these two control mechanisms, but usually not their combination.

Ragas et al. (1997) have reviewed the advantages and disadvantages of different control mechanisms in the permitting processes of releases into surface water. *Emission limit values* (ELV) present a direct and effective method for the limitation of pollutant loadings by restricting the concentration for the mass flux of specific pollutants. ELVs are preferred from an administrative perspective because they are easy to prescribe and to monitor (end-of-pipe sampling). From an ecological perspective, however, a quality control that is based on ELVs alone appears illogical and limited, since it does not consider directly the quality response of the water body itself and therefore does not hold the individual discharger responsible for the water body. To illustrate that point consider a large point source on a small water body or several sources that may all individually meet the ELVs but would accumulatively cause an excessive pollutant loading. *Environmental quality standards* (EQS), set as concentration values for pollutions or pollutant groups, that may not be exceeded in the water body itself (WFD, 2000) have the advantage that they consider directly the physical, chemical and biological response characteristics due to the discharge and therefore they put a direct responsibility on the discharger. But a water quality practice that would be based solely on EQSs could lead to a situation in which a discharger would fully utilize the assimilative capacity of water body up to the concentration values provided by the EQSs. Furthermore, the water quality authorities would be faced with additional burdens because of a more difficult monitoring – where in the water body and how often should be measured? – in the case of existing discharges or due to the increased need for a prediction modeling in case of new discharges. The "combined approach" in the WFD combines the advantages of both of these quality water control mechanisms while largely avoiding their disadvantages.

In the future practical implementation of the "combined approach" of the WFD two important questions will have to be addresses by the regulatory authorities: (1) *Where in the water body relative to the discharge point do the EQS-values apply*? Since the WFD provides no specific guidance on that question two extreme interpretations might be applied. First, the EQS-values apply immediately after the discharge with the idea that the whole water body would then be in a state of a good chemical status at every location at every time as indicated by the EQS-values. In that case, however, the EQS-values would be synonymous with the ELV-values! Secondly, the EQS-values apply after complete mixing for river discharges. Since the actual physical mixing processes in rivers are gradually leading to a "discharge plume, considerable areas in the water body would be affected by

concentrations above the EQS-values and would have to be considered as "sacrificial regions", in which a good chemical status would no longer be provided. It is obvious that a compromise, in form of a clear mixing zone regulation, is necessary. (2) *Which procedures shall be used during the permitting process to demonstrate that the discharge will in fact meet the relevant EQS-values in addition to the ELVs*? Not only for existing, but especially also for future, discharges does it seem necessary that different types of predictive models that describe the physical mixing and transport as well as chemical and biological transformation processes be applied so that the water authorities can in fact administer the "combined approach". These models allow to consider different hydrological situations and various scenarios of pollution loadings or central strategies.

2.2 *Mixing processes for continuous point sources in rivers*

When performing design work and predictive studies on effluent discharge problems, it is important to clearly distinguish between the physical aspects of hydrodynamic mixing processes that determine the fate and distribution of the effluent from the discharge location, and the administrative formulation of mixing zone regulations that intend to prevent any harmful impact of the effluent on the aquatic environment and associated uses.

The hydrodynamics of an effluent continuously discharging into a receiving water body can be conceptualized as a mixing process occurring in two separate regions. In the first region, the initial jet characteristics of momentum flux, buoyancy flux (due to density differences), and outfall geometry influence the effluent trajectory and degree of mixing. This region, the "near-field", encompasses the buoyant jet flow and any surface, bottom or terminal layer interaction. In this near-field region, outfall designers can usually affect the initial mixing characteristics through appropriate manipulation of design variables. As the turbulent plume travels further away from the source, the source characteristics become less important and the far-field is attained. In this region ambient environmental conditions will control trajectory and dilution of the turbulent plume through buoyant spreading motions, passive diffusion due to ambient turbulence, and advection by the ambient, often time-varying, velocity field in the river.

For river discharges the problem can be reduced in first order to so-called "passive" sources for which the input momentum and buoyancy effects are of lesser importance and mixing is controlled by the advective and diffusive properties of the ambient flow regime with a resulting discharge plume that follows the prevailing current. Thus, the problem is considered

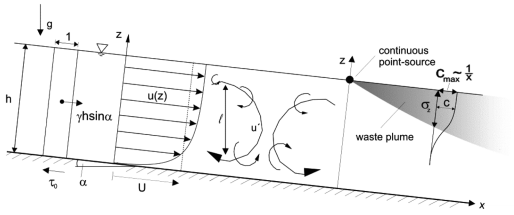

Figure 1. Longitudinal section along an inclined river flow with turbulent flow structure and assumed continuous point source at the water surface.

as a "far-field" effect with passive source characteristics. Research during the last 40 years has led to a solid understanding of the mixing dynamics in rivers as summarized in several textbooks or manuals (e.g., Fischer et al., 1979; Holley and Jirka, 1986; Rutherford, 1994).

The flow in rivers is characterized by turbulence, i.e. more or less large scale eddy motions are superposed on the average flow. The spreading and mixing of mass sources is then controlled by the eddy activities and can be described in analogy to the molecular mixing by an effective turbulent diffusivity E as the product of the velocity u' and size ℓ of the dominant eddies, $E \sim u'\ell$.

A river with a wide aspect ratio, $B \gg h$, where B is the width and h the average depth, is a simple equilibrium flow in which the bottom shear stress τ_o is counteracting the weight component acting in the flow direction (see Fig. 1), $\tau_o = \gamma hS$ where $\gamma = \rho g$ = specific weight of the water, ρ = water density, g = gravitational acceleration, and S = bottom slope = $\sin\alpha$. The friction velocity $u_* = \sqrt{\tau_o/\rho}$, is obtained on dimensional grounds, so that $u_* = \sqrt{ghS}$. u_* is therefore the major quantity characterizing the fluctuating eddy velocities u' in channel flows, $u' \sim u_*$, as has been confirmed by many measurements (Nezu and Nakagawa, 1993). It is related to the average velocity U by the frictional properties (roughness) of the bottom and is typically about 5 to 10% of U, $u_* = (0.05 \text{ to } 0.10)U$, with higher values for rough beds.

The large eddies that correspond to the depth of the base flow, $\ell \sim h$, are most effective for the mixing. Moreover, the eddy structure is characterized by a certain spatial anisotropy, their extent in the vertical direction z is more strongly limited than that in the horizontal direction y that lies transversely to the flow direction x. In summary, the following expressions for the turbulence diffusivities result from the above: The vertical eddy diffusivity E_z is

$$E_z = \alpha_z u_* h \qquad (1)$$

where $\alpha_z = 0.07 \pm 50\%$ (Rutherford, 1994) and the horizontal diffusivity E_y

$$E_y = \alpha_y u_* h \tag{2}$$

where $\alpha_y = 0.5 \pm 50\%$ (Fischer et al., 1979) for rivers with moderate variability, thus without strong meanders and without lateral dead water zones.

If a continuous point source is considered at the water surface a mass plume will evolve as is shown in vertical section in Fig. 1 and in plan view in Fig. 2. The pollutant plume spreads both vertically and transverse. Characteristic for such diffusion processes is the approximately Gaussian concentration distribution in the mass plume with the maximum value c_{max} at the water surface and at the river bank. The standard deviation σ describes here a local value $c = e^{-1/2} c_{max} = 0,61 c_{max}$ and is a practical indicator for plume width.

The distance L_{mv} to the location of complete vertical mixing of the plume is often defined as being to the point when the concentration at the bed becomes 90% of the surface concentration and this can be determined by the method of images (Fischer et al., 1979)

$$L_{mv} = 0.4 \frac{Uh^2}{E_z} \tag{3}$$

Using Eq. 1 ($\alpha = 0.07$) and strong roughness, $u_* = 0.10U$, the distance to the location of complete vertical mixing is given by

$$L_{mv} \approx 50h \tag{4}$$

The transverse spreading of a continuous point source located at the bank in a wide river flow ($B \gg h$) is outlined in Fig. 2. The longitudinal coordinate follows in this case any river curvature and a constant rectangular cross-section is assumed. The distance L_{mh} to the location where complete horizontal mixing over the river cross-section takes place is

$$L_{mh} = 0.4 \frac{UB^2}{E_y} \tag{5}$$

With $\alpha_y = 0.5$ and for strong roughness one obtains

$$L_{mh} \approx 8 \left(\frac{B}{h} \right) B \tag{6}$$

It should be noted that these simple equations for the estimation of complete mixing, Eqs 4 and 6, respectively, are (a) independent of the river velocity and (b) primarily governed by the river morphology. The first is because the turbulent mixing coefficients E_y and E_z scale directly with the mean velocity U! Comparison of the two formulas shows that in a wide river ($B \gg h$), the length for complete vertical mixing is always rather small as has been indicated in Fig. 2. Furthermore, in the initially three-dimensional mixing process (until the location where complete vertical mixing takes place) the drop-off of the maximum mass concentration is relatively fast, $c_{max} \sim x^{-1}$ (Fig. 1), while it occurs more gradually in the vertically mixed, thus two-dimensional, mixing phase, $c_{max} \sim x^{-1/2}$ (Fig. 2).

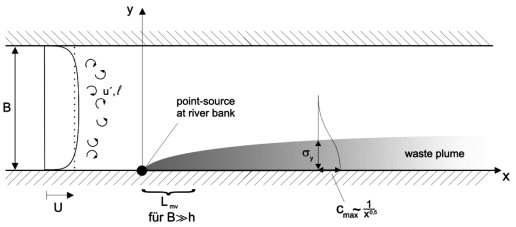

Figure 2. Transversal spreading for a continuous point-source located at the bank of a wide river flow ($B \gg h$), plan view.

Table 1. Examples for the complete mixing of a passive point source located at water surface and at bank of a river.

		Distance to complete mixing	
Example	B/h	Vertical L_{mv}	Horizontal L_{mh}
(i) Large river $B = 250$ m, $h = 3$ m	≈80	150 m	160 000 m
(ii) Small river $B = 5$ m, $h = 0{,}5$ m	10	25 m	400 m

Two examples are used for the practical illustration of the mixing dynamics of point sources in rivers: (i) Large river (approximately River Rhine near Karlsruhe, Germany, at average discharge), $B = 250$ m, $h = 3$ m, and (ii) small river, $B = 5$ m, $h = 0.5$ m. The calculations given in Table 1 show that complete vertical mixing occurs reasonably fast (150 m and 25 m, respectively), while complete lateral mixing requires considerably larger distances (160 km and 0.4 km, respectively)!

Several comments are in order: (1) The distance to complete vertical mixing will be somewhat reduced if the finite dimensions of the discharge opening are considered or if the source location is varied within the water column, e.g. located at mid-depth. Thus, the discharge design can play a certain role in this initial region. (2) The design features play a lesser role regarding the passive lateral spreading in the far-field. Only the lateral position of the discharge point is a potential factor: e.g. if the source is located in the center of the

river the distances for complete mixing are reduced by a factor 4 (since B/2 is used instead of B in Eq. 5 as the controlling lateral dimension). Beyond that, only the flow conditions in the river are decisive: For uniform flow conditions the estimation according to Eq. 6 would be somewhat low, while for strongly heterogeneous conditions – e.g. strong river meanders, or lateral constrictions that induce secondary flows – the actual distance might be somewhat shorter. (3) Both vertical and lateral complete mixing can be influenced by active mixing processes in the near-field of the discharge. Active mixing by momentum jets – especially in case of multiple diffuser discharges in rivers (e.g. Schmid and Jirka, 1999) – and buoyancy effects due to density differences lead, in general, to a reduction of the length for complete mixing. Models for the classification and prediction of these mixing complexities are available (e.g. Jirka et al., 1996).

Regardless of potential amplifications and complexities, the following rules of thumb apply for the mixing properties of point sources in rivers: (1) Complete vertical mixing is a rapid process with maximal dimensions of a few decades of the water depth. (2) Complete lateral mixing requires large distances. For typical river morphology (B/h = 10 to 100) the complete mixing will require from 100 to 1000 river widths (see also Endrizzi et al., 2002).

These analytical predictions for the delayed lateral mixing that are based on the description of the turbulent river flow properties have been confirmed through numerous field observations, in particular aerial photographs of "visible" plumes, taken from a period before recent source reductions were imposed, as shown in Fig. 3.

Figure 3. Aerial photograph (ca. 1960) of an industrial discharge located near the middle of the regulated River Rhine upstream of Lake Constance (Bodensee). The gradual lateral plume growth of the pollutant is typical for mixing processes in rivers. (Photograph courtesy of D. Vischer, Zurich).

2.3 *Consequences of the "combined approach": need for mixing zone regulations*

The mixing processes due to discharges into water bodies occur according to well understood physical principles, as has been shown above for the case of rivers, and lead to a spatial and temporal configuration of the mass plume and the associated concentration distribution. To what degree do the water quality control measures of the new EC-WFD, in particular its "combined approach" consisting of emission limit values (ELV) and environmental quality standards (EQS), correspond to these physical facts?

The relevant values for ELV and EQS for various pollutants and pollutant groups can be found in different directives of the EC (see e.g. Appendix IX of the WFD) or of the national authorities. By way of example for further analysis, Table 2 contains the values for two chemical pollutants (cadmium and triochlorethane). The ratio ELV/EQS is 10 for triochlorethane and 500 for cadmium. The range of 5 to 1000 is typical for most chemical as well as physical parameters, such as heat (temperature). This ratio describes the impact of the pollutants on the ecosystem, since the ELV is considered to protect against acute (lethal) effects on organisms, while the EQS is supposed to prevent long-time chronic influences. The ratio also expresses the necessary dilution that must be attained through physical mixing or – to

Table 2. Examples for emission limit values (ELV) and environmental quality standards (EQS) for two selected pollutants.

Pollutant example	Emission limit values ELV	Environmental quality standards EQS	ELV / EQS
Cadmium	0.5 mg/ℓ (83/513/EEC)	1 µg/ℓ (76/464/EEC)	500
Trichlorethane	0.1 mg/ℓ (AbwV, Germany, 2000)	10 µg/ℓ (76/464/EEC)	10

some extent – through biological decay and chemical transformation processes.

There can be other ways of prescribing ELV-values, namely through the specification of a "best available technology (BAT)". For example, for sewage outfalls this may be described as some form of treatment, at least primary, or enhanced (e.g. chemically) primary, or a secondary biological treatment stage for nitrogen removal, or a tertiary stage for phosphorus removal. The requirement may be set by national authorities depending on type of water body and its use (fisheries or recreation) or on sensitive ecological zones. In general, such BAT requirements assure a certain degree of nutrient removal. Other indicator parameters, such as bacteria or viruses, are also reduced in the treatment process. For example, while the typical total coliform count for raw sewage ranges from 10^6 to 10^8/100 ml it gets reduced by a factor 100 to 1000 during secondary and by 1000 to 10,000 during tertiary treatment (Larsen, 2000). Assuming an average factor of 1000 the effluent values for total coliform would then be 10^3 to 10^5/100 ml. Existing EC regulations provide some EQS-values for total coliform, e.g. the 500/100 ml given by the EC Bathing Water Directive. Thus, ELV/EQS ratios between 2 to 200 can be obtained from the above estimates. This compares to the "traditional" dilution requirement of about 50 to 100 that has been used for many years for outfall design in the coastal waters of several European countries (Larsen, 2000).

Both measures, concentration values and removal degrees are useful to reduce and control water pollution, but where do these values apply? The "end-of-pipe" specification for the ELV is clear and unequivocal in Art. 2 (40) of the WFD:

"*The emission limit values for substances shall normally apply at the point where the emissions leave the installation, dilution being disregarded when determining them*".

Surprisingly, and quite illogical from the viewpoint of the physical features of the mixing processes, the WFD does not provide any information on the spatial application of the EQS-values. It also does not oblige the national authorities to establish such specification. Therefore, it must be expected that considerable uncertainties and highly variable interpretations or monitoring methods will occur in the practice of water authorities, both as regards the continuing approval of existing discharges as well as the permitting of new ones. The "combined approach" that appears sensible for an integrated ecological water pollution control is in danger of being by-passed or undermined in its practical implementation.

From discussions with personnel from regional water authorities the authors know of two extreme interpretations regarding this omission in the WFD: (1) The EQS-value shall be applied "as near as possible" to the discharge point in order to obtain a good chemical status in an area as large as possible. This highly restrictive interpretation negates the fact that the physical mixing process cannot be reduced to extremely small areas (in the limit this approaches an "end-of-pipe" demand for EQS!), but requires a certain space – in particular for imposed high ELV/EQS ratios. It undermines the balanced objectives of the "combined approach". (2) In case of rivers, the EQS-value applies after "complete mixing in the water body". However, as was shown in the preceding section the longitudinal extent of the pollutant plume until full lateral mixing is attained can be considerable, even in small rivers. This highly generous interpretation could therefore lead to a condition that large regions within a pollutant plume of the point source would be exposed to concentration values above the EQS and would, therefore, represent "sacrificial stretches". A similar evaluation can be found in a recent German strategy report on water research (DFG-KOWA, 2003): "The occasional assumption that environmental quality standards apply only after complete mixing leads in most water body types to intolerably large distances since mixing processes usually occur gradually…".

Thus, the new "combined approach" concept of the WFD is lacking a clear and factually correct mixing zone regulation that preserves the water quality objectives of the "combined approach" and accounts for the physical aspects of the mixing processes. Therefore, a future amendment of the EC-WFD and national regulations for its implementation, respectively, should contain the following approximate wording:

"*The environmental quality standards apply in the case of point sources outside and at the edge of the mixing zone. The mixing zone is a spatially restricted region around the point source whose dimensions shall be specified either according to water body type and use or on an ad-hoc basis.*"

The mixing zone defined in the above statement is a regulatory formulation with the following general attributes: (1) The term "mixing zone" signifies explicitly that mixing processes require a certain space. (2) The term "spatially restricted" should guarantee that the mixing zone shall be minimized by the regulatory authority for the purpose of attaining the environmental quality goals. (3) While the mixing zone includes a portion – namely the initial one – of the actual physical mixing processes, these processes will continue beyond the mixing zone where they lead to further concentration drop-offs in the pollutant plume below the EQS-values. (4) The definition is restricted to "point sources" since diffuse sources usually do not contain clearly distinct mixing processes.

The regulatory concept of mixing zones can also be found in the water quality regulations of other countries. As an example, the U.S. Environmental protection Agency defines in its Water

Quality Handbook:

"*… the concept of a mixing zone as a limited area or volume of water where initial dilution of a discharge takes place*" (USEPA, 1994). A number of supplementary restrictions further define this water quality control principle such as "*… the area or volume of an individual mixing zone … be limited to an area or volume as small as practicable that will not interfere with the designated uses or with the established community of aquatic life in the segment for which the uses are designated*," and the mixing zone shape be "*… a simple configuration that is easy to locate in the body of water and avoids impingement on biologically important areas.*"

Once the principle of a mixing zone has been adopted and defined in the EC-WFD and/or national regulations it is also necessary that national water authorities provide clear guidance for the actual specification of mixing zone dimensions. Two major possibilities exist here:

(a) Specification of numeric mixing zone dimensions according to water body type and biological characteristics:

In the case of *discharges into a river* (see Fig. 4), the width of the mixing zone B_{MZ} can be restricted to a fraction of the river width, e.g. $B_{MZ} = n_B\ B$, with the goal that the majority of the river cross-section provides for unhindered passage of river fauna (fish), or the length of the mixing zone L_{MZ} can be described, e.g. $L_{MZ} = n_L\ B$, with the goal that high concentrations along the river banks are constrained, or both prescriptions may apply jointly. The multiples n_B and n_L – with typical ranges $n_B = 0.1$ to 0.5 and $n_L = 1$ to 5 – may be set by the water authorities based on regional considerations taking into account water body type, water use and biological characteristics.

For the case of *coastal discharges* Jirka et al. (2004) have given analogous recommendations for mixing zone around submerged diffuser outfall structures.

(b) Specification of mixing zone dimensions in an ad-hoc manner:

After prior ecological evaluations or predictions the discharger can request the authority for a mixing zone with a certain dimension with the claim that this would guarantee an integrated water quality protection. Based on its own examinations the authority can agree with that proposal or else demand further restrictions.

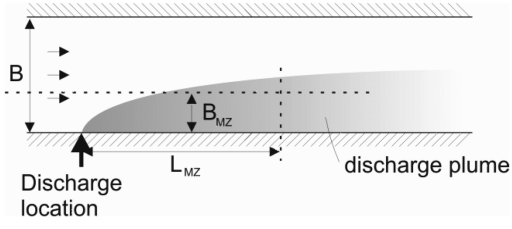

Figure 4. Example of regulatory mixing zone specifications for discharges into rivers: Width of mixing zone B_{MZ}, and/or length of mixing zone L_{MZ}, both defined relative to the river width B.

2.4 *Increased application of modeling techniques for mixing processes*

As another consequence of the "combined approach" of the new WFD values it appears that both dischargers as well as water authorities must increase the application of quantitative predictions of substance distributions in water bodies (water quality parameters in general, mixing processes in particular). This holds for both existing discharges (diagnosis) as well as planned future discharges (prediction).

There are several diagnostic and predictive methodologies for examining the mixing from point sources and showing compliance with EQS-values:

(1) *Field measurements or tracer tests* can be used for existing discharges in order to verify whether EQS-values are indeed met. Field measurements are costly, often difficult to perform, and usually limited to certain ambient conditions. Frequently, they must be supported through mathematical model predictions, on one hand, to establish a clear linkage to the considered discharge (especially if more than one discharge exists), and on the other hand, to synthesize conditions allowing for variabilities in the hydrological or oceanographic conditions or in the effluent rates.

(2) *Hydraulic model studies* replicate the mixing process at small scale in the laboratory. They are supported by similarity laws and are quite reliable if certain conditions on minimum scales are met as has been demonstrated in the past. But just like field tests, they are also costly to perform and inefficient for examining a range of possible ambient/discharge interaction conditions.

(3) *Simple analytical equations or nomograms* (e.g. Rutherford, 1994; Holley and Jirka, 1986) are often satisfactory to predict reliably the mixing behavior of a pollutant plume. For example, the maximum pollutant concentration c_{max} as a function of distance x along the flow for a passive point source at the bank of a river (see Fig. 2) is given by

$$c_{max} = \frac{2 Q_{co}}{h\sqrt{4\pi E_y U x}} \qquad (7)$$

where Q_{co} is the pollutant mass flux of the source (mass/time) and E_y is the lateral turbulent diffusivity from Eq. 2. The factor 2 on the right hand side signifies the reflection effect of the impermeable river bank. In many river applications with relatively uniform cross-sections Eq. 7 would be satisfactory for a conservative

prediction, possibly combined with parameter sensitivity studies (see coefficient α_y in Eq. 2) in order to predict the maximum pollutant concentration along the bank and to demonstrate compliance with the EQS-values. Simple amplifications of Eq. 7 in the form of a stream tube method (see Fischer et al., 1979) are available for strongly meandering and non-uniform river sections.

(4) *Mixing zone models* are simple versions of more general water quality models. They describe with good resolution the details of physical mixing processes (mass advection and diffusion), but are limited to relatively simple pollutant kinetics by assuming either conservative substances or linear decay kinetics. This is acceptable for most applications, since residence times in the spatial limited mixing zones (see previously mentioned specifications) are typically short so that chemical or biological mass transformations are usually unimportant. As for all computer-based models that are concerned with environmental problems – here with water quality as a common good! – the scientific transparency of the predictive models is essential. That means not only that the governing equations and all relevant assumptions must be clearly published but also the actual calculation module must be available as public domain software and thus scientifically verifiable. User interfaces as well as pre- and post-processing modules can, of course, be added, developed and distributed in a for-profit manner in an open market. Undoubtedly, the main problem in the application of mixing zone models is the estimation of its applicability by the user. In particular, simple model types are often limited to certain flow situations. Model assumptions and limitations must be clearly stated by the model developer. But even then it may be difficult for the user with limited experience in these complex processes of fluid mechanics to judge whether a model is applicable for a specific situation. The application of expert systems seems advisable for that problem. An expert system can lead the user in sequential steps through data acquisition, it performs the selection of a specific sub-model or predictive equation depending on the physical situation, it provides the graphical display and interpretation of the predictive values with regard to the compliance with EQS-values and mixing zone regulations, and finally it may provide recommendations regarding additional sensitivity studies or design changes for the optimization of the mixing process. Ragas (2000) provides a comparison of different mixing zone models. The mixing zone model CORMIX (Doneker and Jirka, 1991; Jirka et al., 1996), in particular, is characterized by its wide applicability to many water body types (rivers, lakes, estuaries, coastal waters) and has been successfully used for water quality management under different regulatory frameworks.

(5) *General water quality models* may be required in more complex situations. In simple water bodies, such rivers, coastal regions or estuaries with well defined uni-directional current regimes or with simple reversals, and with moderate pollutant loadings, the use of mixing zone models alone may suffice to arrive at, or to evaluate, a design of a point source discharge that meets regulations. However, in coastal regions with multiple current regimes (inertial, tidal, wind- or buoyancy driven) and in rivers and coastal regions with large pollutant loadings, especially where several sources may interact and additional diffuse sources may exist, mixing zone models must be supplemented by larger-scale (far-field) transport and water quality models. The latter are capable of prediction over greater distances in the water body the concentration distributions for different pollutants, but also for nutrients and other bio-chemical parameters with due consideration of mass transformation and exchange processes. They do not, however, have the high spatial resolution that is required to predict mixing processes and the compliance with EQS-values in a limited mixing zone. An effective and sensible approach for strongly loaded water body reaches is therefore the prior application of general water quality models in order to predict background concentrations in the vicinity of the considered point source. Superimposed on these background considerations are then the additional concentrations within the pollutant plume as predicted by the mixing zone model. For rivers, the model AVG of the German ATV-DVWK, the model QUAL-2 of the U.S. EPA, and the model RWQM1 of the International Water Association are all examples of general water quality models. Such models also form the basis of management procedures for attaining a good quality status in the case of multiple sources, i.e. by following the principle of a distributed waste load allocation for individual water users.

The ultimate goal of European water quality policy as promulgated in the Water Framework Directive of 2000 is the attainment of a good quality status by the year 2015. Therefore, a future amendment of the WFD and of corresponding national implementation procedures must contain a clear and unequivocal mixing zone regulation in order to not jeopardize that goal. Increased usage of several types of water quality models by both dischargers and regulatory authorities will be another key mechanism for reaching that goal.

3 INSTANTANEOUS RELEASE PROBLEMS IN RIVERS

3.1 *River alarm models*

Accidents happen, as the adage says. While the water quality impact of continuous discharges can be

controlled and reduced by water authorities through the aforementioned permitting process, there exist limited control options for accidental pollutant releases or spills. Of course, increased safety regulations and/or redundant design requirements are important for minimizing industrial, mining or navigational accidents that cause short-time chemical pollutant releases in or along rivers. Yet despite such measures accidental spills are bound to occur, albeit with decreased likelihood and frequency.

The major option for water authorities lies in enabling a rapid emergency response to warn downstream users and to mitigate secondary damages, e.g. by shutting down of water intakes during passage of the pollutant mass or limiting recreational uses. The key element for response planning are so-called "river alarm models (RAM)" that allow the on-line operational tracking and prediction of the released pollutant mass by forecasting its movement and dispersion along the river channel. The first such RAM was instituted by the Commission on the Hydrology of the River Rhine in cooperation with the International Commission for the Protection of the River Rhine (ICPR) in the wake of the dioxin spill from the Sandoz plant, Basel, Switzerland, in 1986 that heavily damaged flora and fauna along the entire river. Other recent spill disasters of major proportions have been along the Dnjepr, Russia (1970s), the Guadalquivir, Spain (1998), and the Tisza, Rumania (2001), all of these resulting from the failure of retention dikes for chemical or mixing process waters.

Alarm models are currently being implemented by different European river basin authorities, and presumably around the world. Common for these RAMs is a one-dimensional formulation in order to facilitate the on-line installation on PCs within the water authorities and operation with a minimum of hydrological information on initial and boundary conditions. To a great degree these RAMs are highly empirical as the parameters describing the transport and dispersive characteristics of the pollutant mass in the one-dimensional formulation are subject to large uncertainty, particularly so in river channels with major heterogeneities. These include rivers with highly variable natural morphology, side arms and dead zones as well as regulated river with groins or spur-dikes and secondary floodways. Because of this predictive uncertainty it is necessary to conduct dye dispersion tests in the river in order to deduce the required model parameters. These tests are very time-consuming and expensive and are always limited to the given hydrologic regime (low, average or high flow). A thorough mechanistic understanding of the generic role of channel heterogeneities on mass transport and dispersion is needed to improve the predictive capabilities of existing RAMs and help in the formulation of new ones for other rivers.

3.2 *Dispersion processes for instantaneous mass releases in rivers*

Turbulent flow and transport in a river is, of course, a three-dimensional process. Hence, the concentration c(x, y, z, t) following an instantaneous release of pollutant mass M in a given steady-state velocity field $\vec{q} = (x, y, z)$ is given by the three-dimensional advection diffusion equation (Fischer et al., 1979) in which the turbulent diffusivities E_x, E_y, E_z (each a function of x, y, z) describe the turbulent spreading process (Reynolds-averaged over the time scale of fluctuations). x is the longitudinal coordinate following the river channel, y the lateral and z the vertical coordinate. Under the assumption of uniform unidirectional mean flow – either a straight river channel or in a natural coordinate system following a mildly curving channel – the mean velocity field $\vec{q} = (u, v, w)$ simplifies to $u(y, z)$, $v = 0$, $w = 0$ and diffusivities are functions of y, z only. In principle, the three-dimensional advection–diffusion equation – for general or simplified uniform geometry – can be solved by numerical computational techniques subject to some closure approach on the turbulent diffusivities.

In the practice of RAMs – as for many other water quality or hydraulic problems – the general three-dimensional solution is not feasible for operational reasons or often not necessary. In that case simpler solutions by spatially averaging over one or two transverse dimensions can be obtained. For RAMs the averaging over the entire channel cross-section A, thus integrating over y and z, is typical practice. The one-dimensional mass conservation equation that results from this averaging process reads for a conservative pollutant

$$\frac{\partial C}{\partial t} + U\frac{\partial C}{\partial x} + \frac{\partial}{\partial x}\widetilde{u''c''} = \widetilde{E_x \frac{\partial^2 c}{\partial x^2}} \qquad (8)$$

in which C(x, t) is the cross-sectionally averaged (mean) concentration, U the mean velocity and ~ denotes cross-sectional averaging. The term on the right-hand side specifies the turbulent diffusion (i.e. the role of time-averaged fluctuations) in the longitudinal direction. The crucial term, however, is the so-called "small-scale advective" flux $\widetilde{u''c''}$ which represents the spatial correlation of the deviations of velocity $u''(y, z) = u - U$ and concentration $c''(y, z) = c - C$ from its mean values.

The result of the "small-scale advection" process is shown schematically in Fig. 5 for a uniform channel flow with an internally shear and velocity profile u(y, z). For short times, the concentration distribution strongly resembles the shape of the velocity profile while additional turbulent diffusion causes spreading in all directions, especially also in the transverse direction. For long times, the interaction between the

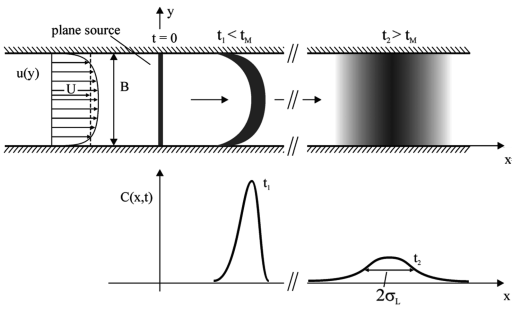

Figure 5. Schematics of longitudinal dispersion process in uniform river. For short times the cross-sectional profile C(x, t) is strongly skewed, for long times it assumes a Gaussian distribution.

longitudinal stretching mechanism due to shear flow and the transverse mixing mechanism due to turbulent diffusion is pronounced and enters an asymptotic state that is called the "longitudinal dispersion" mechanism. In this stage the cross-sectional concentration distribution is essentially homogeneous and is Gaussian in shape in the longitudinal direction. Furthermore, the standard deviation σ_L of this distribution grows $\sigma_L \sim \sqrt{t}$, all attributes that resemble a Fickian diffusion process, i.e. mass diffusion as an ensemble result of many individual independent random processes. In his ground-breaking papers, Taylor (1953, 1954) showed that this dispersion process can be represented by an equivalent advection–dispersion equation

$$\frac{\partial C}{\partial t} + U\frac{\partial C}{\partial x} = E_L \frac{\partial^2 C}{\partial x^2} \tag{9}$$

in which the longitudinal turbulent diffusion term in Eq. 8 has been neglected as being much smaller than the dispersion term. E_L is the coefficient of longitudinal (or shear flow) dispersion.

Taylor has also shown – in his case for axisymmetric pipe flow – that the value of E_L can be computed directly from the distribution of the shear flow u(y, z) and the transverse diffusivities $E_y(y, z)$ and $E_z(y, z)$ through triple integration. For the case of a purely vertically sheared two-dimensional uniform channel flow, u(z) and $E_z(z)$ only, this triple integration reads

$$E_L = -\frac{1}{h}\int_o^h u'' \int_o^z \frac{1}{E_z}\int_o^z u'' dz dz dz \tag{10}$$

in which h is the water depth.

Eq. 10 was first evaluated by Elder (1959) for the turbulent logarithmic velocity profile and associated diffusivities to yield

$$E_L = 5.9 u_* h \tag{11}$$

in which u_* is the shear velocity as the major factor characterizing turbulent eddy velocities.

In another seminal contribution, Fischer (1967) dealt with dispersion processes in natural river channels, that are typically wide and shallow, $B/h \gg 1$, in which B is the river width. He showed that while the velocity profile is doubly sheared u(y, z) the vertical shearing effect u(z) (i.e. Elder's approach) is of lesser importance while the lateral shear $\bar{u}(y)$ becomes dominant as it operates over a much larger scale (B). Here $\bar{u}(y)$ is the vertically averaged velocity profile that has been sketched in Fig. 5. Fischer represented Taylor's integral in depth-averaged form

$$E_L = -\frac{1}{A}\int_o^B (\bar{u} - U) h \int_o^y \frac{1}{E_y h}\int_o^y (\bar{u} - U) h \, dy \, dy \, dy \tag{12}$$

in which $E_y(y)$ is the depth-averaged lateral diffusivity (see Eq. 2). The evaluation of Eq. 12 with measured lateral velocity profile from either laboratory or field experiments showed generally very satisfactory agreement with the dispersion coefficient that has been measured from corresponding dye tracer tests through growth of the variance σ_L^2,

$$E_L = \frac{1}{2}\frac{d\sigma_L^2}{dt} \tag{13}$$

where $t = x/U$ corresponds to the travel time between subsequent measurement stations.

As stated above, the advection–dispersion equation, Eq. 9, the associated values of E_L, and finally its solution

$$C(x,t) = \frac{M}{A\sqrt{4\pi E_L t}}\left\{\exp\left[-\frac{(x - Ut)^2}{4E_L t}\right]\right\} \tag{14}$$

are only valid in the final dispersive stage of the mixing process. The duration of the initial or convective stage is given by the transverse mixing time t_M. For the case of river channels, t_M is given by (Fischer, 1967; Fischer et al., 1979)

$$t_M = 0.4\frac{B^2}{E_y} \tag{15}$$

which corresponds, $t_M U = L_{mh}$, to the associated mixing distance L_{mh} given in Eq. 5. During the convective stage, $t > t_M$, the mean concentration distribution is strongly skewed (see Fig. 5). The behavior of the pollutant mass ("cloud") furthermore depends on the discharge details, whether more or less uniform across the river or whether a release in mid-river or near a bank.

3.3 *The role of channel heterogeneities: influence of groin fields*

It has long been recognized that the dispersion process in natural river channels may be greatly enhanced

beyond the simple shear flow effects in a uniform channel as described in the preceding. Higher order influences, such as dead-zones or retarded flow zones caused by overbank flows, meanders, side arms, partially vegetated areas, and groin fields cause additional flow non-uniformities which result in increased stretching of the pollutant cloud, i.e. increased dispersion once a new asymptotic stage has been reached, as well as a reduction (retardation) of the effective transport velocity c below the cross-sectional mean velocity U, $c < U$.

No consistent, mechanistically justifiable approaches to this problem of channel heterogeneities have been developed to date. A high degree of empiricism prevails on that issue in current practice, e.g. on RAM implementation and operation. Since heterogeneities in channel morphology are irregularly distributed along river distance, one approach has been to accept an unavoidable degree of uncertainties in the value of E_L. A number of empirical equations – or empirical adjustments of theoretical equations as given above – can be found in the literature reflecting this state of affairs. For example, Fischer et al. (1979) give

$$E_L = \alpha \frac{U^2 B^2}{u_* h} \qquad \text{with } \alpha = 0.011 \tag{16}$$

based on an evaluation of Eq. 12 for "typical" lateral velocity profiles and irregularities. They cite that data comparisons show inaccuracies by a factor of ± 4 or larger. Mazijk (1996) reports yet larger deviations (factor of 10) with dye tracer data for different stretches of the River Rhine. This is hardly acceptable as predicted maximum concentration values as well as cloud widths are proportional to $\sqrt{E_L}$ (see Eq. 14) leading to substantial operational decision-making uncertainty.

A further consequence of variable channel heterogeneity is the apparent extension of the convective stage of mixing. Since the morphology is constantly changing an asymptotic dispersive state is never reached. This is exemplified by the tracer test results for the River Rhine (Fig. 6) where at distances greatly exceeding a mixing distance t_M (estimated as about 50 km for the release station) a strong skewness persists. (It is worth noting, however, that by virtue of Eq. 15 a curve C(t) at a given station will always be slightly skewed; only curves C(x) at a given time become truly symmetric!) For that reason the RAM (see Mazijk, 1996) contains an empirical adjustment of Eq. 15 in the form

$$C(x,t) = \frac{M}{\frac{Q}{c}\sqrt{4\pi E_L t}} \left\{ \exp\left[-\frac{(x-ct)^2}{4E_L t} \right] \right\} \left\{ 1 + \frac{1}{6} H_3\left(\frac{x-ct}{\sqrt{2E_L t}} \right) \right\} \tag{17}$$

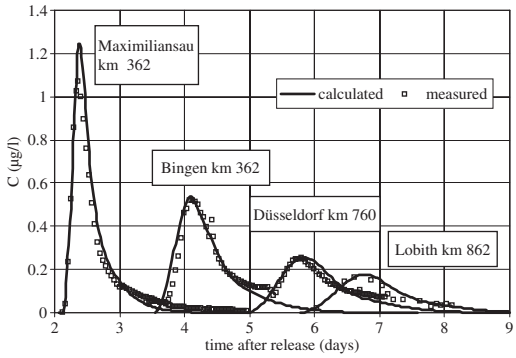

Figure 6. Concentration curves from dye tracer test on River Rhine. Tracer release near Basel (km 170) (after Mazijk, 1996).

in which $H_3(\tau) = \tau^3 - 3\tau$ is the Hermite polynominal of third order to impose a certain skewness. Q is the river discharge and c is the transport velocity, related to the mean velocity U

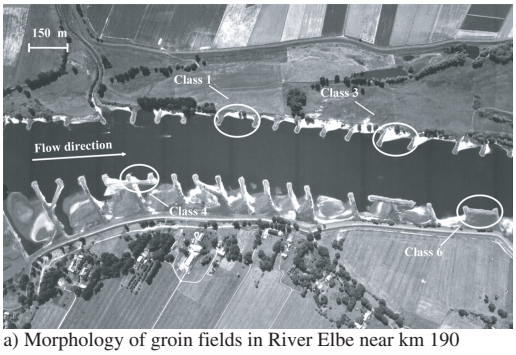
$$c = \frac{U}{1+\beta} \tag{18}$$

where β is nominally the ratio of active stream cross-sectional area A_s to the dead-zone cross-sectional area A_D, $\beta = A_s/A_D$, but in practice is used as best-fit parameter. Fischer's Eq. 16 is used for E_L, with α being another best-fit parameter.

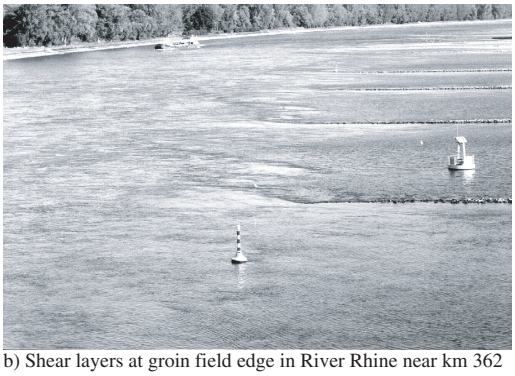
A best-fit model calibration is certainly possible whenever high quality tracer test data sets covering different stretches and hydrologic regimes are available. This is the case for the River Rhine so that the existing Rhine-RAM constitutes a reasonably reliable pollution routing and forecasting tool. It is not satisfactory, however, from a fundamental mechanistic viewpoint and is a severe drawback for the establishment of new RAMs for other major rivers for which tracer data is limited and new extensive tests would be a costly and time-consuming undertaking in each instance.

A research study has been undertaken at the Institute for Hydromechanics (IfH) with the ultimate purpose of reducing the existing uncertainty in specifying transport parameters for RAMs and, thus, improving their prognostic abilities avoiding elaborate calibration effects. An initial focus of the study has been the systematic effect on mass dispersion of a system of groin fields that are arranged regularly along the river bank. This morphological situation is frequently found in regulated European rivers as shown in Fig. 7.

Weitbrecht (2004) (see also Weitbrecht et al., 2004) studied the effect of an infinite series of groin fields on asymptotic mass dispersion in two steps: first, a detailed fluid mechanical understanding of the exchange dynamics at the edge of an individual groin



a) Morphology of groin fields in River Elbe near km 190



b) Shear layers at groin field edge in River Rhine near km 362

Figure 7. Groin fields on rivers.

field, and second the integrative effect of a sequence of many groin fields.

(a) *Exchange mechanisms between main channel and groin fields*: Groin fields form – depending on their geometry – more or less "dead-zones", i.e. the mean field-averaged forward convective velocity is zero. However, there is an effective shear zone (see Fig. 7b) at the groin field boundary to the mean channel: these causes both a net circulatory mechanism as well as intermittent turbulent exchange between the main river and the groin field. When a pollutant cloud propagates in the main channel a fraction of the cloud mass gets advected into the groin field, is temporarily retained and finally gradually returned into the main river. Thus, understanding the intensity of the exchange mechanism as a function of groin field morphology is key to quantifying the aggregate effect of groin field sequences on dispersion.

Figure 8 shows the tilting laboratory flume at the IfH with 20 m length and 1.82 m width that was used in a series of tests to study groin field flow dynamics. Typical flow velocities were $U = 0.16$ m/s and flow depths $h = 0.046$ m, giving a channel Reynolds number of about 7500, thus well into the Reynolds

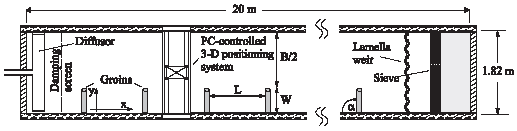


Figure 8. Schematic top view of the laboratory flume tests at IfH for groin field dynamic.

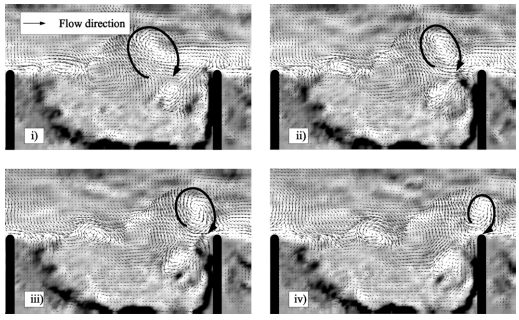

Figure 9. Sequence of instantaneous velocity vectors and vorticity fields (light shading negative vorticity, dark positive) for experiment with groin field aspect ratio $W/L = 0.4$. Time interval between PIV images is 1s.

invariant regime so that the results seem transferable to prototype conditions. Different groin field geometries, $W/L = 0.17$ to 3.3, in which W = groin length and L = spacing length between groins (see Fig. 8), variable inclination lengths and variable depth h_D in the groin field, less than the main channel depth h_s were studied schematically.

The major experimental techniques for deducing the exchange dynamics were surface particle-image-velocimetry (PIV) as described by Weitbrecht et al. (2002) and a planar-concentration-analysis (PCA) of an instantaneous volumetric dye injection within the groin field (see Kurzke et al., 2002). Figure 9 shows a sequence of PIV-generated images with instantaneous velocity and vorticity field. The generation of large coherent structures within the shear layer at the groin field boundary is evident leading to mean and turbulent transport in and out of the groin field. The structure of the mean gyres for groin field with different aspect rating can be seen in Fig. 10. A number of statistical analyses can be performed with these data. A key element is the definition of the exchange velocity E from the instantaneous lateral velocity values v_B at the groin field boundary, i.e. the line of length L connecting the groin heads,

$$E = \frac{1}{2L}\int_{o}^{L} |v_B|\,dx \qquad (19)$$

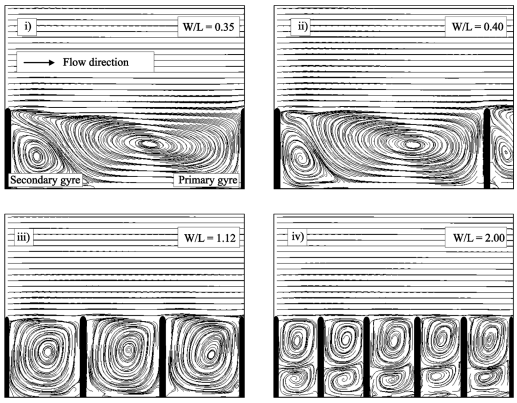

Figure 10. Time averaged surface streamline patterns for different groin field aspect ratios W/L.

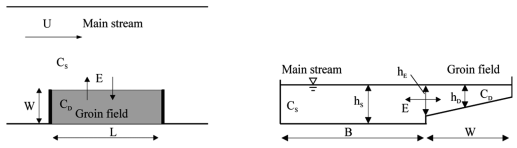

Figure 11. Plan view and cross-section of groin field processes represented as a dead-zone model.

Normalization with the mean stream velocity U gives the dimensionless exchange coefficient

$$k = \frac{E}{U} \tag{20a}$$

As an alternative and independent method for deducing the exchange coefficient the whole groin field volume was injected instantaneously with a volumetric dye source. This was done with a special injection box connected to some 800 injection needles in a 3 cm × 3 cm array. These produced small turbulent dye clouds that rapidly merged forming a uniform volume source. The loss of total dye mass was monitored with the calibrated PCA system and followed fairly well an exponential loss curve with a time constant T_D. Using a dead-zone model (see Fig. 11) as a simple parameterization T_D can be related to a dimensionless exchange coefficient k

$$k = \frac{W}{T_D U}\frac{h_E}{h_D} \tag{20b}$$

Both independent results, Eqs. 19 and 20a,b, were found to be in excellent agreement with each other.

A groin field morphometric parameter was defined by Weitbrecht (2004)

$$\frac{R_D}{h_s} = \frac{WL}{(W+L)h_s} \tag{21}$$

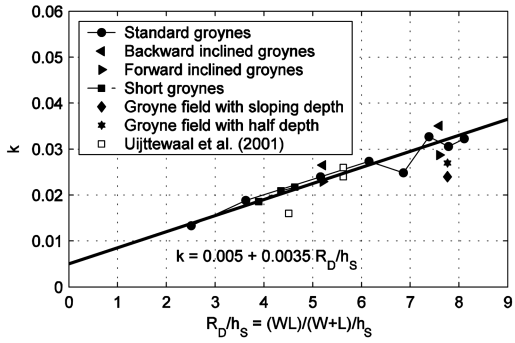

Figure 12. Dimensionless exchange coefficient k at groin field boundary as a function of groin field morphometric parameter R_D/h_S.

where R_D represent a sort of "hydraulic radius" for the groin field. The measured exchange values correlate well with this parameter as shown in Fig. 12, covering a wide range of groin field types and shapes, including data by Uijttewal et al. (2001). The data are well presented by the linear relation

$$k = 0.005 + 0.0035\frac{R_D}{h_s} \tag{22}$$

which can be used as the basis for further predictive work. The observed range of k agrees well with the range 0.01 to 0.03 reported by Valentine and Wood (1979) from the analysis of field data. These authors, however, did not report any morphometric dependence.

(b) *Integrating the effect of a groin field sequence on river dispersion*: Once k (Eq. 22) is given as the boundary information at the edge of the main river channel the advection–diffusion equation can, in principle, be solved to yield the value of the dispersion coefficient in the composite system (main river plus groin field sequence). Valentine and Wood (1977) have proposed a Dead-Zone Model as two coupled differential equations for that purpose. Unfortunately, no analytical solutions are known and numerical methods would take very long to converge to the dispersive regime, being fraught by numerical dispersion in the process.

Weitbrecht (2004) formulated a Lagrangian particle tracking model (LPTM) as an alternative method for obtaining values for the asymptotic regime. A mass of many discrete particles is released initially and uniformly over the system cross-section. The model performs for each time step and for each particle a forward convective step according to the local velocity value u(y) and a random transverse diffusive step proportional to the square root of the local diffusivity $E_y(y)$. A special adjustment is made on the latter step to prevent a "noise-induced" drift component due to gradients $\partial E_y/\partial y$. The lateral boundary condition at a solid

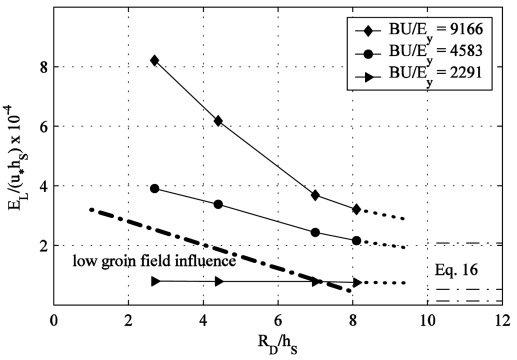

Figure 13. Effective asymptotic dispersion coefficients, normalized as $E_L/(u_* h_s)$, for composite river/groin field system as a function of groin field morphometry R_D/h_S and main river Peclet number $Pe = UB/E_y$. Results from LPTM simulations. Fischer's estimates (Eq. 16) for rivers without groin fields are shown as dash-dotted lines for the three cases of Pe.

side wall (bank) is a reflection condition, while at the groin field boundary a retention condition is imposed, i.e. particles are held for the average retention time T_D before they are released back into the flow.

The LPTM is a useful and convenient method that can be used efficiently on a PC to produce stable statistics on concentration distributions, including lengths of convective period and skewness distributions (for examples, see Weitbrecht et al., 2004). It has been run with the normalized velocity and diffusivity distributions corresponding to the experimental conditions given above.

Some of the LPTM results are summarized in Fig. 13 which displays the asymptotic normalized dispersion coefficient, $E_L/(u_* h_s)$, as a function of two parameters: a main channel Peclet number $Pe = UB/D_y$ and the groin field morphometry parameter R_D/h_s.

Several observations can be made from these qualitative simulations:

- The transverse mixing Peclet number Pe measures the role of forward advection relative to transverse diffusion. Increasing Pe (e.g. by decreasing E_y) also increases the asymptotic dispersion coefficient, consistent with the form of the triple integral (see Eq. 12).
- Decreasing the groin field morphometry factor R_D/h_s means decreasing k and increasing the retention time T_D and causes generally an increase in the value of E_L.
- There appears to be, however, a regime of low Pe and low R_D/h_s (region on lower left in Fig. 13) in which the groin field retention effect is no longer important. In this regime the advection in the main channel is so weak (slow) that the strong exchange effect acts by rapidly absorbing and returning pollutant mass so that the retention effect is no longer visible. The limit line is given by a ratio of transverse mixing time to retention time, $t_M/T_D \approx 10$.
- The orders of magnitude of the normalized coefficients $E_L/(u_* h_s)$ are 0 (10^4). These are quite plausible and agree with some reported field data for many natural channels, e.g. see surveys in Fischer et al. (1979) or Rutherford (1994). For comparison, Fischer's estimates (Eq. 16) for rivers without groin fields are plotted in the right margin of Fig. 13. The drastic enhancement of longitudinal dispersion due to groin fields is evident from these comparisons.

In summary, the study has shown that a systematic description of groin field flow dynamics can lead to an improved quantitative prognosis of the flow and transport parameters in reasonably complex riverine systems. Hopefully, these results and further parametric studies will lead to improvements in the formulation of future river alarm models.

4 CONCLUDING REMARKS

The quantitative understanding of mixing and dispersion processes in rivers is a key element in successful strategies for water quality control and management. Despite great advances that have been made over the last half century there remain a number of challenging research questions that need to be resolved.

For continuous discharges, that are usually subject to a routine permitting process by water authorities, the specification of transverse mixing is most important for meeting given mixing zone regulations. Secondary current and coherent eddy structures, especially in curved or meandering channels, e.g. in the wake of structures or islands, will influence mixing processes.

Many more open research questions concern the longitudinal dispersion process due to instantaneous or accidental pollutant releases in river systems with complex morphology. In order to decrease the present parameter uncertainty systematic studies are needed on the effect of river heterogeneities, such as meandering, overbank floodways and side arms, partly vegetated flow zones, and groin fields, all with variable hydrological conditions, such as water levels.

Finally, the interaction of these physical processes with the chemical and biological transformations that govern the fate of particular chemicals need to be addressed. This includes pollutant sorption processes with fine organic or inorganic suspended or bottom sediments and with biota.

River Flow 2004 – Greco, Carravetta & Della Morte (eds.)

Debris flows and their modeling

T. Takahashi
Kyoto University, Kyoto, Japan

ABSTRACT: This paper reviews the existing models of debris flow categorizing into the single-phase flow model and the two-phase flow model. Classic single-phase models such as the viscoplastic fluid model and the dilatant fluid model are simple and still give powerful tools in predicting the average behaviors of flow as long as the parameter values included in respective models are properly determined. But, they are often difficult to determine on the a priori arguments of materials and topographical conditions. The behaviors of debris flows are diversified depending on the properties of solid material, solid concentration, flow magnitude, river channel conditions, etc., and they often change their sediment transporting modes while in motion. The two-phase models that consider the debris flow is comprised of the mixture of two continuum media of fluid phase and solid phase are able to classify debris flows and able to analyze the physics of respective flows. As examples of those models, author's theories for inertial debris flow and viscous debris flow are introduced.

1 MODELS FOR MULTI-PHASE FLOW

Many simulation models for granular flow with the negligible effects of interstitial fluid (in a vacuum or in the atmosphere) have been given (single-phase model). They can be categorized into the continuum media model and the discrete particle model. The former model describes the granular assembly as a continuum media and its characteristics are analyzed by the Eulerian forms of the continuity and momentum equations. The discrete characteristics of particle motion are necessarily neglected. The latter model, on the other hand, traces the motion of each particle by the Lagrangian equation.

In the continuum media model, the characteristics of flow as a granular assembly are intrinsic in the stress terms in the Eulerian momentum equation. These terms are obtained from the relationship between the stress and the strain of the continuum that is called the constitutive equation. Although the general constitutive equation under the arbitrary conditions of particle density, particle size distribution, and particle interactions is difficult to obtain, if an appropriate form of it under a particular flow condition is given, the continuum media model can be an operative method to explain the flow characteristics en masse under that condition.

The discrete particle model describes every particle's motion in flow by the Newton's second law equation under the effects of contact forces between the neighboring particles. Two kinds of approach for treating the contact have been adopted: the hard-contact technique and the soft-contact technique.

In the hard-contact technique, particles are considered as rigid bodies, and the contact arises only between the two adjacent particles in an instantaneous moment (Campbell and Brennenn 1985, Straub 2001). This technique has shortcoming on the handling of the simultaneous collision of multiple bodies.

The soft-contact technique is free from the shortcomings in the hard-contact technique (Campbell 2001). At the moment of soft-contact, particles deform a little and forces proportional to the stiffness of particles act at the contact points. The interaction between particles at a contact point is modeled by the deformation of interface instrument that is composed of spring and dashpot connected in parallel. Two sets of such an instrument are mounted normally and tangentially on each contact point. To handle non-cohesive particle, a joint that is nonresistant to tension in normal direction and a slipping joint that is effective under a tangential force beyond a threshold should be connected to the respective sets of instrument (Gotoh & Sakai 1997). Thus, many parameter values must be given beforehand, and if particle number becomes large, load on computer becomes enormous. The implementation of simulation makes clear the motion of individual particles that may be difficult to observe in the physical model tests. But, the quantitative characteristics of average flow such as depth and velocity can be obtained only after the completion of simulation.

In the case of debris flow, the interstitial liquid is water or slurry, so the relative density of particles in flow is small, and therefore, the effects of interstitial fluid often play important roles. Then, the flow should be considered as composed of two phases. Liquid phase is naturally described by the Eulerian flow equation, but as mentioned above, the solid phase may be described as a continuum media or as an assembly of discrete particles.

If solid phase is considered as a continuum media and described by the Eulerian equations, mathematically the model becomes Euler-Euler coupling model. In this model, two momentum equations each for liquid and solid phases are given. These are as following (Iverson 1997):

$$\sigma C\left(\partial \mathbf{v}_s / \partial t + \mathbf{v}_s \cdot \nabla \mathbf{v}_s\right) = \nabla \cdot \mathbf{T}_s + \sigma C \mathbf{g} + \mathbf{F} \tag{1}$$

$$\rho(1-C)\left(\partial \mathbf{v}_f / \partial t + \mathbf{v}_f \cdot \nabla \mathbf{v}_f\right) = \nabla \cdot \mathbf{T}_f + \rho(1-C)\mathbf{g} - \mathbf{F} \tag{2}$$

where $\mathbf{v}_s$ = velocity of solid; $\mathbf{v}_f$ = velocity of fluid; C = solid volume concentration in flow; σ = density of particle; ρ = density of fluid; $\mathbf{g}$ = acceleration due to gravity; $\mathbf{T}_s$ = solid phase stress tensor; $\mathbf{T}_f$ = fluid phase stress tensor; and $\mathbf{F}$ = interaction force per unit volume that results from momentum exchange between the solid and fluid constituents.

Addition of these two equations yields a momentum conservation equation applicable to the bulk mixture. This procedure eliminates the assessment of complicated interactions between fluid and solid phase. If nearly steady uniform flow is considered and the relative velocity between solid and fluid is neglected in Cartesian coordinate system, following two equations are finally obtained (Takahashi 1991):

$$P_{ds} + P_f = (\sigma - \rho) g \cos\theta \int_z^h C dz \tag{3}$$

$$T_{ds} + T_f = g \sin\theta \int_z^h \rho_T dz \tag{4}$$

where P_{ds} = pressure in solid phase; P_f = pressure in fluid phase in excess over hydro-static one; T_{ds} = shear stress in solid phase; T_f = shear stress in fluid phase; ρ_T $\{=(\sigma-\rho)C+\rho\}$ = apparent density of debris flow material; θ = slope of flow surface; h = flow depth; and z = height measured from the bottom of flow.

These equations are fundamental equations in the two-phase fluid model describing the stress balance in the flow of mixture. The essential problem in this two-phase mixture theory is how the left-hand sides of Equations 3 and 4 are described.

If solid phase is considered as an assembly of discrete particles, flow should be analyzed by Euler-Lagrange coupling model, in which individual particle motion is solved by the discrete element method earlier described taking the interaction between particles and fluid into account. Some investigations on bed load transport have been done by this method (Gotoh et al. 1994), but debris flow has not been treated by this method.

2 SINGLE-PHASE CONTINUUM MODELS

In the single-phase continuum models, the mixture of particles and fluid is considered as a kind of continuum fluid whose constitutive relation between stress and rate of strain is to be found empirically by the laboratory tests of samples collected from flow or by the deduction from the back analysis of the model applied to the flow in field.

2.1 *Viscoplastic fluid model*

Debris flow commences from the gradual or the abrupt motions of debris block due to the effects of water, and after the motion of considerable distance, it comes out to flat area and stops. Therefore, if one considers the material itself has strength intrinsically, one can explain the starting of motion attributing to the operations of a stress more than that (yielding) strength, and flow stops if the stress in flow becomes smaller than the strength. Debris flow modeling as a kind of viscous fluid having strength is called 'viscoplastic fluid model', and it assumes the relation between the stress and the strain rate as following:

$$\tau = \tau_y + K(du/dz)^n \tag{5}$$

where τ = shearing stress; τ_y = yielding strength; u = velocity at height z; and K and n = positive parameters.

The simplest in the viscoplastic fluid models is the one setting $n = 1$, that is called 'Bingham fluid model'. This model was first proposed independently by Yano & Daido (1965) and Johnson (1965). Later, Johnson (1970) modified his model to the following 'Coulomb-viscous model':

$$\tau = c + \sigma_n \tan\phi + \mu(du/dz) \tag{6}$$

where c = cohesive strength; σ_n = internal normal stress; ϕ = internal friction angle; and μ = Bingham viscosity.

Viscoplastic fluid models, including the Herschel-Bulkley fluid model that sets $n < 1$ (Coussot 1995) and the polynomial models that add the term $(du/dz)^2$ to Bingham fluid model (Julien & O'Brien 1997) or add $(du/dz)^\eta$ to Equation 6 (Chen 1988), are still frequently used especially for the cases of viscous type debris flow.

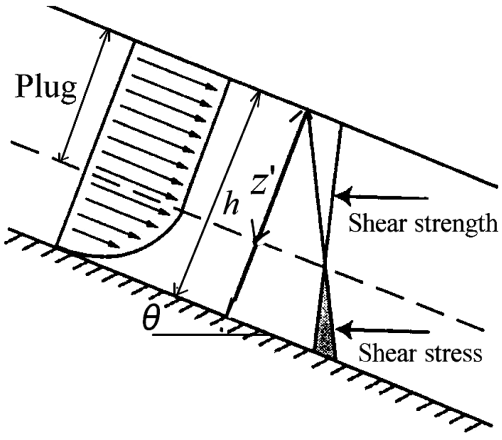

Figure 1. Velocity distribution in Bingham fluid flow.

For example, the stress balance equation for steady uniform Bingham fluid flow is given by

$$\tau_y + \mu(du/dz) = \rho_T g(h-z)\sin\theta \tag{7}$$

The integration of Equation 7 under the boundary condition; $u = 0$ at $z = 0$ gives the velocity distribution throughout the depth as shown in Figure 1 in which z' $(= \tau_y/\rho_T g \sin\theta)$ is the thickness of plug that behaves like a rigid body.

The serious shortcoming of viscoplastic models is the difficulty in determining the crucial parameter values such as τ_y, μ, etc. Those values obtained by laboratory tests and by field observations are usually much different, and they cannot account for the parameter value changes due to the addition or subtraction of water or sediment during in motion. According to the author's observation, the typical viscous type debris flow in the Jiangjia ravine in China lacks the plug that should exist in a viscoplastic fluid flow.

2.2 *Dilatant fluid model*

Debris flow whose main solid components are coarse grains larger than gravel size can often reach to an area flatter than about 4° keeping its high mobility and competence to freight big boulders. Takahashi (1978) inferred such small resistance to flow was caused by the dispersion of grains separated with one another, and the inter-particle collision gave rise to the dispersion of heavier grains than the ambient fluid.

Bagnold (1954) was the first to discover the significance of inter-particle collision as the cause of particle dispersion. His experiments and simple binary grain collision analysis gave the stress-strain relationships in inertial and viscous regimes. In inertial regime, those relationships were given as following:

$$p = a_i \cos\alpha \cdot \sigma\lambda^2 {d_p}^2 (du/dz)^2 \tag{8}$$

$$\tau = p \cdot \tan\alpha = a_i \sin\alpha \cdot \sigma\lambda^2 {d_p}^2 (du/dz)^2 \tag{9}$$

where p = dispersive pressure in flow; a_i = numerical constant; α = collision angle; d_p = grain diameter; λ = linear concentration of grains defined by $\lambda \equiv \{(C_*/C)^{1/3} - 1\}^{-1}$; and C_* = maximum grain concentration when $\lambda = \infty$. He directly measured the excess pressure with grains in flow over that with the plain fluid, so that p in Equation 8 was equivalent to P_{ds} in Equation 3. The grain drag; T_{ds}, corresponding to P_{ds} could not be measured directly but it was deducted from the measured periphery drug that was the total of drugs shared by fluid and grain constituents. Therefore, τ in Equation 9 is equivalent to T_{ds} in Equation 4.

Bagnold used neutrally buoyant solid spheres immersed in a Newtonian fluid in his experiments, but Takahashi (1978) exploited his results to the open channel flow with hyper-concentrated heavy grains assuming uniform distribution of grains throughout depth; the stress balance equations for normal and parallel directions to the bed were given, respectively:

$$\begin{aligned} &a_i \cos\alpha \cdot \sigma\lambda^2 {d_p}^2 (du/dz)^2 \\ &= C(\sigma-\rho)g(h-z)\cos\theta \end{aligned} \tag{10}$$

$$\begin{aligned} &a_i \sin\alpha \cdot \sigma\lambda^2 {d_p}^2 (du/dz)^2 \\ &= \{C(\sigma-\rho)+\rho\}g(h-z)\sin\theta \end{aligned} \tag{11}$$

Referring to the discussion above, this model is an equivalent model to the two-phase model in which the dynamic fluid effects are negligible. But, as far as Equation 11 is concerned, shearing stress in the flow of mixture is described by an expression assuming a single-phase continuum fluid. A kind of fluid having the relationship; $\tau \sim (du/dz)^n$, $n > 1$, is called 'dilatant fluid', so Takahashi's model is called the dilatant fluid model.

Equations 10 and 11 can be easily integrated under the boundary condition; $u = 0$ at $z = 0$, and one can obtain the flow velocity at height z. The result of integration of Equation 11 is given as

$$u = \frac{2}{3d_p}\left(\frac{g\sin\theta}{a_i\sin\alpha}\frac{\rho_T}{\sigma}\right)^{1/2}\frac{1}{\lambda}\left\{h^{3/2} - (h-z)^{3/2}\right\} \tag{12}$$

Mathematically, the velocity distribution function obtained from Equation 10 has not the same expression with the one obtained from Equation 11. Those two

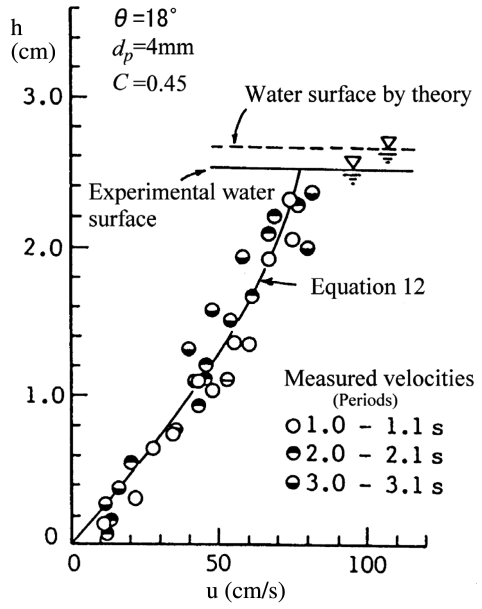

Figure 2. Velocity distribution on rigid bed.

functions become physically equivalent only when the following formula is satisfied:

$$C = \frac{\rho \tan\theta}{(\sigma - \rho)(\tan\alpha - \tan\theta)} \tag{13}$$

For example, if one substitutes $\sigma = 2.65\,\mathrm{gcm}^{-3}$, $\rho = 1.0\,\mathrm{gcm}^{-3}$, $\tan\alpha = 0.75$ and $\theta = 18°$ into Equation 13, one obtains $C = 0.46$. Then, if one puts the mixture of water and grains whose grain diameter is 4 mm and the volume concentration is 0.45, into a rigid bed flume of 18° slope, one observes velocity distribution that fits very well to Equation 12 by giving $a_i = 0.04$ as shown in Figure 2. As another example, if one supplies water onto an erodible bed saturated by water whose slope is steeper than 15°, debris flow develops downstream and approaches an equilibrium state as illustrated in Figure 3. Experiment reveals that in the equilibrium steady flow region grain concentration is given by Equation 13. Thus, the dilatant fluid model can well explain the debris flow in which interparticle collision plays the dominant role, moreover different from viscoplastic fluid model, it can account for the change in solid concentration during in motion (Takahashi 1991).

The assumption of uniform grain distribution throughout depth is, however at least theoretically, too much simplification, and this causes the contradiction that there exists two independent formulae 10 and 11 for one unknown velocity (Iverson & Denlinger

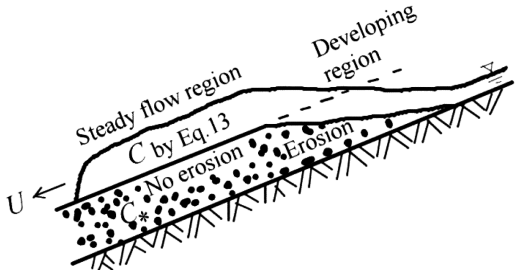

Figure 3. Development of debris flow on erodible bed.

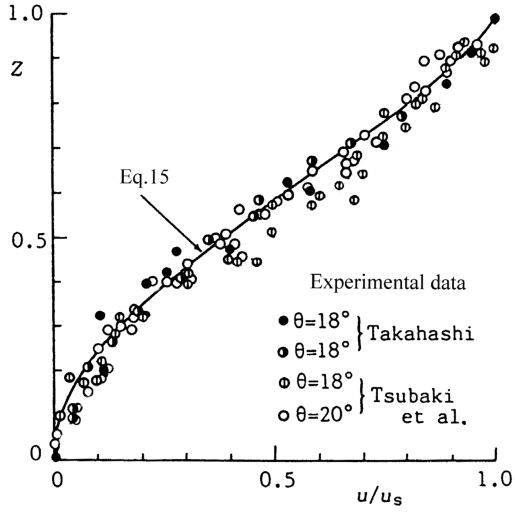

Figure 4. Theoretical velocity distribution and the experimental data.

1987). To dissolve this contradiction, Takahashi (1991) assumed the following formula:

$$\tan\alpha = (C_* / C)^{1/3} \tan\phi \tag{14}$$

Substitution of this formula into Equations 8 and 9 results in rather well fitting to Bagnold's experiment, and also the substitution of this formula into Equations 10 and 11 gives two independent formulae necessary and sufficient to obtain u and C at height z. The results of analysis using these two equations can well explain the vertical grain concentration and velocity distributions on sediment bed. The velocity distribution form is given by

$$\frac{u}{u_s} = 1 - \frac{1}{2}(1 - Z)^{3/2}(2 + 3Z) \tag{15}$$

where u_s = flow surface velocity; and $Z = z/h$. Equation 15 is compared with the experimental data in Figure 4. The vertical velocity distribution on erodible sediment bed (Figure 4) has a peculiar form with

two inflection points; one near the bed and the other near the surface of flow, whereas that on rigid bed, especially when flow contains slightly thinner concentration than equilibrium, has simple concave form (Figure 2) as is explained by the first approximation under the assumption of uniform concentration distribution.

3 TWO-PHASE FLUID FLOW MODEL (MIXTURE THEORY)

As mentioned earlier, how one considers the left-hand side terms in Equations 3 and 4 can be the origin of diverse debris flow theories. The particle dispersive pressure due to inter-particle collision; p_c, and the static skeletal pressure due to enduring contact between particles; p_s, would be the candidates of $P_{ds} \cdot P_f$ exists if the sediment mass contracts volumetrically or if there is a net flux of sediment toward the bed (Iverson 1997). Herein, only quasi-steady flow is considered, so $P_f = 0$. The shear stress due to inter-particle collision; τ_c, the shear stress due to enduring contact between particles; τ_s, and the streaming stress due to migration of particles in one layer to other layer; τ_k, would be the candidates of T_{ds}. The deformation stress within interstitial fluid; τ_μ, and the turbulent mixing stress; τ_t, would be the candidates of T_f. All such candidates cannot prevail simultaneously, but some among others prevail in a particular regime. Therefore, through the discussion of dominant stresses, debris flows can be classified.

3.1 *Coulomb mixture theory (Quasi-static flow)*

Iverson & Denlinger (2001) claims that the Coulomb friction term; τ_s, is almost always larger than the particle collision term; τ_c, stating that the Savage number, defined by Equation 16, in various field examples and the large scale experiment by USGS is smaller than 0.1 as the evidence, and they develop a Coulomb mixture theory as the one only suitable to debris flow.

$$N_{Sav} = \frac{\sigma (du/dz)^2 d_p^{\ 2}}{(\sigma - \rho) gh} \tag{16}$$

The numerator of Formula 16 is, as is clear from Equation 8, the term representing the particle collision effects, and the denominator is the term representing effective pressure at the bottom of flow due to weight of granular mass. They say the denominator is the gravitational grain contact stress that produces Coulomb friction, but it must be noted that the static gravitational contact stress can be transferred from the flow surface to the bottom only when a skeletal structure due to the enduring contact of grains extends throughout the depth. To furnish this necessity, the local solid fractions everywhere should exceed a threshold level C_3. According to Bagnold (1966), C_3 value for natural beach sand is about 0.51. It is true that the denominator represents the effective pressure at the bottom of flow, but it is not necessarily transferred as the static gravitational contact stress. It is transferred as the collision stress when grain concentration is smaller than C_3. If $C \tan\theta$ is multiplied to the denominator, the term represents the effective pressure at the bottom precisely, but the term multiplied by $C \tan\theta$ to the numerator does not represent the magnitude of collision stress. It is $a_i \cos\alpha\lambda^2$ that is to be multiplied as is evident in Equation 8, and Equation 10 is nothing but to show the collision stress balances with effective pressure. Therefore, their Coulomb mixture theory is considered as a model that is suitable for very densely concentrated quasi-static flow.

Herein, we do not dwell on the details of Coulomb mixture theory.

3.2 *Classification of dynamic debris flows*

Dynamic debris flow in this section is defined as the one except for the quasi-static debris flow, in which dynamic stresses predominate in governing the behaviors of debris flow. The total shear stress $\tau (= T_{ds} + T_f)$ in a grain and water mixture is, as mentioned earlier, described as

$$\tau = \tau_c + \tau_k + \tau_s + \tau_\mu + \tau_t \tag{17}$$

If C is larger than about 0.2, τ_k becomes smaller than τ_c and the difference between the two stresses tends to become drastically large as C becomes larger (Takahashi & Tsujimoto 1997). If C is smaller than 0.5, τ_s is almost equal to zero (Bagnold 1966). Therefore, in a dynamic debris flow whose average concentration of coarse grains (except for the constituent making up interstitial slurry) is between 0.2 and 0.5, and if τ_t/τ_c and τ_μ/τ_c are small, $\tau_c/\tau \approx 1$ is satisfied. Debris flow in which the stress due to the collision of particles dominates among others is called 'stony debris flow'. On the other hand, debris flow in which $\tau_t/\tau \approx 1$ is satisfied is called 'turbulent muddy debris flow', and the one in which $\tau_\mu/\tau \approx 1$ is satisfied is called 'viscous debris flow'.

Equation 9 and the other previous theoretical considerations on the constitutive relations of granular flows confirm (Campbell 1990)

$$\tau_c = \sigma d_p^{\ 2} f_1(C)(du/dz)^2 \tag{18}$$

and fluid mechanics give the following forms:

$$\tau_\mu = \mu f_2(C)(du/dz) \tag{19}$$

$$\tau_t = \rho_T l^2 (du/dz)^2 \tag{20}$$

where $f_1(C)$ and $f_2(C)$ = functions of C; μ = viscosity of interstitial fluid; and l = mixing length. From these Equations, one obtains the following formulae:

$$\frac{\tau_t}{\tau_c} \sim \left(\frac{\rho_T}{\sigma}\right)\left(\frac{h}{d_p}\right)^2 \frac{1}{f_1(C)} \tag{21}$$

$$\frac{\tau_\mu}{\tau_c} = \frac{\lambda^{1/2}}{B_a}\frac{f_2(C)}{f_1(C)} \tag{22}$$

$$\frac{\tau_t}{\tau_\mu} \sim R_e \frac{1}{f_2(C)} \tag{23}$$

where $B_a\,(\equiv \sigma\lambda^{1/2}d_p^2(du/dz)/\mu)$ is called Bagnold number and $R_e\,(\equiv \rho_T Uh/\mu)$ is Reynolds number, in which $l \approx h$ and $l(du/dz) \approx U$ are assumed and U = cross-sectional mean velocity.

Summarizing the above discussions, one will come to a conclusion that dynamic debris flows occur in the domain within the ternary diagram as shown in Figure 5, where the three axes represent relative depth, Bagnold number and Reynolds number, respectively. The region where Bagnold number is large and the relative depth is small is that for stony debris flow occurrence. In the region where Bagnold number and Reynolds number are small, viscous debris flow occurs, and in the region where the relative depth and Reynolds number are large, turbulent muddy debris flow occurs. Thus, the areas close to the three apices are occupied by the existence areas of stony, viscous and muddy debris flows, respectively, and the rest of the area in the triangle should be the area of 'hybrid debris flows'.

Previous experiments show that if large particle's transport concentration (Herein, the large particle is defined as the one not being suspended by turbulence, and the transport concentration is defined as the ratio of large particle discharge to the total discharge of large particles plus fluid phase including suspended sediment.) is smaller than about 0.2, large particles cannot disperse in the entire depth of flow. Large particle's mixture layer appears only in the lower area of flow and the upper area is the one of plain water flow layer, small particle's suspension flow layer or slurry flow layer. This type flow can be called 'immature debris flow' in contrast to '(mature) debris flows' in which large particles are dispersed in the entire depth.

Thus, sediment transport phenomena can be categorized by the transport concentrations as plain liquid flow, individual particle transport (bed load and suspended load; $0 < C \leq 0.02$), immature debris flow ($0.02 < C \leq 0.2$), debris flow ($0.2 < C \leq 0.5$), quasi-static debris flow ($0.5 < C \leq 0.6$), and sliding of rigid earth body ($0.6 < C$). The boundary C values indicated are for reference, they should depend on properties of particles such as cohesion, grain shape and the distributions of grain sizes.

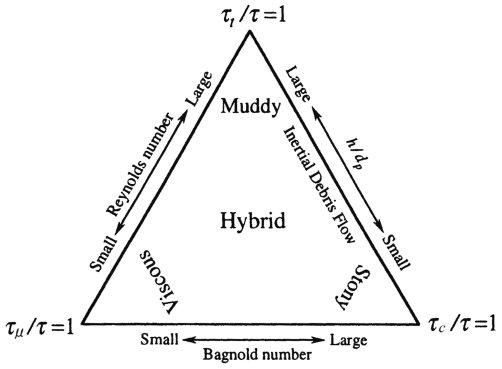

Figure 5. The domain of existence of various type debris flows.

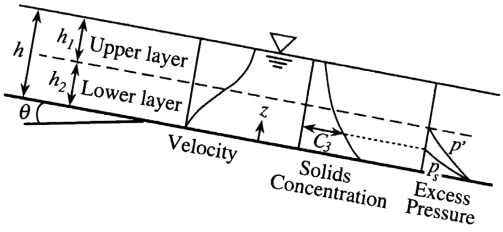

Figure 6. The structure model of an inertial debris flow.

3.3 *Generalized theory for inertial debris flow*

Debris flows that occur in the domain adjacent to the axis representing relative depth in Figure 5 are sometimes called 'inertial debris flow', because the inertial terms; τ_c or τ_t, dominate in flow. The hybrid flow in the inertial debris flow consists of the lower particle collision layer and the upper turbulent suspension layer as illustrated in Figure 6. The ratio of these two layers in flow depends on the relative depth; h/d_p, and the concentration. If relative depth is small and the particle collision layer occupies the entire flow, it is a stony debris flow. If relative depth is large and the turbulent suspension layer occupies almost entire depth, it is a turbulent muddy debris flow. Herein, the theory of Takahashi & Satofuka (2002) is introduced.

Consider an inertial debris flow as illustrated in Figure 6, because τ_μ can be neglected, the balance of force equations in the lower layer in the direction of main flow and perpendicular to it are written as

$$\tau_c + \tau_k + \tau_s + \tau_t = g\sin\theta \int_z^h \{(\sigma-\rho)C + \rho\}dz \tag{24}$$

$$p_c + p_s = g\cos\theta \int_z^{h_2} (\sigma-\rho)Cdz \equiv p' \tag{25}$$

where p' = effective pressure transmitted directly particle to particle; and h_2 = thickness of lower layer. The

upper limit of integration of Equation 25 is h_2, because the particle load in the upper layer is supported by turbulence and it is transmitted to the lower layer as hydro-static pressure.

If solids concentration at the bottom of flow is C_*, the dynamic pressure; p_c, at the bottom must be zero because no flow can exist at such a high concentration as C_*. Therefore, at the bottom all the effective pressure; p', should be borne by the static pressure; p_s. If solid concentration decreases upward, at the height where C becomes equal to C_3, p_s becomes zero. The vertical distribution function of p_s is not yet known, but following function is assumed:

$$p_s = \begin{cases} \dfrac{C - C_3}{C_* - C_3} p' & ; \quad C > C_3 \\ 0 & ; \quad C \le C_3 \end{cases} \tag{26}$$

The relation between p_s and τ_s is assumed as the following Coulomb's equation:

$$\tau_s = p_s \tan\phi \tag{27}$$

The balance of force equation in the upper layer is given as following:

$$\tau_c + \tau_t = \int_z^h \rho_T g \sin\theta dz \tag{28}$$

Takahashi & Tsujimoto (1997) gave the following constitutive equations for dry granular flow:

$$\tau_c = \frac{4}{5}\sqrt{\frac{1}{15\pi}}\frac{1+e}{\sqrt{1-e}} C^2 (1+\lambda)\sigma {d_p}^2 \left(\frac{du}{dz}\right)^2 \tag{29}$$

$$\tau_k = \frac{1}{3(1+\lambda)}\sqrt{\frac{1}{15\pi(1-e)}}\sigma {d_p}^2 \left(\frac{du}{dz}\right)^2 \tag{30}$$

$$p_c = \frac{2}{15} C^2 (1+\lambda)\frac{1+e}{1-e}\sigma {d_p}^2 \left(\frac{du}{dz}\right)^2 \tag{31}$$

where e = restitution coefficient of particles.

Turbulent mixing stress; τ_t, is given by Equation 20, where the mixing length is assumed as $l = \kappa z$, in which κ is Karman constant. Question may arise that in the densely concentrated lower layer, mixing length would have the scale of void between particles. Previously, Takahashi (2000) developed a theory adopting such a concept; $l = d_p/\lambda$ in the lower particle mixing layer and $l = \kappa z$ in the upper turbulent layer. But, interstitial fluid is widespread as a continuum fluid in the entire depth, and so the mixing length may have larger scale than the void between particles. No matter which mixing length is adopted, in the lower layer, τ_t is far smaller than τ_c and τ_s, and it little affects the velocity and the solid concentration there. However, considering the intensity of turbulence, ρ_T in the lower layer is regarded as the density of interstitial fluid, whereas in the upper layer, it is regarded as that of the mixture.

Substitution of these constitutive relations and Equation 26 into Equations 24 and 25 gives the velocity and the solid concentration distributions in the lower layer.

In the upper layer, the substitution of Equations 20 and 29 into Equation 28 gives the velocity distribution. The distribution of solid concentration can be obtained assuming that particles are dispersed by turbulence obeying the similar diffusion equation applicable to normal suspended load analysis.

The criteria whether the upper layer exists and how high the boundary between the upper and the lower layers from the bottom of flow are as following:

1. $w_s/u_* < 1$, where $w_s =$ settling velocity of particles; and $u_* = \sqrt{gh\sin\theta}$. If this criterion is not satisfied particles are not suspended, and in this case, $h_2 = h$.
2. The minimum solid concentration in the lower layer appears at the upper boundary of the lower layer, above that height τ_c is no more larger than τ_t. The experiments for immature debris flow show that the minimum solid concentration; $C_{\lim}$, performed by inter-particle collision is about $0.5C_*$ (Takahashi 1991). Therefore, although it is somewhat expedient, the boundary height is set where the solid concentration calculated in the lower layer, from lower to upper direction, at first becomes equal to $0.5C_*$.

If calculated solid concentration is larger than $C_{\lim}$ in the entire depth, even the criterion (1) is satisfied, there is no upper layer, and $h_2 = h$. If, at certain height, calculated solid concentration becomes smaller than $C_{\lim}$, but the criterion (1) is not satisfied, it is immature debris flow.

Theoretical solid concentration and velocity distributions were obtained corresponding to the conditions; $\sigma = 2.65\ \mathrm{gcm^{-3}}$, $\rho = 1.0\ \mathrm{gcm^{-3}}$, $\tan\phi = 0.7$, $e = 0.3$, $\kappa = 0.3$, $C_* = 0.65$, and $C_3 = 0.5$. Figure 7 shows the examples of the results of calculation, where flow depth is held constant at 2 cm.When particle diameter is 7 mm, even for a steep channel slope of 18°, the condition for particle suspension is not satisfied but particles are dispersed in the entire depth due to the action of inter-particle collision, and the velocity is small. It is stony debris flow. For the same size particles, when channel slope is 6°, particles cannot be dispersed in the entire depth, and it is immature debris flow. When particle diameter is 1mm, even the channel slope is as flat as 6°, the condition for particle suspension is satisfied, and there exists the upper layer in which particles are in suspension. It is hybrid type debris flow.

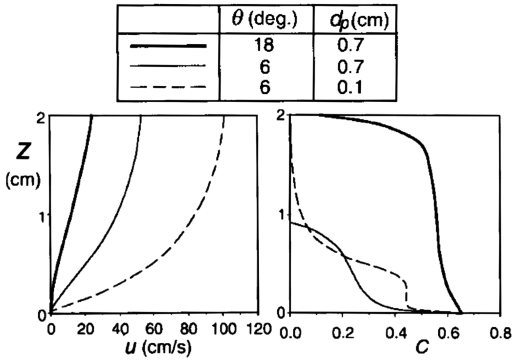

Figure 7. Velocity and particle concentration distributions by the theory.

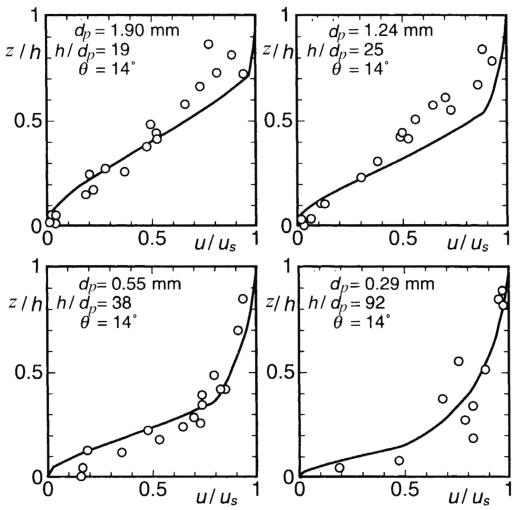

Figure 8. Theoretical and experimental velocity distributions.

Figure 8 compares the theoretically obtained velocity distributions with the experimental data of Hirano et al. (1992), where the velocity is normalized by the surface velocity; u_s. Debris flows in the experiments were generated by supplying water from upstream onto the water saturated erodible bed flume 20 cm in width and 7 m in length. Bed slope was held constant at 14°. The relative depth; h/d_p, was changed by changing both the supplying water discharge and the particle size. The theoretical as well as experimental velocity distribution curves have a tendency to lower the height of boundary between the upper and the lower layers (breakpoint on the curve) and to increase the degree of concavity as the relative depth increases. Moreover, the theoretical curves well fit to the experimental results.

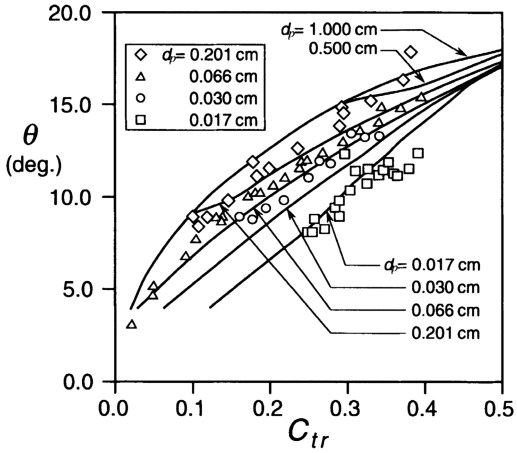

Figure 9. Theoretical and experimental equilibrium transport concentrations.

Figure 9 is a comparison of the theoretical equilibrium transport concentrations; C_{tr}, with author's experimental results. In the experiments debris flows were generated by abruptly supplying water from upstream onto the water saturated erodible bed in a flume 9.9 cm in width and 10 m in length. Bed slope was changed, and the discharge of sediment plus water; Q_T, was held constant at 531 cm^3s^{-1} by trial and error. Four kinds of materials 0.201, 0.066, 0.030 and 0.017 cm in the median diameters, with densities between 2.64 and 2.66 gcm^{-3} and internal friction angles between 38.5° and 39°, were used for the erodible bed. The debris flow samples were collected with a bucket at the outlet of the flume to measure Q_T and C_{tr}. As shown in Figure 9, the theory can well explain the tendency that the smaller the particle diameter, the larger the equilibrium transport concentration becomes under a certain channel slope. This figure further shows that, in comparison with the previous discussion (Takahashi 2000), the revision of mixing length formula improves the goodness of fit to the experiments in the views of boundary plane height between upper and lower layer and solid concentration in upper layer.

In Figure 9, other than those corresponding to the experiments, the theoretical curves for $d_p = 1$ cm and 0.5 cm are also drawn. Under the experimental conditions discussed herein, particles larger than 1 cm in diameter cannot be suspended by turbulence even for the steep channel of 15°. The reason for branching of curves corresponding to $d_p = 0.5$ cm and 0.2 cm from the curve for $d_p = 1$ cm is due to the beginning of suspension from the respective branching points. The theoretical curve for $d_p = 1$ cm almost coincides with the concentration calculated by substituting $\tan\phi = 0.8$ into Takahashi's previous

equilibrium concentration formulae (Takahashi 1991); i.e., for stony debris flow

$$C_\infty = \frac{\rho \tan\theta}{(\sigma - \rho)(\tan\phi - \tan\theta)} \tag{32}$$

and for immature debris flow

$$C_{tr} = 6.7 C_\infty{}^2 \tag{33}$$

Equation 33 is valid only when C_{tr} calculated by this equation is smaller than C_∞ calculated by Equation 32.

It must be noted here that $\tan\phi$ is set equal to 0.8 in the calculation of Equations 32 and 33, but in the calculation of theoretical curves, $\tan\phi$ is set equal to 0.7 (see Equation 27 and parameter values used in the calculation). Why such a different value should be used will become clear by the following explanation.

If particle diameter is large ($d_p > 1$ cm), the settling velocity of particle is given by Newton's equation, and the criterion 1) for particle suspension is written as

$$\frac{h}{d_p} > \frac{\sin\theta}{3.31(\sigma/\rho - 1)} \tag{34}$$

If $\theta = 10°$ and $(\sigma/\rho - 1) = 1.65$ are substituted into this equation, $h/d_p > 32$ is obtained. This means that if the relative depth in an inertial debris flow is smaller than about 30, it is stony debris flow. From the condition 34 and Equation 29, Equation 21 is rewritten as the following formula:

$$\frac{\tau_t}{\tau_c} < \frac{\rho}{\sigma}\left\{\frac{\sin\theta}{3.31(\sigma/\rho - 1)}\right\}^2 \frac{5\sqrt{15\pi(1-e)}}{4(1+e)C^2(1+\lambda)} \tag{35}$$

The largest range value of the right hand side of this formula is obtained by the substitution of $C = 0.2$, $e = 0.3, \theta = 15°. \sigma/\rho = 2.65$, and $C_* = 0.65$. The result is $\tau_t/\tau_c < 0.05$. Namely, in stony debris flow, the turbulent mixing stress is at most 5% of the particle collision stress. This is the reason for a wide applicability of single-phase dilatant fluid model in which fluid stress is neglected. Effective fluid friction being negligible, energy dissipation in stony debris flow is almost solely accomplished (because τ_k is negligibly small) by the solid interfacial friction occurring intermittently during the instant of collision. The effective friction angle α (the angle of encounter between two particles) for densely ($C \approx 0.5$) concentrated flow should be approximately equal to ϕ (Bagnold 1966). If solid concentration decreases as small as about 0.2 in stony debris flow, the angle of encounter between two particles becomes larger than ϕ due to enlarged free distance between particles. Thus, referring to Equation 14, if $\tan\phi$ is 0.7, the average value of $\tan\alpha$ for stony debris flow whose grain concentration is between 0.5 and 0.2 should be about 0.8. Therefore, the equilibrium particle concentration formulae; Equations 13 and 32, are practically identical if average $\tan\alpha$ value is used as $\tan\phi$ in Equation 37.

3.4 *Newtonian fluid model for viscous debris flow*

Quasi-steady debris flows that occur in the domain adjacent to the axis representing Bagnold number in Figure 5 would flow in an orderly manner in which the coarse particles move nearly parallel to the bed keeping tracks within their embedded layer.

Experiments (Bagnold 1954) revealed that the transition from inertia to viscous conditions occupied the range from 450 to 40 in terms of Bagnold number. In the transition range, the total shear stress would be given by

$$\tau = \tau_c + \tau_k + \tau_\mu \tag{36}$$

and as the Bagnold number increases, grain elements; $\tau_c + \tau_k$, becomes surpassed the fluid element; τ_μ, so it approaches stony debris flow. Contrary if Bagnold number becomes small, the dynamic grain elements diminish gradually approaching viscous debris flow. But, in viscous range, according to Bagnold's discussion, although the grain collision stress and grain streaming stress are negligibly small, the effect of grain existence remains to increase the apparent viscosity of mixture. Therefore, the total shear stress in viscous debris flow is a mixed shear stress due to the effect of fluid viscosity as modified by the presence of grains, and cannot be split into grain and fluid elements. Thus, the following formula is given:

$$\tau = \tau_{\mu_a} \tag{37}$$

where $\tau_{\mu_a} =$ viscous fluid stress due to the apparent viscosity μ_a.

The issues in viscous debris flow are why coarse grains heavier than the ambient fluid can be dispersed in laminar viscous flow without collisional effect, and how the apparent viscosity of mixture is estimated. Takahashi et al. (2000) proposed a new Newtonian flow model extending an investigation for neutrally buoyant particles in viscous fluid (Phillips et al. 1992).

The theory considers that the particles experience encounters between adjacent shearing surface and they cause the particle flux; $\mathbf{N_c}$, perpendicular to the main flow direction as following:

$$\mathbf{N_c} = -K_c d_p{}^2 (C^2 \nabla\gamma + C\gamma\nabla C) \tag{38}$$

where $\gamma = du/dz$; and $K_c =$ numerical constant. The term encounter herein does not necessarily mean the interfacial contact, only an approach can cause a

squeezing flow in the interstitial fluid that moves the particle perpendicular to the main flow, because viscosity of fluid is large.

If coarse particles are distributed anisotropically, the apparent viscosity varies spatially. Because the apparent viscosity is larger in the higher concentration region than in the smaller concentration region, the resistance to particle migration into the higher concentration region is larger than into the thinner concentration region. This mechanism gives rise to the particle flux; $\mathbf{N}\mu_a$, as following:

$$\mathbf{N}_{\mu_a} = -K_{\mu_a}\gamma C^2 \frac{d_p^{\,2}}{\mu_a}\frac{d\mu_a}{dC}\nabla C \tag{39}$$

where $K_{\mu_a} =$ numerical constant.

The coarse particles tend to deposit due to gravity, and the flux is given as following:

$$\mathbf{N}_s = -\frac{2}{9}C\frac{d_p^{\,2}(\sigma-\rho)g\cos\theta}{\mu}G(C) \tag{40}$$

where $G(C) =$ hindrance function to account for highly concentrated group settling. Here,

$$G(C) = \frac{1-C}{\eta} \tag{41}$$

is assumed, where $\eta =$ specific viscosity. According to Krieger (1972), it is given as

$$\eta = \frac{\mu_a}{\mu} = \left(1-\frac{C}{C_*}\right)^{-1.82} \tag{42}$$

In a steady state, these three fluxes should balance so as to perform null particle flux perpendicular to the main flow direction. This condition is given by

$$K_c\left(C^2\frac{d\gamma}{dz}+C\gamma\frac{dC}{dz}\right)+K_{\mu_a}\gamma C^2\frac{d\mu_a}{dC}\frac{dC}{dz} + \frac{2}{9}C\frac{(\sigma-\rho)g\cos\theta}{\mu}G(C)=0 \tag{43}$$

The balance of force equation in such a steady uniform flow is given by

$$\tau = \mu_a\gamma = \rho g h\sin\theta\left\{\left(1-\frac{z}{h}\right)+\frac{\varepsilon}{h}\int_z^h C dz\right\} \tag{44}$$

where $\varepsilon = (\sigma-\rho)/\rho$.

Substitution of Equation 44 into Equation 43 yields the particle concentration distribution function;

$$\frac{dC}{dZ} = \frac{F_1}{F_2F_3} \tag{45}$$

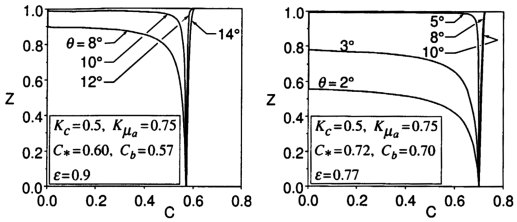

Figure 10. The theoretical distribution of the coarse particle concentrations.

where $F_1 = -(2/9)\varepsilon(1-C)/(K_c\tan\theta)+C(1+\varepsilon C)$; $F_2 = 1+1.82\{(K_{\mu_a}/K_c)-1\}C/C_*(1-C/C_*)^{-1}$; and $F_3 = 1-Z+\varepsilon\int_Z^1 CdZ$.

Figure 10 shows two examples of solid concentration distribution calculated under the combinations of parameters; $C_* = 0.6$, $C_b = 0.7$, $\rho = 1.38\,\mathrm{gcm}^{-3}$ ($\varepsilon \approx 0.9$), and $C_* = 0.72$, $C_b = 0.70$, $\varepsilon = 0.77$. The respective combinations of parameters correspond to the conditions in our laboratory experiment and in the Jiangjia Gully in China. For both cases $K_c = 0.5$ and $K_{\mu_a} = 0.75$ are adopted from the experimental results obtained by Phillips et al. (1992). The concentration at the bottom of flow; C_b, is assumed a little smaller value than C_*, because substitution of $C = C_*$ into Equation 45 cannot make sense. As is clear in Figure 10, when the channel slope is steep, very high solid concentration is maintained up to the surface of flow, and for the relatively mild slope channel, the high concentration abruptly decreases in the upper region. This is the case of immature viscous debris flow.

The coarse particle concentration in a certain slope channel becomes large and uniform as ε becomes small. Namely, the denser the interstitial fluid, the flatter the area the debris flow of a certain solids concentration will reach.

The equilibrium coarse particle concentration for a given channel slope can be obtained by integrating Equation 45. The results corresponding to the conditions used in obtaining Figure 10 are shown in Figure 11. The respective curves show the solid concentration can easily be saturated beyond a certain channel slope, and the value of saturation is, as is clear in Figure 10, approximately equal to C_b. This fact suggests that, as long as flow rate is sufficient, once a saturated flow is formed in an upstream steep channel, it runs down the gradually flattening channel keeping its constant concentration until the slope becomes flatter than a critical one on which the equilibrium concentration is smaller than the saturated value and deposition commences.

The velocity distribution can be obtained by solving Equation 44 under the boundary condition; at $Z = 0$, $u' = 0$, where $u' = u/u_*$. The solution cannot be obtained analytically, but provided the viscosity is approximated as constant from bottom to a height

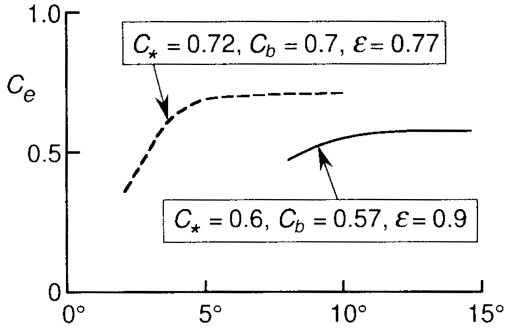

Figure 11. Equilibrium coarse particle concentrations versus channel slopes.

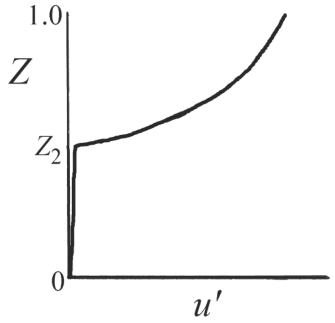

Figure 12. Schematic velocity distribution in an immature viscous debris flow.

$(Z = Z_2)$, it has the tendency like shown in Figure 12. It is given by the following equation:

$$u' = \begin{cases} \dfrac{\rho u_* h}{\mu_a}(1+\varepsilon\overline{C})(Z - \dfrac{1}{2}Z^2) & ; 0 \le Z \le Z_2 \\ \dfrac{\rho u_* h}{\mu}\left\{Z - \dfrac{1}{2}Z^2 + X(Z_2 - \dfrac{1}{2}Z_2{}^2)\right\} & ; Z_2 < Z \le 1 \end{cases} \quad (46)$$

where $X = (1+\varepsilon\overline{C})\mu/\mu_a - 1$; and $\overline{C} =$ mean particle concentration below Z_2.

Well mixed debris flow material in the Jiangjia Gully except for the component larger than 10 mm was imitated by mixing silica sand and kaolin. This material was mixed with water to make the constant solids concentration of $0.56 \sim 0.57$, and it was supplied onto upstream end of experimental flume from a hopper.

The velocity distributions given by Equation 46 are compared with the experimental data in Figure 13, in which $Z_2 = 1$ and $\mu_a = 8.1$ Pa s obtained from the theory explained above, are used. Figure 13(1) is the case of flow on the deposit formed by a previous debris flow surge, and Figure 13(2) is the case of flow on rigid bed. This figure shows that not only the velocity distribution

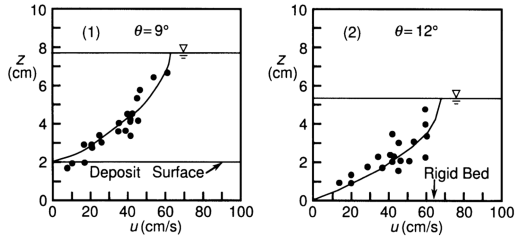

Figure 13. Calculated and experimental velocity distributions.

obeys the Newtonian laminar flow equation equally well on erodible and rigid beds, but also the absolute velocity values are well explained by this theory.

Recently, Armanini et al. (2003) did the similar theoretical and experimental discussion that took the yield strength of interstitial fluid into account.

4 CONCLUSION

In this paper, various concepts for modeling debris flows are reviewed. Under the present state of the art, the mixture model that considers the debris flow material is a mixture of two continua; one is the interstitial fluid and the other is a kind of continuum media comprised of granular assembly, is influential. By the adoption of appropriate constitutive relations, the mixture model is not only able to classify diverse debris flows based on fundamental mechanics but also the behaviors of respective debris flows are explained. Although not being discussed in this paper, application of this model can handle practically important problems such as the predictions of occurrence magnitude and hazardous area.

However, many themes requiring further investigations remain. The examples of those problems are: the effects of wide range distribution of particles on the dynamic behaviors of various debris flows, the determination of the critical size of fine particle that behaves as a coherent whole with interstitial water and the estimation of the physical properties of such a coherent body, the value of solid concentration that determines the transition from quasi-static debris flow to dynamic debris flow in the case that the material is composed of very wide range distribution, the clear-cut definition of transitions between viscous debris flow and stony debris flow, and between viscous debris flow and turbulent muddy debris flow in the ternary diagram, and the mechanics of hybrid debris flows.

Mixing and dispersion in rivers

Gerhard H. Jirka

Institute for Hydromechanics, University of Karlsruhe, Karlsruhe, Germany

ABSTRACT: Water quality in rivers results from the physical, chemical and biological processes that take

place due to multiple pollutant loadings along a river stretch. A sound understanding and description of these

processes – usually encapsulated into predictive models – is needed so that design engineers and water authorities

can develop appropriate discharge solutions and control strategies that meet applicable water quality laws and

objectives. Continuous discharges from municipal, industrial or agricultural sources are subject to a permitting

process by water authorities. The “combined approach” in the new EC-Water Framework Directive (WFD,

2000) consisting of environmental quality standards in addition to emission limit values promises improvements

in the quality characteristics of surface waters. However, the specification of where in the water body the

environmental quality standards do apply is missing in the WFD. This omission will limit its administrative

implementation. A clear mixing zone regulation is needed so that the quality objectives of the WFD are not

jeopardized. Instantaneous or accidental pollutant releases are another source of pollution loadings on rivers.

Water authorities rely increasingly on “river alarm models” that predict the downriver propagation and dispersion

of the pollutant mass as well as biochemical decay or adsorption processes. Currently, these models are fraught

with considerable parameter uncertainties and an improved understanding of the transport mechanics in river

systems with strong morphological variability is needed to minimize these. This is demonstrated for the case of

rivers with a long sequence of groin fields that alternately retain and release the pollutant mass, greatly increasing

the longitudinal dispersion.

1 INTRODUCTION

Rivers have always been the recipients of liquid

water discharges from human activities, be it domestic sources, industrial or agricultural effluents, or mining process waters. Over the last two centuries, since the age of industrialization, the massive increase of indus trial production accompanied by the growth of large urban populations has led to severe water pollution problems on many rivers, turning some of them into essentially open cloacae. In many of the developed countries, this adverse situation has fortunately been mitigated since stringent water quality protection laws were instituted in the period between the 1960s and 1980s so that modern pollution control schemes were implemented. Nevertheless, undesirable water qual ity conditions may persist and further improvements are needed even in these countries. Sadly, however, a rapidly worsening water situation takes place in many of the lesser developed countries, some of the urban megalopolises with unbridled population growth and uncontrolled industrial development being the worst examples.

Riverine water quality, with its spatial and tem peroral distribution attributes, is the result of various physical, chemical and biological processes that occur due to the multiple pollutant loadings in a river stretch. A sound understanding and description of these processes – usually encapsulated into predictive models – is needed so that design engineers and water authorities can develop appropriate discharge solutions and control strategies that meet applicable water quality laws and objectives. It is

useful to distinguish two types of pollutant discharge problems as these have different physical response characteristics as well as different pollution control strategies that are used by water authorities. These are continuous discharge problems on one hand and instantaneous release problems on the other. Continuous discharge problems are given by the more or less steady discharge of pollutants from “point sources” (e.g. effluents from treatment plants, from industries or from mining sources) and from “diffuse sources” (or “non-point sources”, e.g. runoff from agricultural land or from urban drainage areas). These discharges occur continuously – even though they may undergo diurnal or seasonal variations – are somewhat controllable – especially so for the “point sources” – and are subject to water quality regulations. For the countries of the European Union the new EC-Water

Framework Directive (WFD, 2000) has the objective

of an integrated catchment-oriented water quality pro

tection for all European waters with the purpose of

attaining a good quality status by the year 2015. The

water quality evaluation for surface waters shall rely

predominantly on biological parameters (such as flora

and fauna) – however, aided by hydromorphological

(such as flow and substrate conditions) and physico

chemical quality components (such as temperature,

oxygen or nutrient conditions) – and on specific pollu

tants (such as metals or synthetic organic compounds).

A good chemical quality status is provided when the

environment quality standards (specified as concen

tration values) are met for all pollutants or pollutant

groups.

Instantaneous release problems are given by the

more or less sudden release of a pollutants mass into a

river or adjacent to a river. These are mostly accidental releases or “spills”, e.g. from industrial accidents, navigation mishaps, or failure of chemical holding tanks or ponds. The released pollutant mass propagates downstream in the river while gradually being dispersed and partially retained, due to various heterogeneities in the river channel. In order to plan short-term response measures for such accidental spills water authorities increasingly demand the establishment of co-called “river alarm models” that predict the propagation and dispersion of the pollutant mass in the river.

This article reviews the major physical, i.e. hydrodynamic, mechanisms that control these two types of pollutant discharge problems. It points out a major deficiency within the new WFD regulations, i.e. the absence of a clear “mixing zone” definition for continuous point sources, that is likely to limit its effectiveness in improving riverine water quality (see also Jirka et al., 2004). The article also indicates outstanding research needs in this area.

2 CONTINUOUS POINT SOURCE DISCHARGES IN RIVERS

2.1 Regulatory mechanisms for water quality control

The WFD defines new strategies against water pollution as a consequence of releases from point or diffuse

sources. A new aspect of the EC water policy is the

“combined approach”, i.e. both limitations on pol

lutant releases at the source due to promulgation of

emission limit values as well as the establishment of

environmental quality standards. Releases of pollu

tants – especially from point sources – must meet both

requirements. For most European member countries

this new policy means a considerable deviation from

current water quality management practice by which

the releases of pollutants has been controlled by either one of these two control mechanisms, but usually not their combination. Ragas et al. (1997) have reviewed the advantages and disadvantages of different control mechanisms in the permitting processes of releases into surface water. Emission limit values (ELV) present a direct and effective method for the limitation of pollutant loadings by restricting the concentration for the mass flux of specific pollutants. ELVs are preferred from an administrative perspective because they are easy to prescribe and to monitor (end-of-pipe sampling). From an ecological perspective, however, a quality control that is based on ELVs alone appears illogical and limited, since it does not consider directly the quality response of the water body itself and therefore does not hold the individual discharger responsible for the water body. To illustrate that point consider a large point source on a small water body or several sources that may all individually meet the ELVs but would accumulatively cause an excessive pollutant loading. Environmental quality standards (EQS), set as concentration values for pollutions or pollutant groups, that may not be exceeded in the water body itself (WFD, 2000) have the advantage that they consider directly the physical, chemical and biological response characteristics due to the discharge and therefore they put a direct responsibility on the discharger. But a water quality practice that would be based solely on EQSs could lead to a situation in which a discharger would fully utilize the assimilative capacity of water body up to the concentration values provided by the EQSs. Furthermore, the water quality authorities would be faced with additional

burdens because of a more difficult monitoring – where in the water body and how often should be measured? – in the case of existing discharges or due to the increased need for a prediction modeling in case of new discharges. The “combined approach” in the WFD combines the advantages of both of these quality water control mechanisms while largely avoiding their disadvantages. In the future practical implementation of the “combined approach” of the WFD two important questions will have to be addresses by the regulatory authorities: (1) Where in the water body relative to the discharge point do the EQS-values apply? Since the WFD provides no specific guidance on that question two extreme interpretations might be applied. First, the EQS-values apply immediately after the discharge with the idea that the whole water body would then be in a state of a good chemical status at every location at every time as indicated by the EQS-values. In that case, however, the EQS-values would be synonymous with the ELV-values! Secondly, the EQS-values apply after complete mixing for river discharges. Since the actual physical mixing processes in rivers are gradually leading to a “discharge plume, considerable areas in the water body would be affected by

concentrations above the EQS-values and would have

to be considered as “sacrificial regions”, in which a

good chemical status would no longer be provided.

It is obvious that a compromise, in form of a clear

mixing zone regulation, is necessary. (2) Which pro

cedures shall be used during the permitting process

to demonstrate that the discharge will in fact meet the

relevant EQS-values in addition to the ELVs? Not only

for existing, but especially also for future, discharges

does it seem necessary that different types of predictive

models that describe the physical mixing and transport

as well as chemical and biological transformation pro

cesses be applied so that the water authorities can in

fact administer the “combined approach”. These mod
els allow to consider different hydrological situations
and various scenarios of pollution loadings or central
strategies.

2.2 Mixing processes for continuous point sources in rivers

When performing design work and predictive stud
ies on effluent discharge problems, it is important to
clearly distinguish between the physical aspects of
hydrodynamic mixing processes that determine the
fate and distribution of the effluent from the discharge
location, and the administrative formulation of mix
ing zone regulations that intend to prevent any harmful
impact of the effluent on the aquatic environment and
associated uses.

The hydrodynamics of an effluent continuously
discharging into a receiving water body can be con
ceptualized as a mixing process occurring in two
separate regions. In the first region, the initial jet char
acteristics of momentum flux, buoyancy flux (due to
density differences), and outfall geometry influence
the effluent trajectory and degree of mixing. This
region, the “near-field”, encompasses the buoyant jet
flow and any surface, bottom or terminal layer inter
action. In this near-field region, outfall designers can
usually affect the initial mixing characteristics through

appropriate manipulation of design variables. As the turbulent plume travels further away from the source, the source characteristics become less important and the far-field is attained. In this region ambient environ mental conditions will control trajectory and dilution of the turbulent plume through buoyant spreading motions, passive diffusion due to ambient turbulence, and advection by the ambient, often time-varying, velocity field in the river.

For river discharges the problem can be reduced in first order to so-called “passive” sources for which the input momentum and buoyancy effects are of lesser importance and mixing is controlled by the advective and diffusive properties of the ambient flow regime with a resulting discharge plume that follows the prevailing current. Thus, the problem is considered Figure 1. Longitudinal section along an inclined river flow with turbulent flow structure and assumed continuous point source at the water surface. as a “far-field” effect with passive source characteristics. Research during the last 40 years has led to a solid understanding of the mixing dynamics in rivers as summarized in several textbooks or manuals (e.g., Fischer et al., 1979; Holley and Jirka, 1986; Rutherford, 1994). The flow in rivers is characterized by turbulence, i.e. more or less large scale eddy motions are superposed on the average flow. The spreading and mixing of mass sources is then controlled by the eddy activities and can be described in analogy to the molecular mixing by an effective turbulent diffusivity E as the product of the velocity u ′ and size of the dominant eddies, E~ u ′ . A river with a wide aspect ratio, B h, where B is the width and h the average depth, is a simple equilibrium flow in which the bottom shear stress τ o is counteracting the weight component acting in the flow

direction (see Fig. 1), τ o = γhS where γ = ρg= specific weight of the water, ρ=water density, g= gravitational acceleration, and S= bottom slope= sin α. The friction velocity u ∗ = √ τ o /ρ, is obtained on dimensional grounds, so that u ∗ = √ ghS. u ∗ is therefore the major quantity characterizing the fluctuating eddy velocities u ′ in channel flows, u ′ ~ u ∗ , as has been confirmed by many measurements (Nezu and Nakagawa, 1993). It is related to the average velocity U by the frictional properties (roughness) of the bottom and is typically about 5 to 10% of U, u ∗ = (0.05 to 0.10)U, with higher values for rough beds. The large eddies that correspond to the depth of the base flow, ~ h, are most effective for the mixing. Moreover, the eddy structure is characterized by a certain spatial anisotropy, their extent in the vertical direction z is more strongly limited than that in the horizontal direction y that lies transversely to the flow direction x. In summary, the following expressions for the turbulence diffusivities result from the above: The vertical eddy diffusivity E z is

where α z = 0.07± 50% (Rutherford, 1994) and the

horizontal diffusivity E y

where α y = 0.5± 50% (Fischer et al., 1979) for rivers

with moderate variability, thus without strong mean

ders and without lateral dead water zones.

If a continuous point source is considered at the

water surface a mass plume will evolve as is shown in

vertical section in Fig. 1 and in plan view in Fig. 2.

The pollutant plume spreads both vertically and trans

verse. Characteristic for such diffusion processes is

the approximately Gaussian concentration distribu

tion in the mass plume with the maximum value c max

at the water surface and at the river bank. The stan

dard deviation σ describes here a local value c= e -1/2

c max = 0, 61c max and is a practical indicator for plume

width.

The distance L mv to the location of complete vertical

mixing of the plume is often defined as being to the

point when the concentration at the bed becomes 90%

of the surface concentration and this can be determined

by the method of images (Fischer et al., 1979)

Using Eq. 1 (α= 0.07) and strong roughness,

u ∗ = 0.10U, the distance to the location of complete

vertical mixing is given by

The transverse spreading of a continuous point

source located at the bank in a wide river flow (B

h)

is outlined in Fig. 2. The longitudinal coordinate fol

lows in this case any river curvature and a constant

rectangular cross-section is assumed.The distance L mh

to the location where complete horizontal mixing over

the river cross-section takes place is

With α y = 0.5 and for strong roughness one obtains

It should be noted that these simple equations for the

estimation of complete mixing, Eqs 4 and 6, respec

tively, are (a) independent of the river velocity and

(b) primarily governed by the river morphology. The

first is because the turbulent mixing coefficients E y

Figure 2. Transversal spreading for a continuous
pointsource located at the bank of a wide river flow (B

h), plan view. Table 1. Examples for the complete mixing of

a passive point source located at water surface and at bank of a river. Distance to complete mixing Example B/h Vertical L mv Horizontal L mh (i) Large river ≈80 150 m 160 000 m B= 250 m, h= 3 m (ii) Small river 10 25 m 400 m B= 5 m, h= 0,5 m and E z scale directly with the mean velocity U! Comparison of the two formulas shows that in a wide river (B

h), the length for complete vertical mixing is always rather small as has been indicated in Fig. 2. Furthermore, in the initially three-dimensional mixing process (until the location where complete vertical mixing takes place) the drop-off of the maximum mass concentration is relatively fast, c max ~ x −1 (Fig. 1), while it occurs more gradually in the vertically mixed, thus two-dimensional, mixing phase, c max ~ x −1/2 (Fig. 2). Two examples are used for the practical illustration of the mixing dynamics of point sources in rivers: (i) Large river (approximately River Rhine near Karlsruhe, Germany, at average discharge), B= 250 m, h= 3 m, and (ii) small river, B= 5 m, h= 0.5 m. The calculations given in Table 1 show that complete vertical mixing occurs reasonably fast (150 m and 25 m, respectively), while complete lateral mixing requires considerably larger distances (160 km and 0.4 km, respectively)! Several comments are in order: (1) The distance to complete vertical mixing will be somewhat reduced if the finite dimensions of the discharge opening are considered or if the source location is varied within the water column, e.g. located at mid-depth. Thus, the discharge design can play a certain role in this initial region. (2)The design features play a lesser role regarding the passive lateral spreading in the far-field. Only the lateral position of the discharge point is a potential factor: e.g. if the source is located in the center of the

river the distances for complete mixing are reduced by

a factor 4 (since B/2 is used instead of B in Eq. 5 as

the controlling lateral dimension). Beyond that, only

the flow conditions in the river are decisive: For uni

form flow conditions the estimation according to Eq. 6

would be somewhat low, while for strongly heteroge

neous conditions – e.g. strong river meanders, or lateral

constrictions that induce secondary flows – the actual

distance might be somewhat shorter. (3) Both verti cal and lateral complete mixing can be influenced by active mixing processes in the near-field of the dis charge. Active mixing by momentum jets – especially in case of multiple diffuser discharges in rivers (e.g. Schmid and Jirka, 1999) – and buoyancy effects due to density differences lead, in general, to a reduction of the length for complete mixing. Models for the clas sification and prediction of these mixing complexities are available (e.g. Jirka et al., 1996).

Regardless of potential amplifications and com plexities, the following rules of thumb apply for the mixing properties of point sources in rivers: (1) Com plete vertical mixing is a rapid process with maximal dimensions of a few decades of the water depth. (2) Complete lateral mixing requires large distances. For typical river morphology (B/h= 10 to 100) the com plete mixing will require from 100 to 1000 river widths (see also Endrizzi et al., 2002).

These analytical predictions for the delayed lat eral mixing that are based on the description of the turbulent river flow properties have been confirmed through numerous field observations, in particular aerial photographs of “visible” plumes, taken from a period before recent source reductions were imposed,

as shown in Fig. 3.

2.3 Consequences of the “combined approach”: need for mixing zone regulations

The mixing processes due to discharges into water bodies occur according to well understood physical principles, as has been shown above for the case of rivers, and lead to a spatial and temporal configuration of the mass plume and the associated concentration distribution. To what degree do the water quality control measures of the new EC-WFD, in particular its “combined approach” consisting of emission limit values (ELV) and environmental quality standards (EQS), correspond to these physical facts?

The relevant values for ELV and EQS for various pollutants and pollutant groups can be found in different directives of the EC (see e.g. Appendix IX of the WFD) or of the national authorities. By way of example for further analysis, Table 2 contains the values for two chemical pollutants (cadmium and triochlorethane). The ratio ELV/EQS is 10 for triochlorethane and 500 for cadmium. The range of 5 to 1000 is typical for most chemical as well as

Figure 3. Aerial photograph (ca. 1960) of an industrial discharge located near the middle of the regulated River Rhine upstream of Lake Constance (Bodensee). The gradual lateral plume growth of the pollutant is typical for mixing processes in rivers. (Photograph courtesy of D. Vischer, Zurich).

Table 2. Examples for emission limit values (ELV) and environmental quality standards (EQS) for two selected

pollutants. Emission Environmental ELV Pollutant limit values quality standards example ELV EQS EQS Cadmium 0.5 mg/ 1 µg/ 500 (83/513/EEC) (76/464/EEC) Trichlorethane 0.1 mg/ 10 µg/ 10 (AbwV, Germany, (76/464/EEC) 2000) physical parameters, such as heat (temperature). This ratio describes the impact of the pollutants on the ecosystem, since the ELV is considered to protect against acute (lethal) effects on organisms, while the EQS is supposed to prevent long-time chronic influences. The ratio also expresses the necessary dilution that must be attained through physical mixing or – to

some extent – through biological decay and chemical

transformation processes.

There can be other ways of prescribing ELV-values,

namely through the specification of a “best available

technology (BAT)”. For example, for sewage outfalls

this may be described as some form of treatment, at

least primary, or enhanced (e.g. chemically) primary,

or a secondary biological treatment stage for nitrogen

removal, or a tertiary stage for phosphorus removal.

The requirement may be set by national authorities

depending on type of water body and its use (fish

eries or recreation) or on sensitive ecological zones.

In general, such BAT requirements assure a certain

degree of nutrient removal. Other indicator parame

ters, such as bacteria or viruses, are also reduced in the

treatment process. For example, while the typical total

coliform count for raw sewage ranges from 10 6 to

10 8 /100 ml it gets reduced by a factor 100 to 1000

during secondary and by 1000 to 10,000 during ter

tiary treatment (Larsen, 2000). Assuming an average factor of 1000 the effluent values for total coliform would then be 10 3 to 10 5 /100 ml. Existing EC regu lations provide some EQS-values for total coliform, e.g. the 500/100 ml given by the EC Bathing Water Directive. Thus, ELV/EQS ratios between 2 to 200 can be obtained from the above estimates. This com pares to the “traditional” dilution requirement of about 50 to 100 that has been used for many years for out fall design in the coastal waters of several European countries (Larsen, 2000).

Both measures, concentration values and removal degrees are useful to reduce and control water pollution, but where do these values apply? The “end-of-pipe” specification for the ELV is clear and unequivocal in Art. 2 (40) of the WFD:

“The emission limit values for substances shall normally apply at the point where the emissions leave the installation, dilution being disregarded when determining them”.

Surprisingly, and quite illogical from the viewpoint of the physical features of the mixing processes, the WFD does not provide any information on the spa tial application of the EQS-values. It also does not oblige the national authorities to establish such specifi

cation.Therefore, it must be expected that considerable uncertainties and highly variable interpretations or monitoring methods will occur in the practice of water authorities, both as regards the continuing approval of existing discharges as well as the permitting of new ones. The “combined approach” that appears sensi ble for an integrated ecological water pollution control is in danger of being by-passed or undermined in its practical implementation.

From discussions with personnel from regional water authorities the authors know of two extreme interpretations regarding this omission in theWFD: (1) The EQS-value shall be applied “as near as possible” to the discharge point in order to obtain a good chemical status in an area as large as possible. This highly restrictive interpretation negates the fact that the physical mixing process cannot be reduced to extremely small areas (in the limit this approaches an “endof-pipe” demand for EQS!), but requires a certain space – in particular for imposed high ELV/EQS ratios. It undermines the balanced objectives of the “combined approach”. (2) In case of rivers, the EQS-value applies after “complete mixing in the water body”. However, as was shown in the preceding section the longitudinal extent of the pollutant plume until full lateral mixing is attained can be considerable, even in small rivers. This highly generous interpretation could therefore lead to a condition that large regions within a pollutant plume of the point source would be exposed to concentration values above the EQS and would, therefore, represent “sacrificial stretches”. A similar evaluation can be found in a recent German strategy report on water research (DFG-KOWA, 2003): “The occasional assumption that environmental quality standards apply only after complete mixing leads in most water body types to intolerably large distances since mixing processes usually occur gradually…”. Thus, the new “combined approach” concept of the WFD is lacking a clear and factually correct mixing zone regulation that preserves the water quality objectives of

the “combined approach” and accounts for the physical aspects of the mixing processes. Therefore, a future amendment of the EC-WFD and national regulations for its implementation, respectively, should contain the following approximate wording: “The environmental quality standards apply in the case of point sources outside and at the edge of the mixing zone. The mixing zone is a spatially restricted region around the point source whose dimensions shall be specified either according to water body type and use or on an ad-hoc basis.” The mixing zone defined in the above statement is a regulatory formulation with the following general attributes: (1)The term “mixing zone” signifies explicitly that mixing processes require a certain space. (2) The term “spatially restricted” should guarantee that the mixing zone shall be minimized by the regulatory authority for the purpose of attaining the environmental quality goals. (3) While the mixing zone includes a portion – namely the initial one – of the actual physical mixing processes, these processes will continue beyond the mixing zone where they lead to further concentration drop-offs in the pollutant plume below the EQS-values. (4) The definition is restricted to “point sources” since diffuse sources usually do not contain clearly distinct mixing processes. The regulatory concept of mixing zones can also be found in the water quality regulations of other countries. As an example, the U.S. Environmental protection Agency defines in its Water

Quality Handbook:

“… the concept of a mixing zone as a limited area

or volume of water where initial dilution of a discharge

takes place” (USEPA, 1994). A number of supple

mentary restrictions further define this water quality

control principle such as “… the area or volume of

an individual mixing zone … be limited to an area

or volume as small as practicable that will not inter

fere with the designated uses or with the established

community of aquatic life in the segment for which the

uses are designated,” and the mixing zone shape be

“… a simple configuration that is easy to locate in the body of water and avoids impingement on biologically important areas.”

Once the principle of a mixing zone has been adopted and defined in the EC-WFD and/or national regulations it is also necessary that national water authorities provide clear guidance for the actual specification of mixing zone dimensions. Two major possibilities exist here:

(a) Specification of numeric mixing zone dimensions according to water body type and biological characteristics:

In the case of discharges into a river (see Fig. 4), the width of the mixing zone B_{MZ} can be restricted to a fraction of the river width, e.g. $B_{MZ} = n_B B$, with the goal that the majority of the river cross-section provides for unhindered passage of river fauna (fish), or the length of the mixing zone L_{MZ} can be described, e.g. $L_{MZ} = n_L B$, with the goal that high concentrations along the river banks are constrained, or both prescriptions may apply jointly. The multiples n_B and n_L – with typical ranges $n_B = 0.1$ to 0.5 and $n_L = 1$ to 5 – may be set by the water authorities based on regional considerations taking into account water body type, water use and biological characteristics.

For the case of coastal discharges Jirka et al. (2004)

have given analogous recommendations for mixing

zone around submerged diffuser outfall structures.

(b) Specification of mixing zone dimensions in an

ad-hoc manner:

After prior ecological evaluations or predictions

the discharger can request the authority for a mixing

Figure 4. Example of regulatory mixing zone specifica

tions for discharges into rivers: Width of mixing zone B MZ
,

and/or length of mixing zone L MZ , both defined relative to

the river width B. zone with a certain dimension with the claim that this would guarantee an integrated water quality protection. Based on its own examinations the authority can agree with that proposal or else demand further restrictions. 2.4 Increased application of modeling techniques for mixing processes As another consequence of the “combined approach” of the new WFD values it appears that both dischargers as well as water authorities must increase the application of quantitative predictions of substance distributions in water bodies (water quality parameters in general, mixing processes in particular). This holds for both existing discharges (diagnosis) as well as planned future discharges (prediction). There are several diagnostic and predictive methodologies for examining the mixing from point sources and showing compliance with EQS-values: (1) Field measurements or tracer tests can be used for existing discharges in order to verify whether EQS-values are indeed met. Field measurements are costly, often difficult to perform, and usually limited to certain ambient conditions. Frequently, they must be supported through mathematical model predictions, on one hand, to establish a clear linkage to the considered discharge (especially if more than one discharge exists), and on the other hand, to synthesize conditions allowing for variabilities in the hydrological or oceanographic conditions or in the effluent rates. (2) Hydraulic model studies replicate the mixing process at small scale in the laboratory. They are supported by similarity laws and are quite reliable if certain

conditions on minimum scales are met as has been demonstrated in the past. But just like field tests, they are also costly to perform and inefficient for examining a range of possible ambient/discharge interaction conditions.
(3) Simple analytical equations or nomograms (e.g. Rutherford, 1994; Holley and Jirka, 1986) are often satisfactory to predict reliably the mixing behavior of a pollutant plume. For example, the maximum pollutant concentration c max as a function of distance x along the flow for a passive point source at the bank of a river (see Fig. 2) is given by where Q co is the pollutant mass flux of the source (mass/time) and E y is the lateral turbulent diffusivity from Eq. 2.The factor 2 on the right hand side signifies the reflection effect of the impermeable river bank. In many river applications with relatively uniform crosssections Eq. 7 would be satisfactory for a conservative

prediction, possibly combined with parameter sensi

titivity studies (see coefficient α y in Eq. 2) in order

to predict the maximum pollutant concentration along

the bank and to demonstrate compliance with the EQS

values. Simple amplifications of Eq. 7 in the form of a

stream tube method (see Fischer et al., 1979) are avail

able for strongly meandering and non-uniform river

sections.

(4) Mixing zone models are simple versions of more

general water quality models.They describe with good

resolution the details of physical mixing processes

(mass advection and diffusion), but are limited to rel

atively simple pollutant kinetics by assuming either

conservative substances or linear decay kinetics. This

is acceptable for most applications, since residence

times in the spatial limited mixing zones (see pre

viously mentioned specifications) are typically short so that chemical or biological mass transformations are usually unimportant. As for all computer-based models that are concerned with environmental prob lems – here with water quality as a common good! – the scientific transparency of the predictive models is essential. That means not only that the govern ing equations and all relevant assumptions must be clearly published but also the actual calculation mod ule must be available as public domain software and thus scientifically verifiable. User interfaces as well as preand post-processing modules can, of course, be added, developed and distributed in a for-profit manner in an open market. Undoubtedly, the main problem in the application of mixing zone models is the estimation of its applicability by the user. In par ticular, simple model types are often limited to certain flow situations. Model assumptions and limitations must be clearly stated by the model developer. But even then it may be difficult for the user with lim ited experience in these complex processes of fluid mechanics to judge whether a model is applicable for a specific situation. The application of expert sys tems seems advisable for that problem. An expert system can lead the user in sequential steps through

data acquisition, it performs the selection of a spe
cific sub-model or predictive equation depending on
the physical situation, it provides the graphical dis
play and interpretation of the predictive values with
regard to the compliance with EQS-values and mixing
zone regulations, and finally it may provide recom
mendations regarding additional sensitivity studies or
design changes for the optimization of the mixing
process. Ragas (2000) provides a comparison of dif
ferent mixing zone models. The mixing zone model
CORMIX (Doneker and Jirka, 1991; Jirka et al., 1996),
in particular, is characterized by its wide applicabil
ity to many water body types (rivers, lakes, estuaries,
coastal waters) and has been successfully used for
water quality management under different regulatory

frameworks. (5) General water quality models may be required in more complex situations. In simple water bodies, such rivers, coastal regions or estuaries with well defined uni-directional current regimes or with simple reversals, and with moderate pollutant loadings, the use of mixing zone models alone may suffice to arrive at, or to evaluate, a design of a point source discharge that meets regulations. However, in coastal regions with multiple current regimes (inertial, tidal, windor buoyancy driven) and in rivers and coastal regions with large pollutant loadings, especially where several sources may interact and additional diffuse sources may exist, mixing zone models must be supplemented by larger-scale (far-field) transport and water quality models. The latter are capable of prediction over greater distances in the water body the concentration distributions for different pollutants, but also for nutrients and other bio-chemical parameters with due consideration of mass transformation and exchange processes. They do not, however, have the high spatial resolution that is required to predict mixing processes and

the compliance with EQS-values in a limited mixing zone. An effective and sensible approach for strongly loaded water body reaches is therefore the prior application of general water quality models in order to predict background concentrations in the vicinity of the considered point source. Superimposed on these background considerations are then the additional concentrations within the pollutant plume as predicted by the mixing zone model. For rivers, the model AVG of the German ATV-DVWK, the model QUAL-2 of the U.S. EPA, and the model RWQM1 of the International WaterAssociation are all examples of general water quality models. Such models also form the basis of management procedures for attaining a good quality status in the case of multiple sources, i.e. by following the principle of a distributed waste load allocation for individual water users. The ultimate goal of European water quality policy as promulgated in the Water Framework Directive of 2000 is the attainment of a good quality status by the year 2015. Therefore, a future amendment of the WFD and of corresponding national implementation procedures must contain a clear and unequivocal mixing zone regulation in order to not jeopardize that goal. Increased usage of several types of water quality models by both dischargers and regulatory authorities will be another key mechanism for reaching that goal. 3 INSTANTANEOUS RELEASE PROBLEMS IN RIVERS 3.1 River alarm models Accidents happen, as the adage says. While the water quality impact of continuous discharges can be

controlled and reduced by water authorities through

the aforementioned permitting process, there exist lim

ited control options for accidental pollutant releases or

spills. Of course, increased safety regulations and/or

redundant design requirements are important for min

imizing industrial, mining or navigational accidents

that cause short-time chemical pollutant releases in

or along rivers. Yet despite such measures acciden

tal spills are bound to occur, albeit with decreased

likelihood and frequency.

The major option for water authorities lies in

enabling a rapid emergency response to warn down stream users and to mitigate secondary damages, e.g. by shutting down of water intakes during passage of the pollutant mass or limiting recreational uses. The key element for response planning are so-called “river alarm models (RAM)” that allow the on-line opera tional tracking and prediction of the released pollutant mass by forecasting its movement and dispersion along the river channel. The first such RAM was instituted by the Commission on the Hydrology of the River Rhine in cooperation with the International Commis sion for the Protection of the River Rhine (ICPR) in the wake of the dioxin spill from the Sandoz plant, Basel, Switzerland, in 1986 that heavily damaged flora and fauna along the entire river. Other recent spill disas ters of major proportions have been along the Dnjepr, Russia (1970s), the Guadalquivir, Spain (1998), and the Tisza, Rumania (2001), all of these resulting from the failure of retention dikes for chemical or mixing process waters.

Alarm models are currently being implemented by different European river basin authorities, and presum ably around the world. Common for these RAMs is a one-dimensional formulation in order to facilitate the on-line installation on PCs within the water authorities

and operation with a minimum of hydrological infor
mation on initial and boundary conditions. To a great
degree these RAMs are highly empirical as the param
eters describing the transport and dispersive charac
teristics of the pollutant mass in the one-dimensional
formulation are subject to large uncertainty, particu
larly so in river channels with major heterogeneities.
These include rivers with highly variable natural mor
phology, side arms and dead zones as well as regulated
river with groins or spur-dikes and secondary flood
ways. Because of this predictive uncertainty it is
necessary to conduct dye dispersion tests in the river
in order to deduce the required model parameters.
These tests are very time-consuming and expensive
and are always limited to the given hydrologic regime
(low, average or high flow). A thorough mechanistic
understanding of the generic role of channel hetero
geneities on mass transport and dispersion is needed to
improve the predictive capabilities of existing RAMs
and help in the formulation of new ones for other

rivers. 3.2 Dispersion processes for instantaneous mass releases in rivers Turbulent flow and transport in a river is, of course, a three-dimensional process. Hence, the concentration c(x, y, z, t) following an instantaneous release of pollutant mass M in a given steady-state velocity field q= (x, y, z) is given by the three-dimensional advection diffusion equation (Fischer et al., 1979) in which the turbulent diffusivities E x , E y , E z (each a function of x, y, z) describe the turbulent

spreading process (Reynolds-averaged over the time scale of fluctuations). x is the longitudinal coordinate following the river channel, y the lateral and z the vertical coordinate. Under the assumption of uniform unidirectional mean flow – either a straight river channel or in a natural coordinate system following a mildly curving channel – the mean velocity field q= (u, v, w) simplifies to u(y, z), v= 0, w= 0 and diffusivities are functions of y, z only. In principle, the three-dimensional advection- diffusion equation – for general or simplified uniform geometry – can be solved by numerical computational techniques subject to some closure approach on the turbulent diffusivities. In the practice of RAMs – as for many other water quality or hydraulic problems – the general threedimensional solution is not feasible for operational reasons or often not necessary. In that case simpler solutions by spatially averaging over one or two transverse dimensions can be obtained. For RAMs the averaging over the entire channel cross-section A, thus integrating over y and z, is typical practice. The onedimensional mass conservation equation that results from this averaging process reads for a conservative pollutant in which C(x, t) is the cross-sectionally averaged (mean) concentration, U the mean velocity and ~ denotes cross-sectional averaging. The term on the right-hand side specifies the turbulent diffusion (i.e. the role of time-averaged fluctuations) in the longitudinal direction. The crucial term, however, is the so-called “small-scale advective” flux u˜ ′′ c ′′ which represents the spatial correlation of the deviations of velocity u ′′ (y, z)= u – U and concentration c ′′ (y, z) = c – C from its mean values. The result of the “small-scale advection” process is shown schematically in Fig. 5 for a uniform channel flow with an internally shear and velocity profile u(y, z). For short times, the concentration distribution strongly resembles the shape of the velocity profile while additional turbulent diffusion causes spreading in all directions, especially also in the transverse direction. For long times, the interaction between the

Figure 5. Schematics of longitudinal dispersion process

in uniform river. For short times the cross-sectional pro

file C(x, t) is strongly skewed, for long times it assumes a

Gaussian distribution.

longitudinal stretching mechanism due to shear flow

and the transverse mixing mechanism due to turbulent diffusion is pronounced and enters an asymptotic state that is called the “longitudinal dispersion” mechanism. In this stage the cross-sectional concentration distribution is essentially homogeneous and is Gaussian in shape in the longitudinal direction. Furthermore, the standard deviation σ_L of this distribution grows $\sigma_L \sim \sqrt{t}$, all attributes that resemble a Fickian diffusion process, i.e. mass diffusion as an ensemble result of many individual independent random processes.

In his ground-breaking papers, Taylor (1953, 1954) showed that this dispersion process can be represented by an equivalent advection–dispersion equation in which the longitudinal turbulent diffusion term in Eq. 8 has been neglected as being much smaller than the dispersion term. E_L is the coefficient of longitudinal (or shear flow) dispersion.

Taylor has also shown – in his case for axisymmetric pipe flow – that the value of E_L can be computed directly from the distribution of the shear flow $u(y, z)$ and the transverse diffusivities $E_y(y, z)$ and $E_z(y, z)$ through triple integration. For the case of a purely vertically sheared two-dimensional uniform channel flow, $u(z)$ and $E_z(z)$ only, this triple integration reads

in which h is the water depth.

Eq. 10 was first evaluated by Elder (1959) for the

turbulent logarithmic velocity profile and associated

diffusivities to yield

in which u ∗ is the shear velocity as the major factor

characterizing turbulent eddy velocities. In another seminal contribution, Fischer (1967) dealt with dispersion processes in natural river channels, that are typically wide and shallow, B/h

1, in which B is the river width. He showed that while the velocity profile is doubly sheared u(y, z) the vertical shearing effect u(z) (i.e. Elder's approach) is of lesser importance while the lateral shear u¯(y) becomes dominant as it operates over a much larger scale (B). Here u¯(y) is the vertically averaged velocity profile that has been sketched in Fig. 5. Fischer represented Taylor's integral in depth-averaged form in which E y (y) is the depth-averaged lateral diffusivity (see Eq. 2). The evaluation of Eq. 12 with measured lateral velocity profile from either laboratory or field experiments showed generally very satisfactory agreement with the dispersion coefficient that has been measured from corresponding dye tracer tests through growth of the variance σ 2 L , where t= x/U corresponds to the travel time between subsequent measurement stations. As stated above, the advection-dispersion equation, Eq. 9, the associated values of E L , and finally its solution are only valid in the final dispersive stage of the mixing process. The duration of the initial or convective stage is given by the transverse mixing time t M . For the case of river channels, t M is given by (Fischer, 1967; Fischer et al., 1979) which corresponds, t M U=L mh , to the associated mixing distance L mh given in Eq. 5. During the convective stage, t> t M , the mean concentration distribution is strongly skewed (see Fig. 5). The behavior of the pollutant mass ("cloud") furthermore depends on the discharge details, whether more or less uniform across the river or whether a release in mid-river or near a bank. 3.3 The role of channel heterogeneities: influence of groin fields It has long been recognized that the dispersion process in natural river channels may be greatly enhanced

beyond the simple shear flow effects in a uniform

channel as described in the preceding. Higher order

influences, such as dead-zones or retarded flow zones caused by overbank flows, meanders, side arms, partially vegetated areas, and groin fields cause additional flow non-uniformities which result in increased stretching of the pollutant cloud, i.e. increased dispersion once a new asymptotic stage has been reached, as well as a reduction (retardation) of the effective transport velocity c below the cross-sectional mean velocity U, c<U.

No consistent, mechanistically justifiable approaches to this problem of channel heterogeneities have been developed to date. A high degree of empiricism prevails on that issue in current practice, e.g. on RAM implementation and operation. Since heterogeneities in channel morphology are irregularly distributed along river distance, one approach has been to accept an unavoidable degree of uncertainties in the value of E L . A number of empirical equations – or empirical adjustments of theoretical equations as given above – can be found in the literature reflecting this state of affairs. For example, Fischer et al. (1979) give based on an evaluation of Eq. 12 for “typical” lateral velocity profiles and irregularities. They cite that data comparisons show inaccuracies by a factor of ±4 or larger. Mazijk (1996) reports yet larger deviations (fac

tor of 10) with dye tracer data for different stretches of the River Rhine. This is hardly acceptable as predicted maximum concentration values as well as cloud widths are proportional to √ E L (see Eq. 14) leading to substantial operational decision-making uncertainty.

A further consequence of variable channel heterogeneity is the apparent extension of the convective stage of mixing. Since the morphology is constantly changing an asymptotic dispersive state is never reached. This is exemplified by the tracer test results for the River Rhine (Fig. 6) where at distances greatly exceeding a mixing distance t M (estimated as about 50 km for the release station) a strong skewness persists. (It is worth noting, however, that by virtue of Eq. 15 a curve C(t) at a given station will always be slightly skewed; only curves C(x) at a given time become truly symmetric!) For that reason the RAM (see Mazijk, 1996) contains an empirical adjustment

of Eq. 15 in the form 0 0.2 0.4 0.6 0.8 1 1.2 1.4 2 4 6 8 time after release (days) C (µ g / l) calculated measured Maximiliansau km 362 Bingen km 362 Düsseldorf km 760 Lobith km 862 3 5 7 9 Figure 6. Concentration curves from dye tracer test on River Rhine. Tracer release near Basel (km 170) (after Mazijk, 1996). in which H 3 (τ)= τ 3 − 3τ is the Hermite polynominal of third order to impose a certain skewness. Q is the river discharge and c is the transport velocity, related to the mean velocity U where β is nominally the ratio of active stream crosssectional area A s to the dead-zone cross-sectional area A D , β=A s /A D , but in practice is used as best-fit parameter. Fischer's Eq. 16 is used for E L , withα being another best-fit parameter. A best-fit model calibration is certainly

possible whenever high quality tracer test data sets covering different stretches and hydrologic regimes are available. This is the case for the River Rhine so that the existing Rhine-RAM constitutes a reasonably reliable pollution routing and forecasting tool. It is not satisfactory, however, from a fundamental mechanistic viewpoint and is a severe drawback for the establishment of new RAMs for other major rivers for which tracer data is limited and new extensive tests would be a costly and time-consuming undertaking in each instance. A research study has been undertaken at the Institute for Hydromechanics (IfH) with the ultimate purpose of reducing the existing uncertainty in specifying transport parameters for RAMs and, thus, improving their prognostic abilities avoiding elaborate calibration effects. An initial focus of the study has been the systematic effect on mass dispersion of a system of groin fields that are arranged regularly along the river bank. This morphological situation is frequently found in regulated European rivers as shown in Fig. 7. Weitbrecht (2004) (see also Weitbrecht et al., 2004) studied the effect of an infinite series of groin fields on asymptotic mass dispersion in two steps: first, a detailed fluid mechanical understanding of the exchange dynamics at the edge of an individual groin

field, and second the integrative effect of a sequence

of many groin fields.

(a) Exchange mechanisms between main channel

and groin fields: Groin fields form – depending on

their geometry – more or less “dead-zones”, i.e. the

mean field-averaged forward convective velocity is

zero. However, there is an effective shear zone (see

Fig. 7b) at the groin field boundary to the mean

channel: these causes both a net circulatory mech

anism as well as intermittent turbulent exchange between the main river and the groin field. When a pollutant cloud propagates in the main channel a fraction of the cloud mass gets advected into the groin field, is temporarily retained and finally gradu ally returned into the main river. Thus, understanding the intensity of the exchange mechanism as a func tion of groin field morphology is key to quantify ing the aggregate effect of groin field sequences on dispersion.

Figure 8 shows the tilting laboratory flume at the IfH with 20 m length and 1.82 m width that was used in a series of tests to study groin field flow dynam ics. Typical flow velocities were U= 0.16 m/s and flow depths h= 0.046 m, giving a channel Reynolds number of about 7500, thus well into the Reynolds Figure 8. Schematic top view of the laboratory flume tests at IfH for groin field dynamic. Figure 9. Sequence of instantaneous velocity vectors and vorticity fields (light shading negative vorticity, dark positive) for experiment with groin field aspect ratio W/L= 0.4. Time interval between PIV images is 1s. invariant regime so that the results seem transferable to prototype conditions. Different groin field geometries, W/L= 0.17 to 3.3, in which W= groin length and L= spacing length between groins (see Fig. 8), variable inclination lengths and variable depth h D in the groin field, less than the main channel depth h s were studied schematically. The major experimental techniques for deducing the exchange dynamics were surface particle-imagevelocimetry (PIV) as described by Weitbrecht et al. (2002) and a planar-concentration-analysis (PCA) of an instantaneous volumetric dye injection within the groin field (see Kurzke et al., 2002). Figure 9 shows a sequence of PIV-generated images with instantaneous velocity and vorticity field. The generation of large coherent

structures within the shear layer at the groin field boundary is evident leading to mean and turbulent transport in and out of the groin field.The structure of the mean gyres for groin field with different aspect rating can be seen in Fig. 10. A number of statistical analyses can be performed with these data. A key element is the definition of the exchange velocity E from the instantaneous lateral velocity values v B at the groin field boundary, i.e. the line of length L connecting the groin heads,

Figure 10. Time averaged surface streamline patterns for

different groin field aspect ratios W/L.

Figure 11. Plan view and cross-section of groin field

processes represented as a dead-zone model.

Normalization with the mean stream velocity U gives

the dimensionless exchange coefficient

As an alternative and independent method for

deducing the exchange coefficient the whole groin

field volume was injected instantaneously with a vol

umetric dye source. This was done with a special

injection box connected to some 800 injection needles

in a 3 cm× 3 cm array.These produced small turbulent

dye clouds that rapidly merged forming a uniform vol

ume source. The loss of total dye mass was monitored

with the calibrated PCA system and followed fairly

well an exponential loss curve with a time constant

T D . Using a dead-zone model (see Fig. 11) as a simple

parameterization T D can be related to a dimensionless

exchange coefficient k

Both independent results, Eqs. 19 and 20a,b, were

found to be in excellent agreement with each other.

A groin field morphometric parameter was defined

by Weitbrecht (2004) Figure 12. Dimensionless exchange coefficient k at groin field boundary as a function of groin field morphometric parameter R D /h S . where R D represent a sort of “hydraulic radius” for the groin field. The measured exchange values correlate well with this parameter as shown in Fig. 12, covering a wide range of groin field types and shapes, including data by Uijttewal et al. (2001). The data are well presented by the linear relation which can be used as the basis for further predictive work. The observed range of k agrees well with the range 0.01 to 0.03 reported by Valentine and Wood (1979) from the analysis of field data. These authors, however, did not report any morphometric dependence. (b) Integrating the effect of a groin field sequence on river dispersion: Once k (Eq. 22) is given as the boundary information at the edge of the main river channel the advection–diffusion equation can, in principle, be solved to yield the value of the dispersion coefficient in the composite system (main river plus groin field sequence). Valentine and Wood (1977) have proposed a Dead-Zone Model as two coupled differential equations for that purpose. Unfortunately, no analytical solutions are known and numerical methods would take very long to converge to the dispersive regime, being fraught by numerical dispersion in the process. Weitbrecht (2004) formulated a Lagrangian particle tracking model (LPTM) as an alternative method for obtaining values for the asymptotic regime. A mass of many discrete particles is released initially and uniformly over the system cross-section. The model performs for each time step and for each particle a forward convective step according to the local velocity value u(y) and a random transverse diffusive step proportional to the square root of the local diffusivity E y (y).A special adjustment is made on the latter step to prevent a “noise-induced” drift component due to gradients ∂E y /∂y.The lateral boundary condition at a solid

normalized as E L /(u ∗ h s), for composite river/groin field

system as a function of groin field morphometry R D /h S and

main river Peclet number Pe=UB/E y . Results from LPTM

simulations. Fischer's estimates (Eq. 16) for rivers without groin fields are shown as dash-dotted lines for the three cases of Pe.

side wall (bank) is a reflection condition, while at the groin field boundary a retention condition is imposed, i.e. particles are held for the average retention time T D before they are released back into the flow.

The LPTM is a useful and convenient method that can be used efficiently on a PC to produce stable statistics on concentration distributions, including lengths of convective period and skewness distributions (for examples, see Weitbrecht et al., 2004). It has been run with the normalized velocity and diffusivity distributions corresponding to the experimental conditions given above.

Some of the LPTM results are summarized in Fig. 13 which displays the asymptotic normalized dispersion coefficient, E L /(u * h s), as a function of two parameters: a main channel Peclet number Pe=UB/D y and the groin field morphometry parameter R D /h s .

Several observations can be made from these qualitative simulations:

- The transverse mixing Peclet number Pe measures the role of forward advection relative to trans

verse diffusion. Increasing Pe (e.g. by decreasing

E y) also increases the asymptotic dispersion coef

ficient, consistent with the form of the triple integral

(see Eq. 12).

- Decreasing the groin field morphometry factor

R D /h s means decreasing k and increasing the reten

tion time T D and causes generally an increase in the

value of E L .

- There appears to be, however, a regime of low Pe

and low R D /h s (region on lower left in Fig. 13) in

which the groin field retention effect is no longer

important. In this regime the advection in the main

channel is so weak (slow) that the strong exchange effect acts by rapidly absorbing and returning pollutant mass so that the retention effect is no longer visible.The limit line is given by a ratio of transverse mixing time to retention time, t M /T D ≈ 10. - The orders of magnitude of the normalized coefficients E L /(u ∗ h s) are 0 (10 4). These are quite plausible and agree with some reported field data for many natural channels, e.g. see surveys in Fischer et al. (1979) or Rutherford (1994). For comparison, Fischer's estimates (Eq. 16) for rivers without groin fields are plotted in the right margin of Fig. 13. The drastic enhancement of longitudinal dispersion due to groin fields is evident from these comparisons. In summary, the study has shown that a systematic description of groin field flow dynamics can lead to an improved quantitative prognosis of the flow and transport parameters in reasonably complex riverine systems. Hopefully, these results and further parametric studies will lead to improvements in the formulation of future river alarm models. 4 CONCLUDING REMARKS The quantitative understanding of mixing and dispersion processes in rivers is a key element in successful strategies for water quality control and management. Despite great advances that have been made over the last half century there remain a number of challenging research questions that need to be resolved.

For continuous discharges, that are usually subject to a routine permitting process by water authorities, the specification of transverse mixing is most important for meeting given mixing zone regulations. Secondary current and coherent eddy structures, especially in curved or meandering channels, e.g. in the wake of structures or islands, will influence mixing processes. Many more open research questions concern the longitudinal dispersion process due to instantaneous or accidental pollutant releases in river systems with complex morphology. In order to decrease the present parameter uncertainty systematic studies are needed on the effect of river heterogeneities, such as meandering, overbank floodways and side arms, partly vegetated flow zones, and groin fields, all with variable hydrological conditions, such as water levels. Finally, the interaction of these physical processes with the chemical and biological transformations that govern the fate of particular chemicals need to be addressed. This includes pollutant sorption processes with fine organic or inorganic suspended or bottom sediments and with biota.

Debris flows and their modeling

T. Takahashi

Kyoto University, Kyoto, Japan

ABSTRACT: This paper reviews the existing models of debris flow categorizing into the single-phase flow

model and the two-phase flow model. Classic single-phase models such as the viscoplastic fluid model and the

dilatant fluid model are simple and still give powerful tools in predicting the average behaviors of flow as long

as the parameter values included in respective models are properly determined. But, they are often difficult to

determine on the a priori arguments of materials and topographical conditions. The behaviors of debris flows

are diversified depending on the properties of solid material, solid concentration, flow magnitude, river channel

conditions, etc., and they often change their sediment transporting modes while in motion. The two-phase models

that consider the debris flow is comprised of the mixture of two continuum media of fluid phase and solid phase

are able to classify debris flows and able to analyze the physics of respective flows. As examples of those models,

author’s theories for inertial debris flow and viscous debris flow are introduced.

1 MODELS FOR MULTI-PHASE FLOW

Many simulation models for granular flow with the

negligible effects of interstitial fluid (in a vacuum or in

the atmosphere) have been given (single-phase model).

They can be categorized into the continuum media

model and the discrete particle model. The former model describes the granular assembly as a continuum media and its characteristics are analyzed by the Eulerian forms of the continuity and momentum equations. The discrete characteristics of particle motion are necessarily neglected. The latter model, on the other hand, traces the motion of each particle by the Lagrangian equation.

In the continuum media model, the characteristics of flow as a granular assembly are intrinsic in the stress terms in the Eulerian momentum equation. These terms are obtained from the relationship between the stress and the strain of the continuum that is called the constitutive equation. Although the general constitutive equation under the arbitrary conditions of particle density, particle size distribution, and particle interactions is difficult to obtain, if an appropriate form of it under a particular flow condition is given, the continuum media model can be an operative method to explain the flow characteristics en masse under that condition.

The discrete particle model describes every particle's motion in flow by the Newton's second law equation under the effects of contact forces between the neighboring particles. Two kinds of approach for

treating the contact have been adopted: the hardcontact technique and the soft-contact technique. In the hard-contact technique, particles are considered as rigid bodies, and the contact arises only between the two adjacent particles in an instantaneous moment (Campbell and Brennenn 1985, Straub 2001). This technique has shortcoming on the handling of the simultaneous collision of multiple bodies. The soft-contact technique is free from the shortcomings in the hard-contact technique (Campbell 2001).At the moment of soft-contact, particles deform a little and forces proportional to the stiffness of particles act at the contact points. The interaction between particles at a contact point is modeled by the deformation of interface instrument that is composed of spring and dashpot connected in parallel. Two sets of such an instrument are mounted normally and tangentially on each contact point. To handle non-cohesive particle, a joint that is nonresistant to tension in normal direction and a slipping joint that is effective under a tangential force beyond a threshold should be connected to the respective sets of instrument (Gotoh & Sakai 1997). Thus, many parameter values must be given beforehand, and if particle number becomes large, load on computer becomes enormous. The implementation of simulation makes clear the motion of individual particles that may be difficult to observe in the physical model tests. But, the quantitative characteristics of average flow such as depth and velocity can be obtained only after the completion of simulation.

In the case of debris flow, the interstitial liquid is

water or slurry, so the relative density of particles in

flow is small, and therefore, the effects of intersti

tial fluid often play important roles. Then, the flow

should be considered as composed of two phases. Liq

uid phase is naturally described by the Eulerian flow

equation, but as mentioned above, the solid phase may

be described as a continuum media or as an assembly

of discrete particles.

If solid phase is considered as a continuum media

and described by the Eulerian equations, mathemati

cally the model becomes Euler-Euler coupling model.

In this model, two momentum equations each for liq

uid and solid phases are given. These are as following

(Iverson 1997):

where v s = velocity of solid; v f = velocity of fluid;

C = solid volume concentration in flow; σ= density

of particle; ρ= density of fluid; g= acceleration due

to gravity; T s = solid phase stress tensor; T f = fluid

phase stress tensor; and F= interaction force per

unit volume that results from momentum exchange

between the solid and fluid constituents.

Addition of these two equations yields a momentum

conservation equation applicable to the bulk mixture.

This procedure eliminates the assessment of compli

cated interactions between fluid and solid phase. If

nearly steady uniform flow is considered and the rel

ative velocity between solid and fluid is neglected in

Cartesian coordinate system, following two equations

are finally obtained (Takahashi 1991):

where P ds = pressure in solid phase; P f = pressure

in fluid phase in excess over hydro-static one;

T ds = shear stress in solid phase; T f = shear stress in

fluid phase; ρ T {= (σ− ρ)C + ρ}= apparent density

of debris flow material; θ= slope of flow surface;

h= flow depth; and z= height measured from the

bottom of flow.

These equations are fundamental equations in the

two-phase fluid model describing the stress balance

in the flow of mixture. The essential problem in this

two-phase mixture theory is how the left-hand sides of

Equations 3 and 4 are described.

If solid phase is considered as an assembly of

discrete particles, flow should be analyzed by Euler

Lagrange coupling model, in which individual particle motion is solved by the discrete element method earlier described taking the interaction between particles and fluid into account. Some investigations on bed load transport have been done by this method (Gotoh et al. 1994), but debris flow has not been treated by this method. 2 SINGLE-PHASE CONTINUUM MODELS In the single-phase continuum models, the mixture of particles and fluid is considered as a kind of continuum fluid whose constitutive relation between stress and rate of strain is to be found empirically by the laboratory tests of samples collected from flow or by the deduction from the back analysis of the model applied to the flow in field. 2.1 Viscoplastic fluid model Debris flow commences from the gradual or the abrupt motions of debris block due to the effects of water, and after the motion of considerable distance, it comes out to flat area and stops. Therefore, if one considers the material itself has strength intrinsically, one can explain the starting of motion attributing to the operations of a stress more than that (yielding) strength, and flow stops if the stress in flow becomes smaller than the strength. Debris flow modeling as a kind of viscous fluid having strength is called ‘viscoplastic fluid model’, and it assumes the relation between the stress and the strain rate as following: where τ= shearing stress; τ y = yielding strength; u= velocity at height z; and K and n= positive parameters. The simplest in the viscoplastic fluid models is the one setting n= 1, that is called ‘Bingham fluid model’. This model was first proposed independently by Yano & Daido (1965) and Johnson (1965). Later, Johnson (1970) modified his model to the following ‘Coulomb-viscous model’: where c= cohesive strength; σ n = internal normal stress; φ= internal friction angle; and μ=Bingham

viscosity. Viscoplastic fluid models, including the HerschelBulkley fluid model that sets n< 1 (Coussot 1995) and the polynomial models that add the term (du/dz) 2 to Bingham fluid model (Julien & O'Brien 1997) or add (du/dz) η to Equation 6 (Chen 1988), are still frequently used especially for the cases of viscous type debris flow.

Figure 1. Velocity distribution in Bingham fluid flow.

For example, the stress balance equation for steady

uniform Bingham fluid flow is given by

The integration of Equation 7 under the boundary

condition; u= 0 at z= 0 gives the velocity distribution

throughout the depth as shown in Figure 1 in which

z ′ (= τ y /ρ T g sin θ) is the thickness of plug that behaves

like a rigid body.

The serious shortcoming of viscoplastic models is

the difficulty in determining the crucial parameter

values such as τ y , μ, etc. Those values obtained by

laboratory tests and by field observations are usually

much different, and they cannot account for the para

meter value changes due to the addition or subtraction

of water or sediment during in motion. According

to the author's observation, the typical viscous type

debris flow in the Jiangjia ravine in China lacks the

plug that should exist in a viscoplastic fluid flow.

2.2 Dilatant fluid model

Debris flow whose main solid components are coarse

grains larger than gravel size can often reach to an

area flatter than about 4 ∘ keeping its high mobility

and competence to freight big boulders. Takahashi

(1978) inferred such small resistance to flow was

caused by the dispersion of grains separated with

one another, and the inter-particle collision gave rise

to the dispersion of heavier grains than the ambient

fluid.

Bagnold (1954) was the first to discover the signifi

cance of inter-particle collision as the cause of particle

dispersion. His experiments and simple binary grain

collision analysis gave the stress-strain relationships in inertial and viscous regimes. In inertial regime, those relationships were given as following: where p= dispersive pressure in flow; a i = numerical constant; α= collision angle; d p = grain diameter; λ= linear concentration of grains defined by λ≡{(C ∗ /C) 1/3 −1} −1 ; and C ∗ =maximum grain concentration when λ=∞. He directly measured the excess pressure with grains in flow over that with the plain fluid, so that p in Equation 8 was equivalent to P ds in Equation 3. The grain drag; T ds , corresponding to P ds could not be measured directly but it was deducted from the measured periphery drug that was the total of drugs shared by fluid and grain constituents. Therefore, τ in Equation 9 is equivalent to T ds in Equation 4. Bagnold used neutrally buoyant solid spheres immersed in a Newtonian fluid in his experiments, but Takahashi (1978) exploited his results to the open channel flow with hyper-concentrated heavy grains assuming uniform distribution of grains throughout depth; the stress balance equations for normal and parallel directions to the bed were given, respectively: Referring to the discussion above, this model is an equivalent model to the two-phase model in which the dynamic fluid effects are negligible. But, as far as Equation 11 is concerned, shearing stress in the flow of mixture is described by an expression assuming a single-phase continuum fluid. A kind of fluid having the relationship; τ~ (du/dz) n , n> 1, is called ‘dilatant fluid’, so Takahashi’s model is called the dilatant fluid model. Equations 10 and 11 can be easily integrated under the boundary condition; u= 0 at z= 0, and one can obtain the flow velocity at height z. The result of

integration of Equation 11 is given as Mathematically, the velocity distribution function obtained from Equation 10 has not the same expression with the one obtained from Equation 11. Those two

Figure 2. Velocity distribution on rigid bed.

functions become physically equivalent only when the

following formula is satisfied:

For example, if one substitutes σ= 2.65 gcm −3 ,

ρ= 1.0 gcm −3 , tan α= 0.75 and θ= 18 ∘ into Equa

tion 13, one obtains C = 0.46. Then, if one puts the

mixture of water and grains whose grain diameter is

4 mm and the volume concentration is 0.45, into a rigid

bed flume of 18 ∘ slope, one observes velocity distri

bution that fits very well to Equation 12 by giving

a i = 0.04 as shown in Figure 2. As another example,

if one supplies water onto an erodible bed saturated

by water whose slope is steeper than 15 ∘ , debris flow

develops downstream and approaches an equilibrium

state as illustrated in Figure 3. Experiment reveals that

in the equilibrium steady flow region grain concentra

tion is given by Equation 13. Thus, the dilatant fluid

model can well explain the debris flow in which inter

particle collision plays the dominant role, moreover

different from viscoplastic fluid model, it can account

for the change in solid concentration during in motion

(Takahashi 1991).

The assumption of uniform grain distribution

throughout depth is, however at least theoretically, too

much simplification, and this causes the contradic

tion that there exists two independent formulae 10 and

11 for one unknown velocity (Iverson & Denlinger Figure 3. Development of debris flow on erodible bed. Figure 4. Theoretical velocity distribution and the experimental data. 1987).To dissolve this contradiction,Takahashi (1991) assumed the following formula: Substitution of this formula into Equations 8 and 9 results in rather well fitting to Bagnold's experiment, and also the substitution of this formula into Equations 10 and 11 gives two independent formulae necessary and sufficient to obtain u and C at height z. The results of analysis using these two equations can well explain the vertical grain concentration and velocity distributions on sediment bed. The velocity distribution form is given by where u s = flow surface velocity; and Z = z/h. Equation 15 is compared with the experimental data in Figure 4. The vertical velocity distribution on erodible sediment bed (Figure 4) has a peculiar form with

two inflection points; one near the bed and the other

near the surface of flow, whereas that on rigid bed,

especially when flow contains slightly thinner con

centration than equilibrium, has simple concave form

(Figure 2) as is explained by the first approxima

tion under the assumption of uniform concentration

distribution.

3 TWO-PHASE FLUID FLOW MODEL (MIXTURE THEORY)

As mentioned earlier, how one considers the left-hand

side terms in Equations 3 and 4 can be the origin

of diverse debris flow theories. The particle disper

sive pressure due to inter-particle collision; p c , and

the static skeletal pressure due to enduring contact

between particles; p s , would be the candidates of P ds ·P f exists if the sediment mass contracts volumetrically or if there is a net flux of sediment toward the bed (Iverson 1997). Herein, only quasi-steady flow is considered, so P f = 0. The shear stress due to inter-particle collision; τ c , the shear stress due to enduring contact between particles; τ s , and the streaming stress due to migration of particles in one layer to other layer; τ k , would be the candidates of T ds . The deformation stress within interstitial fluid; τ μ , and the turbulent mixing stress; τ t , would be the candidates of T f . All such candidates cannot prevail simultaneously, but some among others prevail in a particular regime. Therefore, through the discussion of dominant stresses, debris flows can be classified.

3.1 Coulomb mixture theory (Quasi-static flow)

Iverson & Denlinger (2001) claims that the Coulomb friction term; τ s , is almost always larger than the particle collision term; τ c , stating that the Savage number, defined by Equation 16, in various field examples and the large scale experiment by USGS is smaller than 0.1 as the evidence, and they develop a Coulomb mixture theory as the one only suitable to debris flow.

The numerator of Formula 16 is, as is clear from Equation 8, the term representing the particle collision

effects, and the denominator is the term representing

effective pressure at the bottom of flow due to weight of

granular mass. They say the denominator is the grav

itational grain contact stress that produces Coulomb

friction, but it must be noted that the static gravita

tional contact stress can be transferred from the flow

surface to the bottom only when a skeletal structure

due to the enduring contact of grains extends through

out the depth. To furnish this necessity, the local solid fractions everywhere should exceed a threshold level C 3 . According to Bagnold (1966), C 3 value for natural beach sand is about 0.51. It is true that the denominator represents the effective pressure at the bottom of flow, but it is not necessarily transferred as the static gravitational contact stress. It is transferred as the collision stress when grain concentration is smaller than C 3 . If C tan θ is multiplied to the denominator, the term represents the effective pressure at the bottom precisely, but the term multiplied by C tan θ to the numerator does not represent the magnitude of collision stress. It is a i cosαλ 2 that is to be multiplied as is evident in Equation 8, and Equation 10 is nothing but to show the collision stress balances with effective pressure. Therefore, their Coulomb mixture theory is considered as a model that is suitable for very densely concentrated quasi-static flow. Herein, we do not dwell on the details of Coulomb mixture theory. 3.2 Classification of dynamic debris flows Dynamic debris flow in this section is defined as the one except for the quasi-static debris flow, in which dynamic stresses predominate in governing the behaviors of debris flow. The total shear stress τ(=T ds +T f) in a grain and water mixture is, as mentioned earlier, described as If C is larger than about 0.2, τ k becomes smaller than τ c and the difference between the two stresses tends to become drastically large as C becomes larger (Takahashi &Tsujimoto 1997). If C is smaller than 0.5, τ s is almost equal to zero (Bagnold 1966). Therefore, in a dynamic debris flow whose average concentration of coarse grains (except for the constituent making up interstitial slurry) is between 0.2 and 0.5, and if τ t /τ c and τ μ /τ c are small, τ c /τ ≈ 1 is satisfied. Debris flow in which the stress due to

the collision of particles dominates among others is called ‘stony debris flow’. On the other hand, debris flow in which τ t /τ ≈ 1 is satisfied is called ‘turbulent muddy debris flow’, and the one in which τ μ /τ ≈ 1 is satisfied is called ‘viscous debris flow’. Equation 9 and the other previous theoretical considerations on the constitutive relations of granular flows confirm (Campbell 1990) and fluid mechanics give the following forms:

where f 1 (C) and f 2 (C)= functions of C;μ= viscosity

of interstitial fluid; and l= mixing length. From these

Equations, one obtains the following formulae:

where B a (≡ σλ 1/2 d 2 p (du/dz)/μ) is called Bagnold

number and R e (≡ ρ T Uh/μ) is Reynolds number, in

which l≈ h and l(du/dz)≈U are assumed and U =

cross-sectional mean velocity.

Summarizing the above discussions, one will come

to a conclusion that dynamic debris flows occur in

the domain within the ternary diagram as shown in

Figure 5, where the three axes represent relative depth,

Bagnold number and Reynolds number, respectively.

The region where Bagnold number is large and the

relative depth is small is that for stony debris flow

occurrence. In the region where Bagnold number

and Reynolds number are small, viscous debris flow

occurs, and in the region where the relative depth and

Reynolds number are large, turbulent muddy debris

flow occurs. Thus, the areas close to the three apices

are occupied by the existence areas of stony, viscous

and muddy debris flows, respectively, and the rest of

the area in the triangle should be the area of ‘hybrid debris flows’.

Previous experiments show that if large particle’s transport concentration (Herein, the large particle is defined as the one not being suspended by turbulence, and the transport concentration is defined as the ratio of large particle discharge to the total discharge of large particles plus fluid phase including suspended sedi ment.) is smaller than about 0.2, large particles cannot disperse in the entire depth of flow. Large particle’s mixture layer appears only in the lower area of flow and the upper area is the one of plain water flow layer, small particle’s suspension flow layer or slurry flow layer. This type flow can be called ‘immature debris flow’ in contrast to ‘(mature) debris flows’ in which large particles are dispersed in the entire depth.

Thus, sediment transport phenomena can be cate gorized by the transport concentrations as plain liquid flow, individual particle transport (bed load and sus pended load; $0<C \leq 0.02$), immature debris flow ($0.02<C \leq 0.2$), debris flow ($0.2<C \leq 0.5$), quasi static debris flow ($0.5<C \leq 0.6$), and sliding of rigid earth body ($0.6<C$).The boundary C values indicated are for reference, they should depend on properties of particles such as cohesion, grain shape and the

distributions of grain sizes. Figure 5. The domain of existence of various type debris flows. Figure 6. The structure model of an inertial debris flow. 3.3 Generalized theory for inertial debris flow Debris flows that occur in the domain adjacent to the axis representing relative depth in Figure 5 are sometimes called ‘inertial debris flow’, because the inertial terms; τ c or τ t , dominate in flow.The hybrid flow in the inertial debris flow consists of the lower particle collision layer and the upper turbulent suspension layer as illustrated in Figure 6. The ratio of these two layers in flow depends on the relative depth; h/d p , and the concentration. If relative depth is small and the particle collision layer occupies the entire flow, it is a stony debris flow. If relative depth is large and the turbulent suspension layer occupies almost entire depth, it is a turbulent muddy debris flow. Herein, the theory of Takahashi & Satofuka (2002) is introduced. Consider an inertial debris flow as illustrated in Figure 6, because τ μ can be neglected, the balance of force equations in the lower layer in the direction of main flow and perpendicular to it are written as where p ′ = effective pressure transmitted directly particle to particle; and h 2 = thickness of lower layer. The

upper limit of integration of Equation 25 is h 2 , because

the particle load in the upper layer is supported by

turbulence and it is transmitted to the lower layer as

hydro-static pressure.

If solids concentration at the bottom of flow is C * ,

the dynamic pressure; p c , at the bottom must be zero

because no flow can exist at such a high concentra

tion as C * . Therefore, at the bottom all the effective

pressure; p ′ , should be borne by the static pressure; p s
.

If solid concentration decreases upward, at the height

where C becomes equal to C 3 , p s becomes zero. The

vertical distribution function of p s is not yet known,

but following function is assumed:

The relation between p s and τ s is assumed as the

following Coulomb's equation:

The balance of force equation in the upper layer is

given as following:

Takahashi & Tsujimoto (1997) gave the following

constitutive equations for dry granular flow:

where e= restitution coefficient of particles.

Turbulent mixing stress; τ t , is given by Equation 20,

where the mixing length is assumed as l= κz, in which

κ is Karman constant. Question may arise that in the

densely concentrated lower layer, mixing length would

have the scale of void between particles. Previously,

Takahashi (2000) developed a theory adopting such a

concept; l= d p /λ in the lower particle mixing layer

and l= κz in the upper turbulent layer. But, intersti

tial fluid is widespread as a continuum fluid in the

entire depth, and so the mixing length may have larger

scale than the void between particles. No matter which

mixing length is adopted, in the lower layer, τ t is far

smaller than τ c and τ s , and it little affects the velocity and the solid concentration there. However, considering the intensity of turbulence, ρ T in the lower layer is regarded as the density of interstitial fluid, whereas in the upper layer, it is regarded as that of the mixture. Substitution of these constitutive relations and Equation 26 into Equations 24 and 25 gives the velocity and the solid concentration distributions in the lower layer. In the upper layer, the substitution of Equations 20 and 29 into Equation 28 gives the velocity distribution. The

distribution of solid concentration can be obtained assuming that particles are dispersed by turbulence obeying the similar diffusion equation applicable to normal suspended load analysis. The criteria whether the upper layer exists and how high the boundary between the upper and the lower layers from the bottom of flow are as following: 1. w s /u ∗ < 1, where w s = settling velocity of particles; and u ∗ = √ gh sin θ. If this criterion is not satisfied particles are not suspended, and in this case, h 2 = h. 2. The minimum solid concentration in the lower layer appears at the upper boundary of the lower layer, above that height τ c is no more larger than τ t . The experiments for immature debris flow show that the minimum solid concentration; C lim , performed by inter-particle collision is about 0.5C ∗ (Takahashi 1991). Therefore, although it is somewhat expedient, the boundary height is set where the solid concentration calculated in the lower layer, from lower to upper direction, at first becomes equal to 0.5C ∗ . If calculated solid concentration is larger than C lim in the entire depth, even the criterion (1) is satisfied, there is no upper layer, and h 2 = h. If, at certain height, calculated solid concentration becomes smaller than C lim , but the criterion (1) is not satisfied, it is immature debris flow. Theoretical solid concentration and velocity distributions were obtained corresponding to the conditions; σ= 2.65 gcm −3 , ρ= 1.0 gcm −3 , tan φ= 0.7, e= 0.3, κ= 0.3, C ∗ = 0.65, and C 3 = 0.5. Figure 7 shows the examples of the results of calculation, where flow depth is held constant at 2 cm.When particle diameter is 7 mm, even for a steep channel slope of 18 ∘ , the condition for particle suspension is not satisfied but particles are dispersed in the entire depth due to the action of inter-particle collision, and the velocity is small. It is stony debris flow. For the same size particles, when channel slope is 6 ∘ , particles cannot be dispersed in the entire depth, and it is immature debris flow. When particle diameter is 1mm, even the channel slope is as flat as 6 ∘ , the condition for particle suspension is satisfied, and there exists the upper layer in which particles are in suspension. It is hybrid type debris flow.

Figure 7. Velocity and particle concentration distributions

by the theory.

Figure 8. Theoretical and experimental velocity distribu

tions.

Figure 8 compares the theoretically obtained velocity distributions with the experimental data of Hirano et al. (1992), where the velocity is normalized by the surface velocity; u_s. Debris flows in the experiments were generated by supplying water from upstream onto the water saturated erodible bed flume 20 cm in width and 7 m in length. Bed slope was held constant at 14°. The relative depth; h/d_p, was changed by changing both the supplying water discharge and the particle size. The theoretical as well as experimental velocity distribution curves have a tendency to lower the height of boundary between the upper and the lower layers (breakpoint on the curve) and to increase the degree of concavity as the relative depth increases. Moreover, the theoretical curves well fit to the experimental results.

Figure 9. Theoretical and experimental equilibrium transport concentrations.

Figure 9 is a comparison of the theoretical equilibrium transport concentrations; C_{tr}, with author's experimental results. In the experiments debris flows were generated by abruptly supplying water from upstream onto the water saturated erodible bed in a flume 9.9 cm in width and 10 m in length. Bed slope was changed, and the discharge of sediment plus water; Q_T, was held constant at 531 $cm^3 s^{-1}$ by trial and error. Four kinds of materials 0.201, 0.066, 0.030 and 0.017 cm in the median diameters, with densities between 2.64 and 2.66 gcm^{-3} and internal friction angles between 38.5° and 39°, were used for the erodible bed. The debris flow samples were collected with a bucket at the outlet of the flume to measure Q_T and C_{tr}. As shown in Figure 9, the theory can well explain the tendency that the smaller the particle diameter, the larger the equilibrium transport concentration becomes under a certain channel slope. This figure further shows that, in comparison with the previous discussion (Takahashi 2000), the revision of mixing length formula improves the goodness of fit to the experiments in

the views of boundary plane height between upper and lower layer and solid concentration in upper layer. In Figure 9, other than those corresponding to the experiments, the theoretical curves for d p = 1 cm and 0.5 cm are also drawn. Under the experimental conditions discussed herein, particles larger than 1 cm in diameter cannot be suspended by turbulence even for the steep channel of 15 ∘ . The reason for branching of curves corresponding to d p = 0.5 cm and 0.2 cm from the curve for d p = 1 cm is due to the beginning of suspension from the respective branching points. The theoretical curve for d p = 1 cm almost coincides with the concentration calculated by substituting tan φ= 0.8 into Takahashi's previous

equilibrium concentration formulae (Takahashi 1991);

i.e., for stony debris flow

and for immature debris flow

Equation 33 is valid only when C tr calculated by this

equation is smaller than C ∞ calculated by Equation 32.

It must be noted here that tan φ is set equal to 0.8

in the calculation of Equations 32 and 33, but in the

calculation of theoretical curves, tan φ is set equal to

0.7 (see Equation 27 and parameter values used in the

calculation).Why such a different value should be used

will become clear by the following explanation.

If particle diameter is large (d p > 1 cm), the settling

velocity of particle is given by Newton's equation, and

the criterion 1) for particle suspension is written as

If θ= 10 ∘ and (σ/ρ− 1)= 1.65 are substituted into this

equation, h/d p > 32 is obtained. This means that if the

relative depth in an inertial debris flow is smaller than

about 30, it is stony debris flow. From the condition

34 and Equation 29, Equation 21 is rewritten as the following formula:

The largest range value of the right hand side of this formula is obtained by the substitution of C = 0.2, e= 0.3, θ= 15 ∘ . σ/ρ= 2.65, and C ∗ = 0.65.The result is τ t /τ c < 0.05. Namely, in stony debris flow, the tur bulent mixing stress is at most 5% of the particle collision stress. This is the reason for a wide appli cability of single-phase dilatant fluid model in which fluid stress is neglected. Effective fluid friction being negligible, energy dissipation in stony debris flow is almost solely accomplished (because τ k is negligi bly small) by the solid interfacial friction occurring intermittently during the instant of collision.The effec tive friction angle α (the angle of encounter between two particles) for densely (C ≈ 0.5) concentrated flow should be approximately equal to φ (Bagnold 1966). If solid concentration decreases as small as about 0.2 in stony debris flow, the angle of encounter between two particles becomes larger than φ due to enlarged free distance between particles. Thus, referring to Equa tion 14, if tan φ is 0.7, the average value of tan α for stony debris flow whose grain concentration is between 0.5 and 0.2 should be about 0.8.Therefore, the equilibrium particle concentration formulae; Equations 13 and 32, are practically identical if average tan α value is used as tan φ in Equation 37. 3.4 Newtonian fluid model for viscous debris flow Quasi-steady debris flows that occur in the

domain adjacent to the axis representing Bagnold number in Figure 5 would flow in an orderly manner in which the coarse particles move nearly parallel to the bed keeping tracks within their embedded layer. Experiments (Bagnold 1954) revealed that the transition from inertia to viscous conditions occupied the range from 450 to 40 in terms of Bagnold number. In the transition range, the total shear stress would be given by and as the Bagnold number increases, grain elements; τ c + τ k , becomes surpassed the fluid element; τ μ , so it approaches stony debris flow. Contrary if Bagnold number becomes small, the dynamic grain elements diminish gradually approaching viscous debris flow. But, in viscous range, according to Bagnold's discussion, although the grain collision stress and grain streaming stress are negligibly small, the effect of grain existence remains to increase the apparent viscosity of mixture. Therefore, the total shear stress in viscous debris flow is a mixed shear stress due to the effect of fluid viscosity as modified by the presence of grains, and cannot be split into grain and fluid elements. Thus, the following formula is given: where τ μ a = viscous fluid stress due to the apparent viscosity μ a . The issues in viscous debris flow are why coarse grains heavier than the ambient fluid can be dispersed in laminar viscous flow without collisional effect, and how the apparent viscosity of mixture is estimated. Takahashi et al. (2000) proposed a new Newtonian flow model extending an investigation for neutrally buoyant particles in viscous fluid (Phillips et al. 1992). The theory considers that the particles experience encounters between adjacent shearing surface and they cause the particle flux; N c , perpendicular to the main flow direction as following: where γ = du/dz; and K c = numerical constant. The term encounter herein does not necessarily mean the interfacial contact, only an approach can cause a

squeezing flow in the interstitial fluid that moves the

particle perpendicular to the main flow, because vis

cosity of fluid is large.

If coarse particles are distributed anisotropically,

the apparent viscosity varies spatially. Because the

apparent viscosity is larger in the higher concentra

tion region than in the smaller concentration region,

the resistance to particle migration into the higher

concentration region is larger than into the thinner con

centration region. This mechanism gives rise to the

particle flux; Nμ a , as following:

where K μ a = numerical constant.

The coarse particles tend to deposit due to gravity,

and the flux is given as following:

where G(C)= hindrance function to account for

highly concentrated group settling. Here,

is assumed, where η= specific viscosity. According

to Krieger (1972), it is given as

In a steady state, these three fluxes should balance

so as to perform null particle flux perpendicular to the

main flow direction. This condition is given by

The balance of force equation in such a steady

uniform flow is given by

where ε= (σ- ρ)/ρ.

Substitution of Equation 44 into Equation 43 yields

the particle concentration distribution function; Figure 10. The theoretical distribution of the coarse particle concentrations. where F 1 =-(2/9)ε(1-C)/(K c tan θ)+C(1+ εC); F 2 = 1+ 1.82{(K μ a /K c)-1}C/C ∗ (1-C/C ∗) -1 ; and F 3 = 1- Z + ε ∫ 1 Z CdZ . Figure 10 shows two examples of solid concentration distribution calculated under the combinations of parameters; C ∗ = 0.6, C b = 0.7, ρ= 1.38 gcm -3 (ε≈ 0.9), and C ∗ = 0.72, C b = 0.70, ε= 0.77. The respective combinations of parameters correspond to the conditions in our laboratory experiment and in the Jiangjia Gully in China. For both cases K c = 0.5 and K μ a = 0.75 are adopted from the experimental results obtained by Phillips et al. (1992). The concentration at the bottom of flow; C b , is assumed a little smaller value than C ∗ ,

because substitution of C =C ∗ into Equation 45 cannot make sense. As is clear in Figure 10, when the channel slope is steep, very high solid concentration is maintained up to the surface of flow, and for the relatively mild slope channel, the high concentration abruptly decreases in the upper region. This is the case of immature viscous debris flow. The coarse particle concentration in a certain slope channel becomes large and uniform as ε becomes small. Namely, the denser the interstitial fluid, the flatter the area the debris flow of a certain solids concentration will reach. The equilibrium coarse particle concentration for a given channel slope can be obtained by integrating Equation 45. The results corresponding to the conditions used in obtaining Figure 10 are shown in Figure 11. The respective curves show the solid concentration can easily be saturated beyond a certain channel slope, and the value of saturation is, as is clear in Figure 10, approximately equal to C b . This fact suggests that, as long as flow rate is sufficient, once a saturated flow is formed in an upstream steep channel, it runs down the gradually flattening channel keeping its constant concentration until the slope becomes flatter than a critical one on which the equilibrium concentration is smaller than the saturated value and deposition commences. The velocity distribution can be obtained by solving Equation 44 under the boundary condition; at Z = 0, u ′ = 0, where u ′ = u/u ∗ . The solution cannot be obtained analytically, but provided the viscosity is approximated as constant from bottom to a height

Figure 11. Equilibrium coarse particle concentrations

versus channel slopes.

Figure 12. Schematic velocity distribution in an immature

viscous debris flow.

(Z =Z 2), it has the tendency like shown in Figure 12.

It is given by the following equation:

where X = (1+ εC)μ/μ a − 1; and C = mean particle

concentration below Z 2 .

Well mixed debris flow material in the Jiangjia

Gully except for the component larger than 10 mm was

imitated by mixing silica sand and kaolin. This mate
rial was mixed with water to make the constant solids
concentration of 0.56~ 0.57, and it was supplied onto
upstream end of experimental flume from a hopper.
The velocity distributions given by Equation 46 are
compared with the experimental data in Figure 13, in
which Z 2 = 1 and μ a = 8.1 Pa s obtained from the the
ory explained above, are used. Figure 13(1) is the case
of flow on the deposit formed by a previous debris flow
surge, and Figure 13(2) is the case of flow on rigid bed.

Flow structures in meander bends with recirculation zones: implications

for bend movements

ABSTRACT: This paper details the use of field informed numerical modelling (computational fluid dynamics

(CFD)) to investigate the time-averaged three-dimensional flow structures in natural meander bends with zones

of recirculating flow. Three bends of a small meandering river with predominantly gravel bed and pool-riffle

topography were examined. Two of the bends have inner-bank recirculation eddies (one small, one large), and

the third has a large outer-bank eddy. The model is verified and validated using acoustic Doppler velocimeter

(ADV) flow measurements taken at an intermediate flow discharge and bankfull discharge conditions are also

simulated in one bend.The geomorphological and sedimentological changes in the bends over a three-year period

are documented using repeat surveys and the construction of digital elevation models (DEM) of difference. This

investigative strategy has permitted an initial inspection of the links between flow processes and form in these

complicated meander bends.

1 INTRODUCTION

The dominant flow structure through a meander bend is

a helix, which is produced by a difference in flow force

balance at the surface and bed. Faster near-surface flow

moves towards the outer bank as the centrifugal accel

eration acting on it exceeds the centripetal acceleration

due to the associated superelevation. The opposite

holds for slower-moving near-bed flow, which there

fore moves towards the inner bank. Although this sim

ple structure dominates the flow in bends of moderate

curvature and symmetric cross section, in many situa

tions it can be complicated by a significant additional

process. This factor is flow separation and recircula

tion with the associated development of ‘dead zones’

with very low or negative downstream velocities. Flow

separation is often associated with bends of high

curvature (e.g. Leeder and Bridges, 1975; Hickin and Nanson, 1975) and can occur through reverse eddying and slowly recirculating flow at either the outer bank before the bend apex (Carey, 1969; Hickin, 1977; 1978, 1979; Woodyer et al., 1979; Andrle, 1994) or at the inner bank after the apex (Bagnold, 1960; Ippen and Drinker, 1962; Leeder and Bridges, 1975). Some bends have also been noted as having separation at both banks (e.g. Markham and Thorne, 1992; Andrle, 1994). Zones of recirculating fluid in rivers are known to be important for a number of reasons. In the shorter term, they are imperfectly mixed with the main flow and act as traps for nutrients, phytoplankton, and pollutants (e.g. Page and Nanson, 1982; Tipping et al., 1993). They also delaying solute mixing and dispersion through the reach (e.g. Guymer, 1998), form foci of deposition of fine sediment, and create distinctive ecological habitats that can act as refugia sites during higher flows (e.g. Reynolds, 2000). In the longer term, the presence of a recirculating eddy can significantly alter the patterns, directions and rates of bend movement (e.g. Hickin and Nanson, 1975; Reid, 1983; Andrle, 1994). Moreover, the development of fine sediment bars/benches and their subsequent aggradation, colonisation and incorporation into the floodplain can have a significant influence on valley floor stratigraphy (Woodyer et al., 1979; Burge and Smith, 1999), contributing to the formation of large swaths of the total floodplain (Page and Nanson, 1982; Hickin, 1986; Burge and Smith, 1999). Although a few studies have addressed aspects of the flow structure in bends with recirculation (e.g. Leeder and Bridges, 1975; Andrle (1994), Hodskinson and Ferguson (1998)), there have been no attempts at any description of the detailed 3D flow structure. This paper therefore aims to detail and explain the 3D flow structure though a bends with recirculation zones. The paper also aims to address

questions over the similarities and differences between bends with and without recirculation and ascertain whether bends with outer bank recirculation have similar flow structures to those identified in bends with inner bank recirculation. The paper also examines the changes in these bends over a 3-year period and attempts to relate the geomorphological changes.

2 STUDY SITE AND FIELD MEASUREMENTS

The natural meander bends investigated in this paper are situated on the actively meandering River Dean, which flows north-westwards off the Pennine Hills and across the glacial sediments of the Cheshire Plain, Northern England. Its bed and banks consist mainly of gravel but with sand on parts of point bars and in recirculation zones. The Dean has a well-developed pool-riffle morphology and a number of sharp bends along its course, which often exhibit both inner and outer bank separation. Bankfull discharge in the study reach is estimated at between 2.5 and 3.5 $m^3 s^{-1}$. Bankfull width in the reach is typically 4–5 m but varies from 3 to 10 m in places.

Along accessible reaches, 441 meander bends were surveyed in order to assess the frequency of flow separation (see Parsons, 2003, for full details). Of the 441 meander bends identified, 48% had a flow recircula

tion eddy which extended across the channel to at least an eighth of the bend apex width, 21% of had flow separation extending at least a quarter of the way across, and 9% had a recirculation eddy occupying more than half the width. Separation was slightly more common at the outer bank than the inner (33% against 28%) and a few bends had separation on both sides (13%).

Three of these bends were chosen for detailed study, bend 17 which has a small inner-bank separation; bend 37 which has a large inner-bank separation; and bend 25 which has a large outer-bank separation.

2.1 Field measurements

Measurements in bend 37 were made in August 1995 at a time of fairly low and almost steady discharge. The field methods are described by Hodskinson and Ferguson (1998). In brief, the topography was quantified by surveying 12 cross sections, more closely spaced in the sharpest part of the bend. Streamwise and lateral velocity components were measured at the inflow and selected other sections using an electromagnetic current meter. To help specify roughness, a bed-surface grain size distribution was measured by pebble count near the inflow. The topographic, roughness, and inflow data are used below to set up a new CFD model. However, the flow validation data are discarded because they are only 2-D and of coarser spatial and temporal resolution than we subsequently obtained in bend 17. Bend 17 and Bend 25 were investigated in Summer 2000, again at intermediate to low and almost steady discharge. Its

topography was surveyed by total station using breaks of slope to define primary features and spot heights to add detail. These data were used to construct digital elevation models (DEM). The water surface elevation at many points within the submerged area was obtained by recording the vertical angle to the intersection of the reflector rod with the water surface. The edge of the recirculation eddy was also surveyed. Size counts of 100 surface pebbles were made in 1-m 2 quadrats at several locations in the bend to help specify bed roughness. Velocity measurements were made to obtain inflow boundary conditions and spatiallydistributed validation data. The measurements were made using a Sontek™ acoustic Doppler velocity meter (ADV) mounted on a specially-made wading rod. This had an attached spirit bubble to ensure the rod was vertical, and a pair of reflectors on a crossbar which were surveyed from the total station to fix the location and orientation of the ADV probe in the same coordinate system as the DEM and CFD model (see Lane et al., 1998, for details).TheADV measures three orthogonal components of velocity at 25 Hz in a sensing volume of <1 cm 3 about 5 cm below the probe. Inflow measurements were made for 120 s at each of several heights every 0.25 m across the channel. These data were used to calculate stream discharge and interpolate the inflow velocity distribution as a boundary condition for the CFD models. Spatially-distributed test data were collected by fixing the ADV at a height and recording for 60 s at each of a number of locations 1–2 m apart throughout the bends, then doing the same with the ADV set at other set heights. This procedure does not generate vertical or lateral velocity profiles of the kind commonly used to test simulations of laboratory flows, but for our field sites and equipment it was quicker than profiling and thus allowed the collection of more data before there was a significant change in water stage (which fell by only 4 mm during the flow measurement period in bend 17). For all velocity measurements, the signal-to-noise ratio and correlation coefficient were used to check the quality of the velocity measurements. Mean velocities were computed and the series were subject to a low-pass Gaussian filter before turbulent kinetic energy (TKE) was calculated. Repeat morphological surveys were conducted in each bend throughout the study period to investigate the nature of the changes occurring within these complex bends.

2.2 Bend morphologies

Bend 17 (Fig. 1a) is a fairly sharp bend which turns

80 ◦ to the right over a centreline distance of 10 m. The

channel has a bankfull width of 5–6 m so the mean ratio of radius of curvature (R) to width (W) is about 1.4. Total relief from the left-bank floodplain to the deepest part of the pool (near the centreline and past the apex) is 1.4 m.The left, outer bank is 0.9 m high and eroding over its full length.The right, inner bank is less steep and is vegetated down to the low-flow waterline. Neither bank is uniformly curved in plan. The inner bank follows the common pattern of being sharpest at the apex, and the outer bank has a slight reverse curve opposite the apex separating two zones of fairly high curvature. Flow enters over a gravel riffle. This is highest in midstream so there are two talwegs, that on the left being deeper. The mean flow depth varied considerably around the bend, from a maximum of 0.34 m at the inflow to 0.76 m in the pool and 0.51 m at outflow from the bend.The central and outer parts of the bed are gravel throughout, with D 84 ranging from 69 mm on the riffle to 54 mm in the pool, but most of the small point bar at and beyond the apex of the inner bank is sand.

Bend 37 is a sharp right-hand bend with a deep pool towards the outer bank and a small submerged point bar (Fig. 1b). It follows a long, almost straight, riffle and leads immediately into a left-hand bend. The pool

and its eroding outer bank consist of gravel but the point bar is sand-covered. The inner bank is grassed down to the normal waterline.The outer bank is capped by overbank fines with a grass root layer. When sur veyed in 1995 bend 37 turned 130 ∘ to the right over a distance of 15 m along the outer bank and 7 m along the inner bank. These figures together with the mean channel width of 5.5 m give mean R/W ratios of 1.2 and 0.6 at the outer and inner banks. At the time the fieldwork was done the high curvature led to inner bank separation which extended most of the way to the outer bank.

Bend 25 (Fig. 1c) is a sharp right-hand bend which turns ~100 ∘ in 10 m immediately after a left-hand bend. This bend was chosen as a well-developed and representative-looking example of a bend with a large outer-bank recirculation.Within the large recirculation zone a large sandy concave-bank bench has formed.

The left-hand bend immediately upstream is fairly sharp, causing the talweg at the entrance to the bend to be under the true right-hand (inner) bank, which is undercut right to the apex of the bend.Around the inner bank apex, the bank begins to shallow and becomes a point bar towards the exit of the bend. To the left of the talweg in the entrance to the bend there is a high gravel

bar with sand drapes and grass. Bankfull width at the

bend entrance is ~8 m but flow is normally restricted

to a width of only 2–3 m in the right-bank talweg.

Downstream from the entrance, the whole bend widens 7 7 . 2 7 . 2 7 . 2 7 . 4 7 . 4 7 . 4 7 . 6 8 8 8 8 . 2 8 . 2 8 . 4 0 1 2 3 4m 0 1 2 3 4m 0 2 4 6 8m Sand Limit Cross sections Cross sections 7 . 6 Figure 1. rapidly (~10 m) with the left (outer) bank opening into

a fairly elevated backwater area. The right hand side of

the channel deepens rapidly into a central pool (~0.9 m

deep at the flow stage investigated and ~1.5 m deep

at bankfull) which extends past the bend apex, after

which the channel becomes shallower and narrower,

with an exit width~4 m normally, but upwards of 6 m

at bankfull flow when the point bar is submerged. The

outer bank is relatively high (~1.1 m), quite uniformly

curved and composed of gravel with a thin capping of

fine floodplain sediments. From the outer bank apex

onwards it is actively eroding with undercutting of the

grassy floodplain. The fastest flow in the bend follows

the inner bank and the entire central and outer part of

the pool is a recirculation zone. Bend average D 84 is

34 mm, although this varies considerably, from a D 84

of 55 mm on the upstream riffle and 78 mm in the pool to a D 84 of 0.4 mm on the concave bank bench and 0.3 mm in the elevated backwater area. The variation in both width (W) and bank radius of curvature (R c) around the bend makes it difficult to define an over all R c /W ratio. However, R c of the inner bank near the apex is<4 m and that of the outer bank right round the pool is no more than 6 m. Since the channel is ~10 m wide here, the bend R c /W value is of order 1, which is extremely low.

3 FLOW MODELLING, VERIFICATION AND VALIDATION

The CFD modeling was done using version 3.4 of the PHOENICS™ code, which solves the full 3-D Navier Stokes equations discretized over a finite-volume grid. Following Lane et al. (1999) we used a hybrid-upwind numerical interpolation scheme.This takes central dif ferences between cells where diffusion dominates but upwind differences where convection is high (Peclet number >2), so is strictly only first-order accurate, but it is more stable than higher-order schemes which can introduce spurious oscillations into solutions. As solution accuracy controls sensitivity to grid design, we undertook a rigorous grid independence tests. The pressure and momentum equations are coupled though

the SIMPLEST algorithm (Pantankar and Spalding, 1972). The solution was deemed to have converged when mass and momentum flux residuals were less than 0.1% of the inlet flux and spot values in a critical part of the domain were changing by less than 0.01%. Direct solution of the Reynolds stress terms in the Navier-Stokes equations cannot be accomplished for natural channel flows with currently-available com puter power. Here we use Reynolds averaging, and specifically the two-equation k-ε model modified by renormalization group theory (Yakhot et al., 1992), which has been the choice in most recent open channel CFD applications (Hodskinson and Ferguson, 1998; Lane et al., 1999; Nicholas and Smith, 1999; Bradbrook et al., 2000), because of its enhanced performance in areas with high rates of strain. 3.1 Computational grid A separate boundary-fitted curvilinear grid was fitted to the irregular topography of each bend by specifying a series of cross-section planes, then interpolating more planes to define a grid with specified numbers of cells in the streamwise, transverse and vertical directions. The surveyed cross-sections were used for bend 37. For bend 17 and 25, we extracted a series of cross sections from the DEM, which gave greater freedom in the position of each cross section. Rapid changes in cell aspect ratio or orientation were avoided in the interests of numerical stability. The bend 17 model used for the results and analysis had 96 cells longitudinally, 42 across, and 10 vertically. This implies average cell dimensions of ~12×~12×~6 cm at the outer bank. The bend-37 model had 80× 30× 10 cells, with mean dimensions of ~28× 18× 5 cm at the outer bank and the bend 25 model had 110 cells longitudinally, 56 across, and 10 vertically, which translates to ~28× 22× 6 cm at the outer bank apex. In all cases mean cell length decreases across the channel towards the inner bank, and cell height varies according to the local flow depth. To obtain numerical convergence, slight

modifications to each grid had to be made.This included placing vertical banks of 0.05 m near the point bars, on the upstream riffle and around the elevated bed region in bend 25, to avoid vanishing cell heights. The abruptness of the curvature of the inner bank in bend 17 and outer bank in bend 25 also had to be reduced slightly. These grids and cell dimensions were used for validation and flow structure analysis once grid resolution verification checks had been performed, the results of which are detailed below. 3.2 Boundary conditions For each model the necessary boundary conditions relate to inflow, outflow, wall treatment, and water surface. Distributions of velocity across the inflow plane were interpolated from the field measurements described above, using linear interpolation laterally and the law of the wall vertically. A hydrostatic pressure distribution was applied to cells at the outlet plane. Pressure values within the domain are calculated relative to this, so the outlet planes need to be clear of the effects of negative dynamic pressure in areas of reverse flow. Bed and bank roughness was parameterised using Launder and Spalding’s (1974) non-equilibrium version of the law of the wall in the layers of cells touching the rough boundaries. Shear further from the boundaries is modeled explicitly.A uniform roughness

height was adopted for each model, estimated from

the riffle bed grain size distribution using k s = 3.5D 84 .

This exaggerates the skin roughness of the sandy parts

of the bed, but the sand was rippled which adds some

form resistance that is not represented in the model

grid geometry. The free water surface was represented

by the method described in Bradbrook et al. (2000).

This allows for variable porosities in the surface layer

of cells so that mass continuity is maintained without

distorting the streamwise velocity.

3.3 Model assessment

Model assessment initially involved model verifica

tion followed by model validation.

Verification of the models in terms of the spatial discretization applied was performed using a grid convergence-index (GCI) analysis (Roache, 1997; Hardy et al., 2002). Two further simulations were performed with a doubling and halving of the grid resolution, permitting estimation of confidence inter vals for simulations at each resolution by comparison with simulations at other resolutions. Verification of the model solutions were performed by comparing the field ADV measurements with the predicted time average flow velocities (Ucrt, Vcrt, and Wcrt) in the DEM Cartesian directions (x, y, and z). Approxi mate 95% confidence intervals for flow properties on the medium grid, calculated by Roache's method, are mostly around ±10% (and narrower for Ucrt in bend 25 and 37), but wider for vertical velocity Wcrt and in bend 17 and bend 25. Nevertheless, for each model the results show that the original medium-resolution results were close to being grid-independent, and we therefore use them below for validation and then to describe and illustrate the flow structures.

For both bend 17 and bend 25 validation of the model solutions were performed by comparing the field ADV measurements with the predicted time average flow velocities (Ucrt, Vcrt, and Wcrt), the

resultant velocity magnitude (VelMag) and the turbu

lent kinetic energy (Tke). The simulated values were

taken from the nearest cell face in the CFD results,

reflecting the fact that in each case the grid cell size is

much larger than theADV sampling volume.Thus, due

to this scale difference the locations of point compar

isons can differ by~0.1 m in places, which can have an

un quantifiable effect on the quality of the results of the

validation exercise. The older 2-D field measurements

made in bend 37 were regarded as less reliable for

this purpose, though Hodskinson and Ferguson (1998)

found reasonable agreement with their fixed-lid CFD

simulation of that bend.

In both bend 17 and 25 the horizontal velocity com

ponent field measurements and the resultant velocity

magnitude were in close agreement with modeled

(Table 1). Agreement was less good for the vertical Table 1. Agreement between simulated (CFD) and measured (ADV) values in both bend 17 and bend 25 of the five flow variables: velocity magnitude (VelM), its horizontal components Ucrt, Vcrt in the x and y directions of the DEM, its vertical component Wcrt, and the turbulent kinetic energy (Tke). Regression slope CFD on ADV on Variable ADV CFD Correlation Bend 17 (n= 62) VelM (m s −1) 0.82 1.01 0.82 Ucrt (m s −1) 0.83 1.08 0.90 Vcrt (m s −1) 0.91 0.99 0.89 Wcrt (m s −1) 0.37 1.19 0.44 Tke (m 2 s 2) 0.40 1.06 0.43 Bend 25 (n= 40) VelM (m s −1) 1.22 0.78 0.98 Ucrt (m s −1) 1.18 0.80 0.97 Vcrt (m s −1) 1.21 0.70 0.92 Wcrt (m s −1) 0.59 0.46 0.52 Tke (m 2 s 2) 0.18 3.63 0.81

velocity component Wcrt and the Tke. Nevertheless, the prediction of Wcrt direction was generally very good. Although the CFD predictions do not always match perfectly with the measured velocity and turbulence values the

agreement is generally good, and comparable to what has been regarded as acceptable by researchers modeling flume data (Bradbrook et al., 1998; Huang et al., 2002). In view of the additional uncertainties of field data collection we therefore regard the models as adequately validated for use in discussing the flow structures present in the three bends. The validated simulations provided spatially rich information with which to identify and illustrate the flow structures present in the three bends and to investigate how the flow altered with discharge. 4 RESULTS: FLOW STRUCTURES Flow in these bends differs from standard descriptions of curvature-induced helical circulation occupying most or all of the wetted width (e.g. Dietrich, 1987). Fast downstream flow with a helical circulation is present in all three bends, but it is restricted to a freestream occupying less than half the channel width, near the opposite bank to the one with flow separation. Both velocity magnitude and strength of helical circulation decrease along this freestream, and the secondary circulation disappears before the exit of the bend. This is in contrast to the usual situation in which

the helix from one bend can extend through a straight

section into the next bend. In the bends with inner

bank separation the fastest flow is progressively below

the water surface, becoming close to the bed in the

bend with the large recirculation eddy.The locations of

maximum attack on the banks imply different patterns

of bank erosion and bend migration than in ordinary

meanders without flow separation.

Inner-bank separation occurs near the point of

maximum curvature of the bankline (Fig. 2), with

reattachment within a downstream distance of one

channel width. Outer-bank separation occurs where

an inflow near the inner bank crosses the channel at

a sharp bend and impinges near-orthogonally on the

outer bank (Fig. 2). In both cases the recirculation eddy is similar to what occurs in a sudden expansion. It has a near-vertical axis and the strongest reverse flow is close to the bank. Recirculation extends fur ther across the channel at the surface than the bed, because of the different orientations of near-surface and near-bed velocity in the freestream of downstream flow. The bankfull simulation showed only a small reduction in size of the recirculation eddy despite a doubling of mean velocity, and the reverse flow was stronger.

The presence of these large separation zones has a number of significant implications, including controls on the nature and dynamics of fine sediment movement through the river reaches and the residence times and progression of pollutants within and through the sys tem. Moreover, large separation zones also have the potential to alter expected bend movements and future migration patterns. The model results demonstrated that several aspects of the flow structure differed sub stantially to the flow structure found in more classical meander bends: as the downstream flow is steered around the inner bank recirculation zone, the stream wise helix is confined to the outer bank region and is only present in the upstream part of the bend. This

is dissipated through vortex stretching as the flow expands beyond the downstream limit of separation. The maximum near bank velocities were found at the outer bank upstream of the bend apex and the region of reverse flow extended further across the channel at the surface than the bed. It was also discovered that secondary circulation exists within the inner bank recirculation eddy, linked with the freestream outer bank flow through a double hairpin loop motion. This was constructed by flow moving inwards and downwards distally into the recir culation but outwards and upwards proximally where flow is re-entrained into the freestream helical motion. But there is also strong shear between the downstream flow and recirculation eddy, and our field observations showed that Kelvin-Helmholz vortices are shed from the shear layer. These may also constitute a main part of the mixing mechanism in reality. Z Z Figure 2. Simulated surface flow velocity magnitude (contours) with direction (unit sizes vectors). For bend 17 (top) and bed 25 (bottom). 5 RESULTS: BEND MOVEMENTS During the study period both bend 17 and bend 37 have significantly eroded their outer banks (Fig. 3), whilst maintaining the inner bank separation. This bank erosion has been particularly concentrated before the bend apex, resulting in a movement migrating across the floodplain.This is slightly different to what is expected in more classical bends where rates are generally a little lower and the main point of attack on the bank is after the bend apex. Morphological change in bend 25 has also been significant (Fig. 4).A large part of the inner bank has been eroded, as has the outer bank well downstream of the 96 98 100 102 104 106 96 98 100 102 104 106 96 98 100 102 104 106 0.200 -0.200 -0.600 -0.1000

outer bank apex. This has resulted in the opposite to what generally thought to occur in more classical type meander bends. The concave bank bench has grown both in spatial extent and in altitude. These changes suggest a movement away from, and the slow abandonment, of the bank bench. Nevertheless, the high curvature of the inner bankline has remained, and the large separation zone has remained present.

6 CONCLUSIONS

This paper has demonstrated that the flow structures in bends with recirculation zones are significantly different from those traditionally found in more classical, lower curvature, meanders. Bends with separation zones are dominated by the effects of the recirculation and the acceleration of the helical motion in the freestream flow, which in turn produces a zone of high shear between the freestream and the recirculating fluid. This flow structure has a number of implications including altering the rates and directions

of bend movements. In the bends investigated in this paper, bends with inner-bank separation have rapidly eroded their outer bank before the apex while the bend with an outer bank separation has significantly eroded its inner bank.

ACKNOWLEDGEMENTS

D.R. Parsons was in receipt of a UK Natural Environment Research Council studentship, which was tied to grant GR3/9715 awarded to S.N Lane and R.I Ferguson. We also thank the local farmer (Mr Williams) for access to the field site; Richard Smith and Simon Tait of the Department of Civil Engineering, Sheffield University, for assistance in constructing the ADV wading rod; Ben Surridge, Louise Sime, Barry Hankin, and David Mould for assistance with fieldwork.

ABSTRACT: The effects of geometrical constraints on downstream river evolution are numerically investigated

focusing on the Ikeda et al. (1981) model in this work. Despite its simplicity, this model takes spatial memory

effects into account, thus allowing for the description of some basic mechanisms typical of real meander,

appropriately. Moreover, the whole dynamics can be reduced to the study of three governing parameters: the

Parker number Pa, the decay length D and the basic time scale T . The results obtained by spanning a reasonable

range of the parameters D, and Pa, and the relative investigation of bounded river reaches of different shapes and

length, lead to some interesting observations and first

conclusions. These regard the possibility of understanding and potentially quantifying the future changes that occur downstream of the bounded reach as well as providing some useful suggestions on how to control them.

1 INTRODUCTION

Meandering rivers are natural systems in continuous evolution and have long been studied from both an observational and theoretical point of view (e.g. Leopold & Wolman 1960, Allen 1965, Engelund & Skovgaard 1973, Callander 1978, Ikeda et al. 1981, Blondeaux & Seminara 1985, Johannesson & Parker 1989, Lewin 1992, Anderson et al. 1996, Sun et al. 1996, Zolezzi & Seminara 2001, Lancaster & Bras 2003). Important studies in the past, both geomorphological (e.g., Friedkin 1945, Nanson & Hickin 1983, Furbish 1988, Church 1992, Lewin 1992, Whiting & Dietrich 1993) and fluid mechanical (see, for example Ikeda et al. 1981, Blondeaux & Seminara 1985, Johannesson & Parker 1989) have explained the fundamental dynamics of the phenomenon. Such studies thus furnished the basic understanding for other significant theoretical and numerical steps ahead more recently achieved in the description of either short or the long-term behaviour (Liverpool & Edwards 1995, Sun et al. 1996, Zolezzi & Seminara 2001, Edwards & Smith 2002). The picture that arose is that the

dynamics of such rivers is intrinsically unstable and

complex. Whether at one hand such characteristics

attract more speculative studies, on the other hand

the way the planimetric evolution of such river occurs

is an interesting issue also for engineering purposes

(Henriquez et al. 1990, Swanson 1993). For instance, the hydraulic studies can be motivated from the need to investigate the influence of riparian vegetation on bank stability (Millar 2000) or to understand the effects of anthropic modifications. This is the case of meandering rivers whose planimetric evolution may cause erosion of zones where infrastructures are present. Protection of such areas may require the construction of embankments that constrain even long reaches of river and thus limit its morphodynamic evolution. It has been proved, to this regard (see, for example Ikeda et al. 1981, Johannesson & Parker 1989, Zolezzi & Seminara 2001), that planimetric evolution is influenced by both local and neighbour river geometries. In particular, upstream geometry acts on local river dynamics as a fading spatial memory. Rather interesting and relevant to our purposes is, therefore, to show the way the evolution of upstream geometries can influence that of points located downstream. Similarly, the question can also be addressed to understand how these memory effects propagate downstream and eventually whether they can be controlled by geometrically conditioning a given reach of river. The effects of geometrical constraints on downstream river evolution are therefore numerically investigated in this work using the model proposed by Ikeda et al. (1981). Even if at present these results are mainly qualitatively discussed, they allow to infer some interesting considerations related to the possible effects induced by the construction of river

embankments on the evolution of the reach located

downstream of the bound. In particular, these consid

erations regard the influence of the constraint length

and shape, as well as the importance that the spatial

memory assumes, depending on the hydraulics and

pedological characteristics.

2 MODELLING

All the theoretical studies made up to explain the mean dering dynamics start by assuming as generally valid two results that were obtained from the observations made by geomorphologists in the past. These are: (i) the width of the channel tends to remain constant in time thanks to a balancing mechanism of both ero sion at the outer bank and simultaneous deposition at the inner bank; (ii) the erosion at the bank is pro portional to the exceeding (with respect to the mean velocity of the uniform flow U 0) bank velocity u sb by a characteristic coefficient of bank erosion E. Among the most important models of meandering (see, Ikeda et al. 1981, Johannesson & Parker 1989, Zolezzi & Seminara 2001), the pioneering model proposed by Ikeda et al. (1981) has been used. In the next subsec tion it will therefore be recalled and, in light of some recent developments (Edwards & Smith 2002), also discussed.

2.1 The Ikeda-Parker-Sawaj model

This model employs the de SaintVenant equations for a shallow steady incompressible turbulent flow in a sin uous channel. In this model the effects of secondary currents on bedload transport are considered assuming

a semi-theoretical relationship between the bed topog

raphy and the local river curvature.The exceeding bank

velocity u sb can be readily obtained from a linearized

form of the shallow water equations. At constant time,

the u sb satisfies the following differential equation (see

also Sun et al. 1996):

where s is the intrinsic downstream coordinate along

the river axes (Figure 1), b is the half-width of the

channel, C f is a dimensionless friction factor, H the

water depth of the uniform flow, k the local curva

ture of the river centreline, F the Froude number and

the constants A ′ and A s account for the erosion on

a bed slope (erosion factor) and for the convective

transport of downstream momentum, respectively (see

also Johannesson & Parker 1989). The erosion factor

A ′ is a positive constant and literature has provided

evidence that it can vary in the range 2–10 (see, for x y s
n Figure 1. Sketch of the numerical procedure used here to simulate the evolution of meandering patterns. (—) Current pattern; (-) one temporal step later. example Engelund 1974, Hooke 1965, Suga 1963). More recently Edwards & Smith (2002) showed that Equation 1 can be rewritten in a more useful form by introducing the following three parameters: so that it reads where v=Eu sb is the equation assumed for the bank erosion. In this way, the abovementioned quantities D, T and Pa appear to be the effective scaling factors that summarize the hydraulic characteristics of the river provided the current river sinuosity is used to continuously update the hydraulics motion conditions. The decay length D is related to the basic scale of the meander wavelength and corresponds to the distance between the inflection points of the channel and the points where the migration rate vanishes (meander nodes).The Parker number Pa is a dimensionless quantity which measures the strength

of secondary flow relative to the shear in downstream velocity due to the outward hydrostatic head gradient (i.e., the Bernoulli shear). The time T accounts for local soil properties and motion conditions. T and D therefore describe the natural sinuosity-dependent time and length scales of the process, respectively. For a given configuration of meandering river, the contribution of Pa can be considered being roughly constant in time, thus reducing the controlling parameters of the process to only D and T (Edwards & Smith 2002). Equation 2 can be easily integrated to obtain, at a sufficient distance

downstream the origin (see, also Sun et al. 1996),

This equation shows that erosion velocity at a point

depends on the local geometry and on another term

that accounts for the geometry upstream. Therefore,

despite its simplicity, the Ikeda et al. model takes

spatial memory effects into account and this allows

(see, Ikeda et al. 1981, Sun et al. 1996, Edwards &

Smith 2002) to appropriately reproducing some basic

mechanisms typical of real meanders (e.g. wavelength

selection, downstream migration, meander fattening

and upstream skewing).

2.2 Numerical implementation

The numerical model has been implemented assum

ing the river behaves as a planar curve that moves onto

a sloping plane {x, y} by a normal-to-the-curvature

driven instability (see, for example Perona et al. 2002).

This latter is obtained by integrating the Ikeda et al.

(1981) model over the current river shape. This fur

nishes the value of the exceeding bank velocity for all

the points of the river and, then, once it is multiplied for spatial soil erodibility E, the corresponding ero sion velocity. Being the simulations mainly devoted to investigate the short-term behaviour of a given reach downstream of the constraint, it is reasonable to assume that the local soil erodibility is both temporally and spatially constant. In particular, the parameters of the sedimentary environment, i.e. the valley length and width (10000 m and 6000 m, respectively) and the coefficient of erodibility E (1.85 · 10 −8) have been chosen equally for all the simulations presented in this work. The numerical scheme that has been adopted here (see Figure 1) is similar to that already proposed by Sun et al. (1996) (see also Howard 1996), except for the fact that, at each temporal step and according to the current river sinuosity, we update both the bed slope and the steady hydraulics quantities. The points of the river centreline are sampled at a distance equal to b/2 and moves at temporal steps of 5 days. Each point, in particular, is then moved in two times, i.e. following a procedure that allows to consider the vari ations that will occur in the exceeding bank velocity u sb while the curve is moving between the current and the next configuration. Moreover, at each temporal step, the whole curve is re-sampled at the abovementioned

spatial interval in order to reduce as much as possible

numerical instabilities. This allows avoiding the pres

ence of points where the local curvature would increase

too much. An example is that of cutoff events. These

are always rather delicate to consider and there is the

risk that numerical instabilities can occur. To our pur

poses this problem is not relevant here, however it has
Figure 2. Example of constrained reach. The bound has been simulated by imposing zero erodibility to the cells along the river centreline. equally been dealt with by applying a suitable numerical procedure, the details of which will be reported elsewhere (Camporeale et al. 2004). 2.3 Schemes of constraints In order to simulate a suitable constraint scheme we overlapped a grid of square cells (size, 25 m× 25 m) to the river. Each of them account for possible variations in the spatial erodibility; in this way, the presence of a constraint has been described by simply setting to zero the erodibility value of the corresponding cells located along the river centreline. It must be said here that little adjustments of the point of the river usually occur during the re-sampling process. This fact, therefore, can induce those points of the river that lie close to the corners of a bounding cell to shift toward a nearer cell, thus becoming actually unbounded. This risk was avoided at occurrence by extending the value of zero erodibility also to some other adjacent cells (see, for example the sketch shown in Figure 2). Several simulations were done on different schemes of constraint in order to perform the following analysis. First of all, the effects of the constraint length as well as of the geometrical form of the bounded reach were studied. Then an investigation of the influence of the decay length D (i.e. of the hydraulics parameters such, for example, the friction factor, the base flow, etc.) and of the Parker number Pa was also carried out for a fixed constraint scheme. 3 RESULTS AND DISCUSSIONS In order to quantify at a given time of evolution the actual differences among the free and the constrained configurations, the maximum shifting of both the x and y coordinate was measured (Figure 3). After N years of evolution these quantities are a measure of the effects caused by constraints.

The validity of the results obtained from such mea

surements, however, is not easy to generalize because

of the presence of the convolution integral of Equa

tion 3, i.e. of the fading memory resulting from the

shape of the river. To our purposes, however, the

afore-mentioned quantities provided at least a global

picture that allows for formulating some qualitative

considerations below explained.

3.1 Influence of the constraints shape

Figure 4 show the effect of the shape of the con

strained reach for equal hydraulics simulation con

ditions (Q= 325 m 3 /s; C f = 0.0036; b= 35 m; bed

slope= 0.002; A ′ = 10). In both cases, the length of the

constraint was chosen to be equal to 1400 m, approxi

mately. The main difference between the two adopted

configurations is that for the case of Figure 4b the

Figure 3. Shifting in cartesian coordinates x and y

among the free (-) and the bounded (—) configurations.

Figure 4. Influence of the shape of the constrained reach. (a) Embankments built along a river that include a rectilinear

reach do not seem to produce substantial differences in planimetric evolution of the constrained reach (—) when compared to

that (-) of the free configuration. The contrary is evident in (b), where after the same period of evolution (400 ys), the two

configurations look significantly different. constraint has been imaged to limit a river that does not contain any significant straight reaches. The case of Figure 4a, on the contrary, shows a relatively long rectilinear reach just

before the bend where the constraint ends. Being that the spatial memory is calculated as in Equation 3, it is therefore expected that the geometry of the river of Figure 4b will give rise to significant differences in the future planimetric developments if compared to those of Figure 4a. The simulation indeed predicts an evolution of the reaches downstream the constraint that is strongly different. For the first case (Figure 4a), in particular, the river with the constraint does not present significant deviation of its evolution when compared with that of the unbounded river. To this regard, it can be noted that the cutoff event showed in Figure 4a occurred nearly at both the same point and time. This result contrasts quite evidently with that obtained in the case of Figure 4b and the difference is mainly due to the relatively less influent effect of the spatial memory, when calculated over reaches that contain long straight reaches. 3.2 Influence of the constraint length Along with the results presented in the previous paragraph, it is now expected that the length of the constraint can itself influencing the river evolution. This has been investigated by doing 14 simulations over a river that does not show evident straight reaches. The constraint length was gradually augmented in the range 0–1400 m, after each simulation. All the hydraulics parameters were maintained constantly equal to those mentioned in paragraph 3.1. Results are summarized in Figure 5 that show the magnitude of the shifting measured along the x and the y coordinates between the

free and the constrained river at several years of simu

lation.Within the evolution time of 400 years, a general

asymptotic behaviour with respect to the length of the

constraint can be noted for both the coordinate x and y.

In particular, over a constraint length of about 400 m,

the simulation gave rise to approximately the same

difference in the pattern downstream. As the length

of the constraint increased, a general increase in the

longitudinal migration velocity and a corresponding

reduction of the transversal one of the point located

downstream the bound was also observed.

3.3 Influence of decay length and Parker number

Given a river of assigned geometry (e.g., width b) and pedological characteristics (e.g., erodibility E), then Equation 3 shows that the evolution should depend on two parameters that are the decay length D and the Parker number Pa. However, since the contribu tion of the convolution integral also depends on the river shape, the two above-mentioned quantities are not sufficient to generalize the results for all possible river configurations. Notwithstanding this, some clues on the role of the two aforementioned parameters D and Pa can be given once a fluvial geometry has been fixed. For the case studied here and shown in Figure 6, the decay length D was varied within the three values 140, 220, 350 m which correspond to the approxi mate distances downstream 430, 580, 1050 m. These values are related either to the distance downstream after which the influence of the bound is negligi ble within the observation period, or to the length of the upstream geometry beyond which the convolution integral does not show significant variations. Figure 6, in particular, shows the result of a simulation obtained with a value D= 430 m. The corresponding maximum shifting downstream between the free and the bounded

Figure 5. Shifting of the point of the river along the (a)

x and (b) y coordinates for different constraint length and at several

years of simulation. configuration is represented in Figure 7. From these diagrams it is interesting to note that within the investigated range of D the river behaviour may even change completely, thus indicating the important significance attributed to such a parameter. The influence of the Parker number was evaluated by varying it in such a way that the decay length remained constant. This was possible, in particular, by varying the term A ′ among the values 2, 4, 10, i.e. within the reasonable range that has also been recognized in literature. At constant hydraulics conditions of motion (F = 0.75; H = 1.6 m; U 0 = 3 m/s), this allowed to obtain a reasonable variation of the Parker number among the values 1.8, 2.4, 5.4, respectively. As shown in Figure 8, the effect of the Parker number appears to condition more the shifting of the y Figure 6. Case study to investigate the influence of the decay length and the Parker number. The constraint length is 1400 m.

Figure 7. Effect of the decay length on the planimetric developments of the river constrained by the configuration scheme

of Figure 6; maximum shifting of (a) the x and (b) the y coordinates, relative to those of the free configuration.

Figure 8. Effect of the Parker number on the planimetric developments of the river constrained by the configuration scheme

of Figure 6; maximum shifting of (a) the x and (b) the y coordinates, relative to those of the free configuration.

coordinate than that of the x one. Further analyses that

are currently under investigation would seem to asso

ciate the reason for such an effect with a contrasting

behaviour shown by the transversal and longitudinal

migration velocities.

The results so far presented show that changes in

the constructive aspect of fluvial embankments might

produce even marked differences in the downstream

river behaviour. This aspect underlines the importance

of considering such infrastructures as useful under

multiple points of view that could go beyond the

local protection of a given reach of river. An inter

esting applicative example, for instance, can be that

of employing an adequate constrain design to actu

ally either anticipate or postpone those cutoff events

whose natural occurrence might compromise impor

tant benefits deriving from fluvial utilization (e.g.

navigation, irrigation, etc). Given the general charac

ter of the present investigation, all the aforementioned aspects are furthermore emphasized. They can be useful in fact to further motivate studies on river re-naturalization and vegetation dynamics, the importance of which ranges from purely speculative interests up to a better understanding of the role and importance of the riparian vegetation for the whole hydraulics ecosystem. 4 CONCLUSIONS A note concerning the numerical investigation on the effects related to the presence of embankments on river evolution has been discussed in this work. The meandering process has been simulated by means of the basic model of Ikeda et al. (1981) that proven to be useful to both focus and explain some basic mechanisms. A first conclusion is that whenever the construction of an embankment is required, then even significant

changes in the future planimetric developments of

the bounded river can occur if the evolution is com

pared with that obtained without constraints. This is

expected, in particular, for those cases where the con

straint is built along a portion of river mostly sinuous

and lacking of rectilinear reaches. Secondly, for equal

geometrical river configurations and hydraulics con

ditions, the differences in future behaviour depend on the length of the constraint. These results, therefore, underline the importance of a correct definition of such anthropic infrastructures. Furthermore, the influence of the decay length, together with that of the Parker number, improves the knowledge on the role of the effective variables that are involved in the study and provides thus, an interesting starting points for future investigations and further refinements. An example is the possibility of controlling the meandering process either by adopting a suitable constraint scheme or by changing the hydraulics parameters of the interested reaches.

ACKNOWLEDGEMENTS

We wish to thank L. Ridolfi for the interesting discus sions and suggestions and R. Coni for having run the simulations.

Behaviour of small perturbations in 1D mobile-bed models

G. Rosatti, L. Fraccarollo & A. Armanini

CUDAM Center for Advanced Studies on Hydrological Risk in Mountain Areas Dipartimento di Ingegneria Civile

ed Ambientale, Trento

ABSTRACT: The problem of evolution of a single perturbation in a 1D free-surface flow over mobile-bed

is studied theoretically. The proposed method, based essentially on the integration of the canonical form of the

primitive variable system, has been tested against numerical solutions. Moreover, it has been exploited to gain

insight in the mechanism of small perturbation generation.

1 INTRODUCTION

The analysis of the evolution of a small perturbation

in a 1D mobile-bed model is a topic that can help to go into several physical, mathematical and numerical aspects. In particular, this analysis allows to substantiate the use of simplifications or manipulations of the mathematical models, in order to make it easier to find out possible solutions. Furthermore, in numerical models it helps to understand which are the most convenient boundary-conditions to be assigned.

The definition of the problem is very simple: what happen in a channel if the surface elevation, for instance, is locally perturbed? Despite its simplicity the solution is not trivial at all. In fact, this question hides many other ones: how many waves will be generated and which are their speeds of propagation? Do the different physical quantities show an in-phase perturbations or not, and which is the ratio among their amplitudes? Which information actually travels along each wave and how it depends on Froude number?

In this paper we propose a general, simplified approach to obtain the number, the speeds, the signs and the integral amplitudes of the perturbations that are generated by a given initial point-perturbation of the physical variables. This method is essentially based on the integration, along approximated linear wave paths, of the canonical forms of the system of

equations. In such a way a linearized solution of the

problem is looked for, which, nonetheless, keeps fully

the hyperbolic features of the evolving phenomenon.

Compared to the traditional perturbation method, the

present scheme is definitely more simple and more

evident as far as the physical interpretation concerns.

In section 2 it is presented the outline of the method

which leads to a system of equations for the amplitudes of the perturbations. In section 3 the proposed methodology has been applied to a rather complete 1D system of equations that have been obtained applying the conservation of mass and momentum for a two phases fluid. In section 4 analytical results have been compared with the ones obtained by a highly accurate numerical model. In section 5 the analytical result of a classical simplified 1D model has been compared with the corresponding ones coming out from the complete model. Conclusions are presented in section 6. 2 OUTLINE OF THE METHOD The quasi-linear system of equations of a generic 1D mobile-bed model can be written, in compact form, in the following way: where W is the vector of primitive variables, B(W), A(W) are the Jacobian matrixes of the model equations and S(W) is the source term vector. In order to make the notation easier, from now on the dependence on W will not be indicated. The system of equations here considered is strictly hyperbolic, therefore it has real and distinct eigenvalues which can be arranged in descending order: where the integer n represents the number of equations in the model. To catch up the goal of this work, it is necessary to make some hypotheses, which help to clarify

and understand the dynamics of the flow after an

appearing disturbance. It is assumed that there is a

uniform basic flow W =W . The initial perturbation

consists of a small (limited in amplitude and exten

sion) perturbation of any of the primitive variables.

This initial perturbation provokes n propagating waves

which involve all the physical quantities of interest.

Moreover we assume that the path of any generated

wave in the (x, t) domain is represented by a single

straight line.

The method can be summarized in the following

steps:

1. analysis of the eigenvalues of the system (1);

2. rewriting of system (1) in canonical form;

3. integration of the canonical form equations along

the characteristic paths;

4. calculation of the wave amplitudes.

In the following paragraphs the details of these steps

are presented.

2.1 Canonical form of the equations system

The eigenvalues λ i of the system are determined by

the roots of the characteristic polynomial that can be

obtained from the following equation:

where | · | denotes the determinant of a matrix andA,B

are the matrices of eq. (1). The canonical form (Toro

1999) can be obtained by means of the left eigenvec

tors T i (corresponding to λ i), that are defined by the

following equations:

Multiplying eq. (1) for each eigenvector it is possible

to obtain the normal form of the system:

Then, it is possible to manipulate the equations in order

to obtain a new form in which the physical meaning

becomes more evident. Using eq. (4), the system (5)

can be rewritten as:

which can be cast in the following form: where If the terms are considered constant, each equation is a weighted sum of rates of change of the primitive variables along different paths in the space-time domain (characteristic curves) defined by the equations and this sum balances the source term. Under the previous assumptions, the characteristic curves are families of straights lines along which information travels: given a generic point P(x, t), it is possible to draw the outgoing characteristics along which information regarding the point propagate forward in time and space (domain of dependence, Fig. 1). Along each characteristics λ i , variations of all the primitive variables occur, but their relative magnitude is essentially determined by the weight (TB) i k . It may comes out that one of them is much larger than the others: in that case the relevant physical quantity is dominant along the i-th characteristic line. On the other hand, it is possible to draw also the characteristics that reach point P(x, t): variables here depend on the informations travelling along these lines, which fold the domain of influence (Fig. 1). 2.2 The system of equations for the amplitudes The system of equations for the amplitude of the perturbations can be obtained integrating equations (7) Figure 1. Domain of influence and range of dependence for a generic point P(x, t).

along the characteristic lines. Let’s assume, without

loosing in generality, that our problem presents three

characteristic lines: in a space-time plane, with origin

in the place and time where the perturbation is applied,

it is possible to draw three straight lines, starting from

the origin point and with slope equal to 1/λ i : these rep

resent the space-time paths of the three waves that the

initial perturbation generates (Fig. 2).

If we chose a generic time t 1 , the intersections of

the line t= t 1 with the three characteristic lines give

the positions of the waves at that time. Focusing the

attention, for example, on the intersection with λ 3 , it

is possible to integrate along the λ 3 characteristic, the

respective equation of system (7) between t= 0 and

t= t 1 :

Under the assumptions above described, this

becomes:

where W k + k is the value of the k-th variable in

the origin point, i.e. the constant value plus the ini

tial perturbation, and W k + δ k is the value of the k-th

Figure 2. (a) Paths, in the space-time plane, of the waves

generated by an initial perturbation of the water level as
rep

resented in (b); (c) position, in the physical plane, of the

perturbations at time t= t 1 . variable in the point P 3 , i.e. the constant value plus the perturbed situation at time t 1 . Integration leads to: Now, it is possible to write two more equations, similar to equation (13) considering the other characteristic lines (belonging to the λ 1 , λ 2 families) that arrives in P 3 (Fig. 3): It is reminded that W is the basic uniform flow. Equations (13-14) form a linear system that gives the values of the perturbed variables in position the P 3 (Fig. 3). The same procedure can be applied to obtain the values of the wave amplitudes at points P 1 and P 2 . If the source term S in eq. (1) is null or negligible, the system of equations gives a solution that is time-independent. 3 APPLICATION TO A FULLY-COUPLED 1D MOBILE-BED MATHEMATICAL MODEL The proposed method has been applied to the 1D mobile-bed model described in the following. The model is characterized by a two-phase approach with no slip between the velocities of sediments and water. It is defined by the equations of conservation of liquid mass, solid mass and momentum Figure 3. Integration paths, in the space-time plane, used to obtain the amplitude relations valid along λ 3 .

(Fraccarollo & Capart, 2002):

where h is the water depth, u is the depth-averaged velocity, z b is the bed surface elevation, c is the depth-average concentration of sediments, c b is the concentration of sediments in the bed, β is a trans port parameter, = (ρ s − ρ)/ρ is the relative density of sediments and τ is the bottom stress. The concen tration c can be related to u and h by any sediment transport formula. In the following, a simplified power law formula has been adopted:

3.1 Application of the method in case of plane bed and inviscid fluid

In order to simplify the calculation, the proposed method has been applied to a specific case of plane bed and inviscid fluid. With these hypotheses, the source term S is null and the integration along the character istics easier. Nevertheless, as shown previously, these assumption are not necessary to obtain the amplitude relations.

In compact form, the Jacobian matrixes of system (15) are:

where ω= 0.5 βc b g+ 1, κ=βc b u 2 .

The characteristic polynomial (eq. 3) for the present case can be written as: where the coefficients are functions of the physical variables. Explicit expressions for them can be found in Rosatti & Fraccarollo (2002). It is well known that eq. (20) presents two positive and one

negative solutions for each value of the Froude number (Morris & Williams 1996) i.e.: It is possible to obtain the eigenvalues of the problem as a function of the actual value of λ i : where ϑ= κ/u 2 . Inserting eq. (22) in (13-14) one can obtain in explicit form the values of the amplitude as a function of the eigenvalues λ i and the flow parameters u, h,β, c b ,ϑ. Their detailed expression is omitted for shortness. Actual values of the amplitude of the perturbations can be easily evaluated once the flow parameters have been fixed. Setting β= 8.16× 10 −4 , ϑ= 1.65 and c b = 0.65, representative values for sand and gravelbed rivers, the plot of the dimensionless amplitudes as a function of Froude number is the one shown in Figure 4. It can be noticed that the sum of the dimensionless amplitude of the three water-depth waves (δ i h /ϑ) is always 1, i.e. is equal to the initial value. As the Froude number change, the distribution of the initial amplitude along the three waves changes: for Fr→ 0, it is almost equally divided along two waves corresponding to those of the rigid-bed case. For high Froude numbers, the amplitudes along the negative wave λ 3 become negligible while the initial perturbation affects mainly the slower wave λ 2 . As far as the bottom perturbation concerns, the sum of the three amplitudes does not give the initial value (i.e. zero) but it shows a maximum for Froude number slightly smaller than 1 (Fig. 5). This means that the initial water depth perturbation causes essentially a deposition wave on the bottom, the amount of which depends on the Froude number. Moreover, the amplitude of the bottom wave, travelling with the faster wave λ 1 , change its sign for high Froude number, while in the other two cases the sign remains constant. The maximum deposit travels backward while the maximum scour travels forward with λ 2 . These considerations confirm, for high Froude numbers, the result of de Vries (1995) i.e. that it is possible to associate the hydrodynamic perturbation

Figure 4. Dimensionless amplitude of water depth h and bottom elevation z versus Froude number of the unperturbed

condition along each wave; flow parameters are β= 8.16× 10 −4 ,ϑ= 1.65 and c b = 0.65. Apexes refer to the three points P

of Figure 3.

Figure 5. Algebraic sum of bottom dimensionless ampli

tudes versus Froude number.

to the positive waves λ 1 , λ 2 while the bottom variation

is essentially associated with the negative wave λ 3 .

For low Froude numbers, comparison with de Vries's

results is not so straightforward because of the assump

tion of horizontal bed that we have assumed. De Vries

obtained this result by means of consideration on the

order of magnitude of the terms in the expression for

λ i , but he did not achieve anything about the sign

of the perturbations. The proposed approach, instead,

extends those results and explains them in term of

amplitudes of perturbations. 4 COMPARISON WITH A HIGH RESOLUTION NUMERICAL MODEL In order to verify the reliability of the proposed method, despite the simplifications, we have compared the theoretical results with the ones obtained with an highly accurate numerical model whose details can be found in Fraccarollo et al. (in prep.). The numerical model is able to solve system (15a-c) without the simplifying hypothesis assumed in the analytical model and therefore we expect that, from an initial perturbation, waves with finite wavelength would take place. Since the analytical model assume that each wave has small amplitude and wavelength, we expect that analytical results may approximate the integral of the amplitude over the wavelength and not the actual maximum amplitude. The numerical model was applied under the same conditions above described for the theoretical study, i.e. flat, horizontal bed and no bottom stress.The initial perturbation was placed in the origin of the physical plane, regarded only the water depth and spanned over a single computational cell of length x. Its non-dimensional amplitude was assigned to be: In Figures 6 and 7 the results obtained in a subcritical (Fr= 0.65) and in a supercritical (Fr= 1.42) case -10 -5 0 5 10 15 20

respectively are shown. For the case with Fr= 0.65,

Table 1 shows the comparison between the analyti

cal amplitudes and the integral value of the numerical

amplitudes, evaluated by means of:

where L k is the wavelength of the k-th perturbation.

Analogous result has been obtained for the supercriti

cal case.

Comparison shows a good agreement and this

means that, despite the simplifications, the analyti

cal model is able to catch the main features of the

complete nonlinear phenomenon. In particular the pro

posed model is able to give the correct sign of the

perturbation amplitudes and gives an useful insight on
Table 1. Analytical and numerical values of the total amplitude in the case of Fr= 0.64. Analytical Numerical δ 1 h 0.502 0.504 δ 2 h 0.197 0.196 δ 3 h 0.299 0.301 δ 1 z −1.915× 10 −2 −1.914× 10 −2 δ 2 z −0.109 −0.108 δ 3 z 0.127 0.127 the relative importance of the primitive variables along each perturbations in different flow situations. 5 APPLICATION TO A 1D SIMPLIFIED MODEL The proposed method has been applied to the classical 1D model that can be obtained adding the Exner equation to the equations for the water in order to verify to what extent this simplified model is able to show the features of a more complete one. In compact form, the system of equation can be written as follows: where and The normal form of the equations, in the case of horizontal flat bed, can be written as (Armanini 1999): and the equations for the amplitudes can be obtained straightforwardly following the proposed method. In particular, the equations for the λ 1 wave amplitudes

becomes:

where:

It is easy to verify that, for Fr< 2,

i.e. the bottom perturbation changes the sign if com

pared to what obtained by the more complete model

(see in Fig. 4).

This result informs that the use of simplified models

sometimes may lead not only to approximated results

in wave speed and amplitude but also, in the worst

case, to a thorough different description of the physical

solution.

6 CONCLUSION

In this paper an analytical approach able to describe

the evolution of an initial point-perturbation in a 1D,

mobile-bed free-surface flow, is presented. Results of

A new method for the assessment of river network fractal dimensions:

introduction, computation and comparison

ABSTRACT: A new method for the assessment of the fractal dimensions of river networks at given hierarchical

orders is presented. It is based on the analogy between river networks and DLA processes. Starting from the outlet

section of each drainage area, two tangents to the river network tips can be drawn, forming an internal angle.

A supplementary angle is then defined, from which the fractal dimension of a river network is easily computed.An

analogous procedure can be followed considering the tangents to the drainage divide. The ‘supplementary angle

method’ (SAM) has been tested on the Corace river network and basin (Calabria, Italy). An empirical relation

linking the fractal dimensions computed on river networks and on basin areas has been obtained. A comparison

of results from the SAM and the standard box-counting method has been performed, showing an increasing

agreement for higher hierarchical orders.

1 INTRODUCTION

The multifractal theory was introduced by Mandelbrot

(1972, 1974) and developed by Frisch & Parisi (1985)

for the study of turbulent dissipative phenomena and

by Halsey et al. (1986) for the analysis of strange

attractors in the theory of dynamic systems. In the last

few years, several applications have been performed in

different fields, including Diffusion Limited Aggrega

tion (DLA) processes (Witten & Sander 1981; Vicsek

et al. 1990).

In Hydrology, particular interest was devoted to

the study of river basins and networks. In addition

to the description of contributing drainage areas of

given hierarchical order, slopes, dissipation energy,

channel initiation function and width function (Ijjasz

Vasquez et al. 1992; Rinaldo et al. 1992; Rinaldo et al.

1993; Rigon et al. 1993; Rodriguez-Iturbe & Rinaldo 1997), recent results show the possibility of obtaining the multifractal spectrum, f (α), also for negative moment orders (De Bartolo et al. 2004), and a fractal instantaneous unit hydrograph (De Bartolo et al. 2003b). Due to the fact that a multifractal is a union of monofractal sets, the idea has arisen of decomposing the multifractal spectrum into its constituent monofractal parts (De Bartolo et al. 1995; De Bartolo et al. 2003a). Therefore, the present work deals with the study of sub-basins and relative network portions of a natural basin. The analysis of the sub-sets has been performed through a new method, derived from the analogy between river networks and DLA processes.The proposed method, applied graphically, has given the fractal dimensions of the Hortonian sub-structures at different hierarchical orders.

Results have been compared to the fractal dimen

sions obtained with the standard box-counting algo

rithm, showing an increasing agreement for higher

hierarchical orders.

2 ANALOGY BETWEEN RIVER NETWORKS AND DLA PROCESSES

The quantitative description of river networks is due

to Horton (1932, 1945), who proposed the well-known

hierarchical stream classification criterion, then devel

oped and modified by Strahler (1952, 1964).

In particular, Horton investigated the angular prop

erties of river networks. He proposed a junction angle model (Fig. 1), in which the angle T , measured in the horizontal plane, can be assessed as follows:

S M and S T being the gradients (slope tangents) of the main and tributary streams, respectively.

Lubowe (1964) verified that Equation (1) does not give good predictions for streams of the same order, ω. According to Horton (1945) and Lubowe (1964), Howard (1971) noticed that the Hortonian model is not able to predict the junction between two streams of equal declivity, giving Equation (1) zero as result. Therefore, he introduced a new junction angle model (Fig. 2), in which the junction angle, T , is equal to the sum of the entrance angles, E 1 and E 2 :

S 1 , S 2 and S 3 being the gradients of the smaller and larger tributaries and the receiving stream, respec tively. junction angle, T main stream tributary stream

Figure 1. Horton's junction angle model. A strong analogy subsists between the macroscopic river networks and the microscopic clusters studied in DLA processes. In fact, similar procedures can be used to reconstruct the multifractal spectra in both fields of application. In particular, the angular properties of an aggregate are investigated through the geometry of the cone-angle model (Turkevich & Sher 1985) (Fig. 3), where θ is the cone angle. In a DLA cluster containing n particles, the maximal probability, p max , that an incoming random walker from infinity can hit a particle is linked to the minimum Lipschitz-Hölder exponent,α min , of the f (α) spectrum. Following the Turkevich & Scher (1985) conjecture, the fractal dimension, D, can be computed as follows: The authors assumed that the outermost tip of the cluster is associated with p max . Therefore, Equation (4) can be

rewritten: junction angle, T tributary stream 1 tributary stream 2 E 1 E 2 receiving stream Figure 2. Howard’s junction angle model. bisector θ Figure 3. Schematic of the cone-angle model.

where, considering the cone-angle, θ (Fig. 3), the

following relation holds (Turkevich & Scher 1985):

3 THE SUPPLEMENTARY ANGLE METHOD

A strong analogy appears with the river networks and

drainage areas at given hierarchical orders, ω. With

reference to Figure 4, let us consider a generic sub

basin of order ω and area A ω . Starting from the outlet,

it is possible to draw the tangents, t 1 and t 2 , to the river

network tips. Thus the internal angle, β ω,n is identi

fied. Drawing the bisector, the angle β ω,n /2 and the

supplementary angle θ ω,n are obtained. The last one is

analogous to the cone angle, θ. Therefore, Equations

(6) and (5) become respectively:

for ω= 1, 2, . . . ,Ω, where is the basin order. Equa

tion (7) expresses a Lipschitz-Hölder exponent at

the order ω, and Equation (8) the relative fractal

dimension.

Due to the fact that it is simpler to identify the

drainage divide than the river network, the same

graphic method can be adopted for the drainage area

(Fig. 5), obtaining the internal angle, θ ω,A , and the

following exponent and fractal dimension: main stream
sub-basin outlet

bisector t 1 t 2 θ ω,n β ω,n

Figure 4. Schematic of the SAM for the river network. 4 APPLICATION The SAM has been applied to the Corace river basin (Calabria, Southern Italy). The topographic area is A = 294 km 2 and the shape is elongated. The upper reaches of the basin, with elevations ranging from 700 to 1000 m a.s.l., are made up of conglomerate rocks. The gravels are constituted of metamorphic rock fragments and are highly permeable and resistant to erosion processes. In the lower reaches the source rock lithology changes to silt clays interbedded with silty and sandy marine deposits. The Corace river-mouth is constituted of sediments varying in the texture from granules to cobbles. The annual average rainfall depth is about 1500 mm. In Table 1 the number of investigated areas and relative river networks at different hierarchical orders is presented. The basin order is Ω= 6. Figures 6-7 show the Corace river basin and the sub-areas and networks for ω= 2 to 5, extracted from 1:25,000 scale topographic maps. The SAM has been applied to all the river networks and drainage areas for ω= 2 to 6, by computing the supplementary angles θ ω,n and θ ω,A . t 1 main stream sub-basin outlet bisector t 2 θ ω,A β ω,A Figure 5. Schematic of the SAM for the drainage area. Table 1. Number of sub-structures of the Corace river basin at different hierarchical orders. Figure 6. Sub-structures of the Corace river basin for ω= 2

and ω= 3.

Figure 7. Sub-structures of the Corace river basin for ω= 4

and ω= 5.

Results are presented in Table 2. As expected,

θ ω,n >θ ω,A . Figures 8-9 show the supplementary

angles θ ω,n and θ ω,A , respectively, versus the second

order drainage areas, A ω = 2. Analogous graphs have

been obtained for ω= 3 to 6.

For each supplementary angle, the corresponding

α ω and D ω have been evaluated from Equations (7)

to (10). The fractal dimensions for ω= 2 are shown

in Figures 10-11, with the power law curves and the

regression coefficient, R 2 , very close to 1. Analogous

graphs have been obtained forω= 3 to 6. In the case of

drainage divide presenting concavities, the SAM may

produce unreliable results, as in the case of the fractal

dimension greater than 2 in Figure 11. Table 2.

Ratio of fractal dimensions versus ratio of supplementary angles for ω= 2 to 5 (Corace river basin). 5 DISCUSSION The SAM permits an easy assessment of fractal dimensions of river basin sub-structures (networks and drainage areas) at given hierarchical orders. As a comparison, the fractal dimensions have been also computed through a standard box-counting algorithm (see, for example, Feder 1988), as follows: where δ is the cell side size and N (δ) the number of covering cells at resolution δ.

Figure 14. (a) Digitized portion of the Corace river network

and (b) scaling curve obtained with the standard box-counting

method.

0.0

0.5

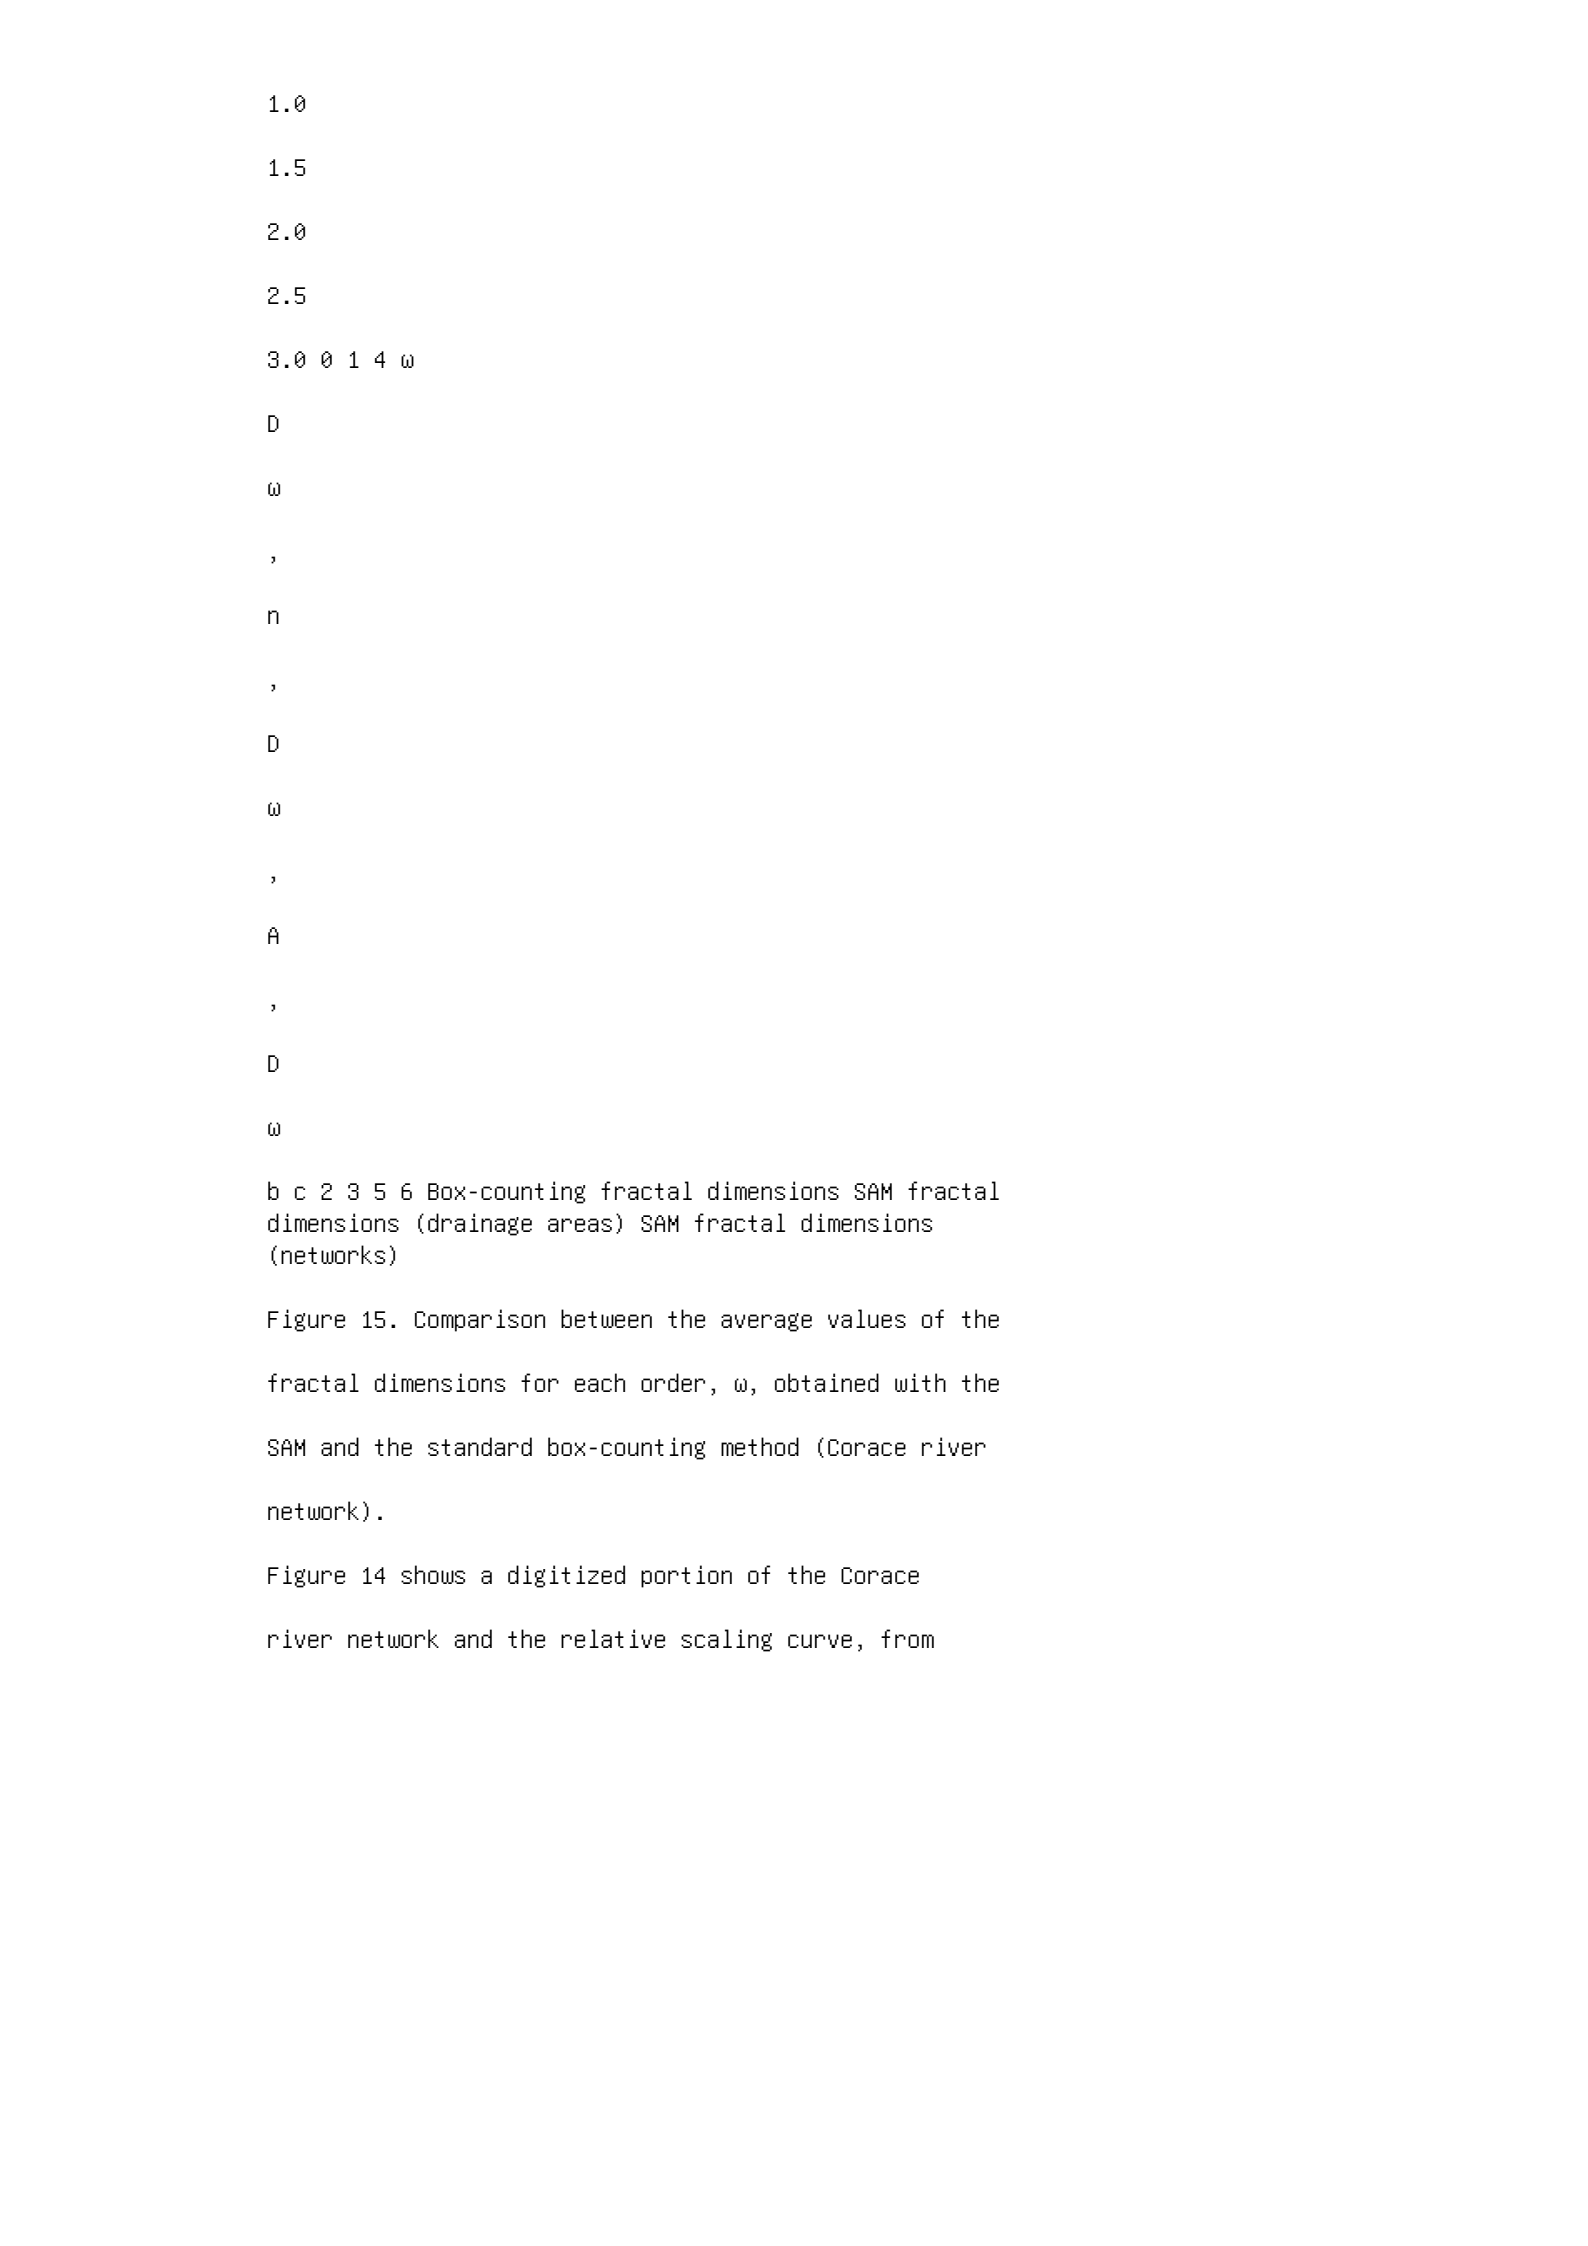

Figure 15. Comparison between the average values of the fractal dimensions for each order, ω, obtained with the SAM and the standard box-counting method (Corace river network).

Figure 14 shows a digitized portion of the Corace river network and the relative scaling curve, from

which the fractal dimension has been computed

between the cut-off lengths, δ min and δ max , by maxi

mizing the correlation coefficient of the least squares

linear regression (De Bartolo et al. 2000).

The average values for each order, ω, of the fractal

dimensions obtained with the SAM and the standard

box-counting method are compared in Table 3 and

shown in Figure 15. Table 3 presents also the average

relative errors, computed as follows: Table 3. Average values of the fractal dimensions and relative errors at different hierarchical orders (Corace river basin). ΔD ω,A-n ΔD ω,bc-n Order, ω D ω,n D ω,A D bc ω (%) (%) 2 1.555 1.641 1.040 5.5 -33.1 3 1.616 1.688 1.216 4.5 -24.7 4 1.641 1.697 1.462 3.4 -10.9 5 1.686 1.741 1.679 3.3 -0.4 where N ω is the number of sub-structures analyzed at the order ω (Table 1). Results show that the SAM applied to drainage areas overestimates D ω,n , with average relative errors not greater than 5.5 % and decreasing for higher orders. Inversely, the standard box-counting method underestimates D ω,n , with average relative errors that are quite high at the lower orders, but very low at the fifth order. Being generally easier to identify the drainage divide than the river network tips, the assessment of the river network fractal dimension might be performed just applying the SAM to the drainage area. 6 CONCLUSIONS The supplementary angle method (SAM) has been presented. The SAM is based on the analogy between river network and DLA processes, in particular on the Turkevich & Scher conjecture, expressed by Equation (4). The SAM permits an easy computation of fractal dimensions of river basin sub-structures (networks and drainage areas) at given hierarchical orders. The first application to the Corace river network and basin (Calabria, Italy), extracted from 1:25,000 scale maps, has produced an empirical relation linking the fractal dimensions computed on river networks and on basin areas. Finally, it has been shown that the SAM and the standard box-counting method lead to closer results as the hierarchical order of sub-structures increases. 2D sediment transport study on Elbe River – Czech Republic

P. Jirinec & J. Spatka

DHI Hydroinform a.s., Prague, Czech Republic

ABSTRACT: The method of two-dimensional mathematical modeling was used for study “Improvement of

Navigation Conditions in Elbe River Reach Strekov – CR/FRG border”. Hydraulic characteristics, which are

important for navigation safety, were determined by the model for situation after construction of two new designed

barrages. Sediment transport and morphology changes were simulated in the whole 40 km long Elbe reach under

flood condition. Simulations of unsteady flow were applied for period of 6.5 days under real catastrophic flood

situation from August 2002 and also for two theoretical floods Q 20 and Q 5 .

Geometry of Elbe river channel, embankment and floodplains were changed based on proposed plan on

construction of Male Brezno and Prostredni Zleb barrages including proposed river bed dredging. Mathematical

model has defined reaches of difficult navigation conditions and has found reaches where ships could be shifted

from their course by transversal flow velocities. The model has also described future sediment transport regime

of lower Elbe reach down Strekov after construction of designed barrages and has demarcated areas for necessary

fairway dredging.

1 INTRODUCTION

For a long time the navigational conditions on the

lower reaches of the Czech section of the Elbe have

needed improving. The main obstacle to navigation is

the corridor’s relatively large longitudinal slope, which

means that in a normal hydrological year the water

depth is insufficient for navigation for most days of

the year. Studies carried out before have shown that a

sufficiently raised depth in a section roughly 40 km

long from Usti nad Labem (km 70.0) to the state

border with Germany (km 110.0) cannot be effec

tively ensured merely through regulatory measures,

or by releases from various parts of the watershed.

The only viable solution is to construct two navigation

steps in combination with regulatory measures (dredg

ing the navigation deep cut in the river bottom or by

concentration structures).

For the proposed conceptual framework of making it navigable it is necessary to verify to what extent the water level will be affected by constructing the barrages and whether the required navigational depths will be attained during low discharges. Likewise it is necessary to map in detail the vector values of speeds in the navigation channel and deal with the flow's effects on vessels (to ensure shipping safety). Finally it is necessary to evaluate the future regime of sediment transport after constructing both planned barrages and above all after realising the essential corridor dredging, which will have a significant impact on the Elbe's sediment regime. Studies carried out previously and newly taken samples of materials from the river bottom including grain-size analyses have demonstrated that the finer fraction material gathers about ten centimetres below the bed pavement. When dredging the bed pavement will be completely removed in many sections and the newly exposed finer bottom material will subsequently be open to the current's effects. The finer the material the more spontaneous the sediment flow that can be expected. The "navigability" conceptual framework assumes dredging will be carried out in three sections with a total length of 25 km. From the standpoint of the current's hydraulic characteristics the deciding factors for initiating sediment movement are water depth and the energy curve's slope. Therefore during flooding there is a far more significant sediment transport as the water depth is at a maximum. As the flood wave passes by the energy curve's slope changes (as a rule it is at its greatest during the wave's onslaught), therefore it is necessary to study the sediment movement and morphological changes to the channel during unsteady flow. The sediment regime during three flood waves was simulated by a mathematical model: – the actual flood wave from August 2002 – as the greatest trustworthily recorded flood in this section of the Elbe – a theoretical flood wave with a peak flow of Q 20 – a

theoretical flood wave with a peak flow of Q 5 .

Figure 1. Hydrograms in Usti nad Labem gauging station – upper boundary.

All of the calculations were made for an iden tical time period of flooding lasting 6.5 days (156 hours). The hydrograms of the actual flood wave from August 2002 in the Czech Hydrometeorological Insti tute (CHMI) gauging station in Usti nad Labem and the theoretical flood waves Q 5 and Q 20 are depicted in figure 1.

2 METHODS AND MATHEMATICAL MODEL

For simulation of the sediment transport the 2D math ematical model MIKE 21C (including the module "ST" – Sediment transport) was used, developed by the firm DHI Water & Environment, Hørsholm (Den mark). The entire length of the interest area was described by computational grid of 2670× 125 points for time consuming calculation of the unsteady flow. The computational grid is denser around structures (bridges, the proposed barrages) at 6–10 points per meter (both lengthwise and crosswise), whilst in sev eral places with a relatively flat flood plain the distance between points is 12 to 20 m. For the study's needs – predicting sediment movement and morphological changes – the level of the interest area's schema

tisation is sufficient. Houses and blocks of houses were modelled with the aid of a considerably raised terrain (insurmountable barriers); fences and other obstacles of a similar character were simulated by lines of increased roughness. The hydraulic roughness and local increases in flow resistance are assigned to every point of the computational grid.

The model enables either a mere monitoring of the channel proclivity to scouring, or forming sediment deposits in the given hydrological regime or a full scale prediction of the morphological changes in real time, during which the bottom's relief is modified by the calculated changes (+ loads, -scours). In all the calculations made in this study the perpetual updating of the bottom's relief was considered. The creation of local depositions and scouring is, to a great degree, influenced by the current's transversal circulation. The MIKE 21C model computes the transversal circulation's intensity in the relationship: where i S = intensity of flow's transversal circulation; u=mean vertical velocity; h=water depth; R S = streamline curvature radius. The mathematical model enables a choice of equations for calculating the flow of the bottom sediments from the following authors: - Meyer-Peter & Müller - van Rijn - Engelund & Hansen - Engelund & Fredsøe In our case we always used the Meyer-Peter & Müller equation: where q b = actual sediment transport rate; s= relative density of bed sediment; d= grain diameter; ′ , c = Shields parameters, as it best fits the conditions in the lower reaches of Czech rivers. The grain diameter of the bed material was set on the basis of the results of a detailed geological study of the Elbe's bottom. Together 19 samples of bottom material were taken from pre-selected profiles in the section Strekov (km 70.0)-Dolni Zleb (km 105.0). Each sample represented a column of bottom material with a diameter of 355 mm, taken to a depth of 2 m. The cores were

documented and subjected to a detailed granulometric analysis, such that each sample had two grain size analyses made – the first characterising the overlying bed pavement, the second being made on the material lying underneath this bed pavement (figure 2). The grain-size analyses were carried out on a standard set of sieves and by measuring the characteristic dimensions of the grains for the screenings. The results are granularity curves, establishing the effective grain size d e and the characteristic grain size d 90 (IGHG. 2003). From the established values of the sampled materials' effective grain size d e a control file "bed granularity map" for calculation of morphological changes was created. Sections, which won't be affected by dredging the Elbe's bottom, are characterised in this granularity map by the pertinent d e values of the bed pavement. The sections to be dredged were projected in detail onto a plan of the river channel (their longitudinal and latitudinal extent) and they are characterised by the

Figure 2. Longitudinal profile of bed grain size.

effective grain size values of the material taken from

below the bed pavement.

When modelling sediment transport (especially if

there is continuous sediment transport in the moni

tored section) the simulation result can be influenced

by the choice of boundary conditions – sediment flow

in the upper profiles or the model's lower bound

ary conditions. Therefore in our study we compared

the influence of two limiting values of boundary

conditions on the sediment flow:

– "zero sediment flow"

– "balanced sediment flow" (the model itself gener

ates such a supply/withdrawal of bottom sediments

for the input/output so that there are no morpholog

ical changes in the cross section of the boundary

condition).

for developing morphological changes in the broader

vicinity of the boundary conditions.

3 RESULTS

3.1 Effect of boundary condition

The effect of the differentially assigned upper bound

ary condition (sediment flow) on the sediment regime

was studied during the onslaught of the August 2002

floods – i.e. during a flood with the highest peak flow

from all modelled flood waves.

With sediment flow set at zero local morphologi

cal changes were found (erosion in the bed line areas,

a deepened navigation deep cut, on the contrary in

the centre of the navigation deep cut souring deposits

were formed) having an effect up to 400 m away from

the upper boundary condition. This was followed by

a 1.5 km long section of the Elbe that had no mor

phological changes whatsoever. When comparing the

state of the balanced sediment flow the character of

the morphological changes was more or less in agree

ment – however deposition continued up to a distance

of 550 m from the upper boundary conditions. From comparing results it is possible to state that the value of the assigned sediment flow on the input to the model (from zero up to a balanced saturation of the flow with sediment) has no effect on the sediment regime over the entire 40 km section. 3.2 The August 2002 flood The proposed barrages

Male Brezno (km 81.7) and Prostredni Zleb (km 99.0) divide the 40 km interest area (km 70.0 up to km 110.0) into three river reaches. In the lower, roughly 11 km long reach from Prostredni Zleb barrage up to Hrensko there has hardly been any sediment transport nor, therefore, morphological changes in the channel (valid for all 3 simulated flood waves), in spite of this dredging has been proposed from Prostrední Zleb up to km 105.4. Likewise above Prostredni Zleb to beyond Boletice (km 90.5) no sediment transport was calculated (undredged section). From here against the flow direction up to Male Brezno barrage there is a section of numerous local scourings (as a rule they occur by concave banks behind the elbow's peak) and local depositions (the majority concentrated along convex banks). The most intensive morphological changes were simulated in the section Techlovice – Jakuby (km 85.0–87.0), where the scours were up to 1 m deep on the overall width of the navigation course and the loads regularly attained heights of 0.7–1 m, exceptionally as much as 2.0 m (figure 3). These remarkable morphological changes are linked to the corridor sections proposed for dredging and likewise are connected with high values of vertical velocities and also with the transverse velocity values (figure 4), which were ascertained in previous research in this locality. Above Male Brezno up to Strekov there are two sections where multiple morphological changes have been calculated. As a rule these scours and loads have a small extent – at most 100 m long and a typical width of probably a third of the navigation course. It is a matter of the section around the municipality Male Brezno (about 1.7 km long), where scours attain a depth of 1.0 m and the loads a height up to 1.5 m. In the second about 3.7 km long reach the scours generally attain a depth of 0.3–0.7 m and the loads a height of 0.3–0.7 m. In the section above the central dock in Usti nad Labem no morphological changes have been ascertained. The deposition formed at 70.0 km cannot be taken to be indicative – it occurs in the direct vicinity of the model's upper boundary conditions. When assessing the corridor's morphological changes induced by the flood wave from August 2002 the morphological changes that arose during the drop in the flood wave were specially processed. The aim of this was to ascertain whether during the floods the same morphological processes occur in all localities (varying only in intensity) or whether in some localities with the increase of the flood there

Figure 3. Simulated morphological changes in river section

Techlovice – Jakuby; the August 2002 flood.

was erosion followed by deposition as the floodwa
ter receded. By comparing the detailed “maps of level
changes in the river bed” (morphological changes as a
consequence of the entire flood wave’s passage on one
hand and the morphological changes due merely to the
drop in the flood wave on the other), it was ascertained
that the character of the morphological processes
during the flood in the section Strekov–Hrensko is
unchanged and is bound to the hydraulic character
istics of the current flow and the river bed material
in the given location. As the flood wave recedes the
process continues with a considerably lower intensity.

3.3 Theoretical floods

The morphological changes to the channel, as a result
of simulating the theoretical flood wave Q 20 , had a sim
ilar character to the morphological changes invoked
by the August 2002 flood. The occurrence and extent
of sections of the morphological changes were prac
tically the same. However the morphological changes

took place with a lesser intensity – the scours reached
Figure 4. Simulated transversal velocities in river section Techlovice – Jakuby; the August 2002 flood.
about 80% of the depth of the scours during the flood from August 2002, the loads only 70% of the height of those from the flood of August 2002. With the passage of the Q 5 flood morphological changes were only ascertained in two relatively short sections. The most significant occurred again in the sectionTechlovice – Jakuby, where scours 0.70 m deep were formed and the deposits generally attained a height of 0.3–0.6 m, exceptionally up to 1.5 m. The character of these morphological changes was also analogous

to the passage of the flood wave of August 2002. In the section above Male Brezno barrage up to Strekov we only calculated morphological changes around the Male Brezno municipality where the scours reached a depth of 0.5 m and deposits a height of 0.6 m. 4 CONCLUSIONS In the lower reach of the Elbe in Bohemia, Strekov – to the German border, sediment transport and morphological development in the river channel with the advent of a flood wave was modelled on a two

dimensional mathematical model. The calculation was

made for the actual flood wave of August 2002 and for

two theoretical waves at Q 20 and Q 5. All of the simu

lated waves had the same time period of 6.5 days (156

hours).

The morphological changes were simulated for the

proposed state of the river channel i.e. after construc

tion of two low navigation steps including proposed

dredging of the water course. The MIKE 21C model

was used to simulate the flow. The granularity of the

river bed material was described in detail by a grain

size map (including removing the river pavement in the

dredged areas of the channel), which stemmed from

sampling the bed sediments and their granulometric

analyses. The study results are a detailed mapping of

the channel’s morphological changes (mainly in the

fairway), which can be expected with the advent of a

flood.

The most important conclusions from the study’s

results are:

– With the advent of Q 5 , Q 20 floods or that of August 2002 an associated movement of bed sediment in the monitored section of the Elbe didn’t arise. Only local morphological changes were ascertained these being connected to areas with lower grain-size (as a consequence of removing the bed pavement during dredging).

– As the floodwaters rose and receded in the moni tored section of the Elbe there were corresponding morphological processes i.e. some sections (zones) of the corridor are permanently eroded, in others there are permanent deposits. The natural helical flow in the elbows has a conspicuous effect upon these processes. In several relatively short sections of the channel (hundreds of metres up to individual kilometres long) scours were formed with the sub sequent nearby deposition. The bed sediment was

Simulation and prediction of river morphologic changes using RubarBE

K. El Kadi Abderrezzak & A. Paquier

Hydrology and Hydraulics Research Unit, Cemagref, Lyon, France

ABSTRACT: RubarBE is a one-dimensional model for routing water and sediment transport through fixed or movable bed channels. The code simulates and predicts changes in bed composition, channel profile and cross-sectional geometry. This paper provides a general description of the concepts, approaches and hypothesis

used in this model. A series of numerical simulations of sediment transport is described in this paper, with the objective of testing the performance and the potential application of RubarBE. The results of the simulations are analysed and discussed. Cross-comparison of different parameters of the model (deposition and scour rate, sediment transport, bed and water profiles …) allows some validation of the system of equations and hypothesis of our modelling system and provides some keys and ideas for further development of the code.

1 INTRODUCTION

Sediment transport and river morphology studies have gained increasing importance in recent years due to environmental concerns and the need to develop engineering and management strategies for sustainable use of water resources and associated infrastructures (Yang 2000). Evaluating the transport, erosion and deposition of sediments is a key element for describing and understanding the behaviour of rivers. Given that, considerable research effort has been put into the simulation of sediment transport and morphology change in rivers. A lot of computer programs have been developed in the last decades. These models provide numerical solutions for complicated situations that include movable bed and sediment transport. Most of the codes that were developed in the past decades, like HEC6 (Thomas & Prashum

1977), IALLUVIAL (Karim & Kennedy 1982) and SEDICOUP (Holly & Rahuel 1990), were built on a one-dimensional approach.

RubarBE described here is a one-dimensional flow and sediment transport model that has been developed by Cemagref in order to solve as simply as possible the requirements of engineers about river problems.

This paper is organised as follows. First, a general description of the concepts and approaches used in RubarBE is provided. Then, several applications of the model are presented to illustrate its capabilities and range of applications. First, the model is tested on problems with theoretical solutions and on laboratory experiments, and then applied to field problems. The results of the numerical simulations are analysed and discussed. 2 DESCRIPTION OF RUBARBE One-dimensional sediment transport models tend to be easier to parameterise and require fewer assumptions about sediment transport processes than twoand three-dimensional models (Candfield et al. 2002). The Hydrology and Hydraulics Research Unit of Cemagref has developed a 1-D model, RubarBE, for predicting variation of longitudinal bed profile along rivers and changes in the cross-sectional geometry. This computer model has two components: a component to simulate the flow and a component to characterise the changes in river morphology due to erosion or deposition of sediment. Classical one-dimensional models that represent sediments only by a mean diameter D 50 clearly do not fully describe the processes that occur in many channels such as armouring. Therefore, RubarBE represents sediments by a mean diameter D 50 and a complementary parameter, the standard deviation σ. The standard deviation is assessed as the square root of the ratio between D 84 and D 16 (√ D 84 /D 16). It was selected as it appears convenient to describe grain size distribution in a river for which

sediments are homogeneous (Shih & Komar 1990). RubarBE includes features such as: • Computing unsteady flow in open channels with both fixed and movable bed and dealing with sub critical and super critical flow regimes. • Taking in account the space lag effects by introducing a specific equation. • Introducing various empirical relationships for calculating the sediment transport capacity in order

to adapt the modelling to the characteristics of the

application.

• Incorporating empirical relations to describe the

mixtures of sediments that occur during the various

calculation steps.

• Computing the distribution of boundary shear stress

in a cross-section by using the Merged Perpendic

ular Method (Khodashenas 1998, Khodashenas &

Paquier 1999).

• Computing the distribution of boundary critical

shear stress in a cross-section by a relation from

(Ikeda 1982).

• Simulating both the changes of riverbed compo

sition and of cross-sectional geometry using the

previous components of the code.

Data requirements for this model are modest,

involving only a few parameters. Thus, the model is

relatively easy to calibrate and to implement.

2.1 Mathematical basic model

RubarBE model relies on:

De Saint Venant equations for water.

Continuity equation for sediments written as

follows:

where A s is bed-material area (m 2), Q s is sediment

discharge (m 3 /s), q s is lateral sediment flow per unit

of length (m 2 /s) and p porosity.

These equations are completed by a sediment

transport capacity formula; for instance, the (Meyer

Peter & Müller 1948) formula for bedload has been

used for the applications here below:

where C s is sediment transport capacity (m 3 /s), θ c is

dimensionless critical stress, D 50 is median diameter

of sediment (m), J is friction slope, L a is the active

width (m) i.e. the width in which sediment transport

is effective, ρ s is density of sediment (kg/m 3), ρ is

density of water (kg/m 3).

Finally, a space lag equation can be added to

introduce a difference between the sediment transport

capacity and the actual transport rate that may differ

if geometry is not uniform. In RubarBE, the actual

sediment transport rate Q s is linked to the sediment

transport capacity C s through the following relation:

where D char is the lag distance (m). De Saint Venant equations are solved by a secondorder Godunov-type explicit scheme (Paquier 1995). If the parameters in the sediment transport function for a cross-section can be assumed to remain constant during a time step, we can suppose that there is a little variation of the cross-sectional geometry (Yang & Simoes 1998). Thereby, sediment routing (equation 1) can be uncoupled from the water surface profile

computations. In practice, this condition can be met by using a small enough time step. Sediment routing is accomplished by a similar finite difference method. Changes in bottom level are performed at every time step. Solving the equation (1) means estimating at every time step, the input and output of sediments for one cell and spreading the erosion or deposition volume across the cell. Values of the cross-sectional flow area A and flow discharge Q are computed at the middle of a cell between two cross-sections. Thus, it is simpler to compute Q s also in this middle and to identify it with respectively input and output of sediments if the sediment cell is shifted by half a space step (Balayn 2001). 2.2 Sediment modelling system Inside one cell, a sedimentary compartment corresponds to a set of sediments that have a coherent behaviour. We distinguish four compartments: • A compartment M am of input sediments and a compartment M av of output sediments. • A compartment A of the active layer: it contains all the sediments that have moved inside one cell during one time step. Sediment particles are continuously exchanged between flow and the active layer. • A compartment B of one or several substrate layers: it reflects historical deposition of sediments on the riverbed or undisturbed subsurface. Sediment particles of each compartment are characterised by the mass M , the mean diameter D and the standard deviation σ. Thus, in a cell, the sediment transfers are schematised as in Figure 1 (Balayn 2001). When sediment particles pass across a cell, they either reach the downstream of the cell, or settle on the active layer. Entrainment of sediment particles from the active layer and its exchanging with flow causes particles travelling from upstream to be mixed with those from the active layer. τ fm is the shear stress below which transported sediment particles begin to deposit. τ mm is the shear stress above which sediment particles begin to move. The mass of the active layer depends on the sediment discharge, the sediment velocities and the dimension of the cell. The model assumes that this mass is defined by Cs*∂x/U, where Cs is the sediment transport capacity, ∂x is the space step and U the mean water velocity.

Figure 1. Representation of the sharing of sediments inside

one cell (Balayn 2001).

The characteristics of the sediments resulting from

the mixing or the sharing of two compartments are

defined in the model by empirical relations (Balayn

2001).

2.3 Computation of cross-section deformation

RubarBE computes the deformation of cross-sections is computed with the assumption that scour and deposition are directly related to shear stress. The distribution of boundary shear stress around the wetted perimeter of an open channel is governed by cross-sectional geometry, roughness distribution and the existence of secondary flows. Precise computation of shear stress distribution is extremely difficult in one-dimensional models. Thus, empirical methods constitute a good alternative.

RubarBE can calculate the boundary shear distribution τj in a cross-section in two ways: either from the uniform equation using water volumetric density ρ, gravity acceleration g, hydraulic radius R and energy slope J ($\tau j = \rho g R J$, R is computed on the base of the total area and perimeter of the flow) or from the Merged Perpendicular Method. The first method assumes that the boundary shear stress is constant around the wetted perimeter. The second one is a geometrical method that assumes that the energy gradient is the same in all the sub areas. More precisely, it shares the wetted area in small sub areas using the lines perpendicular to the bottom follow

ing a complex procedure described in (Khodashenas

1998, Khodashenas & Paquier 1999).

RubarBE can calculate the boundary critical shear

distribution τ ci in a cross-section by a relation from

(Ikeda 1982): where τ cj critical shear stress in point j of the crosssection with slope β j , τ ∗ cj critical shear stress in point j for horizontal bottom (β j = 0 ∘) (which may vary from one point to an other one, considering, for instance, the riverbed material), β j local side slope of cross-section in point j, α=F L /F D , F L and F D are respectively dimensionless lift and drag forces, φ angle of internal friction of sediment. For the tests here below, the following value is selected α= 0.85; τ ∗ cj is calculated by the Shields curve. The mass of sediment eroded or deposited in one cross-section obtained by the computation is distributed along the section. RubarBE incorporates various empirical relationships between deformation and shear stress. In the case of erosion, the deformation ΔZ j of an erodible point j of one cross-section is assumed to be proportional to (τ j − τ cj) 1.5 . In the case of sedimentation, deposited sediment in one cross-section can be distributed in three ways: • The cross-section is adjusted in horizontal layers. • The entire wetted cross-section is moved uniformly up. • The deformation ΔZ j of a “deposit” point j is assumed to be proportional to (1/τ j). 3 APPLICATION CASES AND RESULTS 3.1 Theoretical cases 3.1.1 Knickpoint migration Knickpoint are points of sudden change or inflection in the longitudinal profile of a stream. In general knickpoint may migrate upstream along the channel and have undesirable effects, such as causing banks collapse and undermining bridge piers. Thus, knickpoint development and propagation is a very interesting phenomenon to study. The simulated channel has a rectangular section, 300 m long×10 m wide by 4 m deep.The knickpoint is represented by a backward-facing step in the bed with a slope of 0.01 m/m. The upstream and downstream reaches have a slope of 0.001 m/m. The bed material and sediment feed are composed of the same coarse sand and channel width is constant. Table 1 shows the main characteristics of the simulation. The flow discharge is maintained constant. The sediment feed rate Q s is specified as the sediment transport capacity of the upstream and downstream reaches. On the downstream side, it is assumed that the flow acted like uniform outflow. The porosity p of the bed material is assumed to equal to 40%,

the sediment density ρ s to equal

Table 1. Characteristics of the simulation.

Figure 2. Initial bed, computed equilibrium bed and water surface.

to 2600 kg/m 3 and the angle of internal friction of sediment ϕ to equal to 35 ∘ .

The central riverbed will suffer from degradation. Theoretically, in dynamic equilibrium, the slopes of the three parts of the channel are expected to equal to 0.001 m/m.

The simulation is accomplished with a uniformly spaced mesh, using cross-sections spaced 10 m apart. The lag distance D char is assumed to equal to 1 m. The initial condition for sediment transport is Q s = 17.6 kg/s. The distribution of the boundary shear stress is calculated by τ= ρgRJ . The dimensionless shear tress θ c is assumed to equal to 0.047.

Figure 2 shows the initial bed with the equilib rium bed and the water surface profile. The chan nel is in dynamic equilibrium 280 hours after the start of the simulation. RubarBE was able to pre

dict well the scour depths and the final equilibrium slope (0.001 m/m).There is an overall close agreement between the theoretical solution (a constant riverbed slope of 0.001 m/m) and the result of the simulation.

3.1.2 Irregular straight open channel

Usually, natural channels are characterised by an irregular cross-section. An irregular straight open channel of uniform cross section (Fig. 3) is selected to validate the performance of the code. The simulated channel is 1000 m long and the channel bed slope is 0.0001 m/m. The bed material and sediment feed are composed of the same coarse sand. Table 2 shows the main characteristics of the simulation.

The flow discharge is maintained constant. The

sediment feed rate Q s corresponds to the sediment Figure 3. Channel cross-section. Table 2. Characteristics of the simulation. Water Manning Sediment Standard Sediment discharge coefficient Diameter deviation feed rate Q (m 3 /s) K (m 1/3 /s) D 50 (mm) σ Q s (kg/s) 300 45 1 2.3 29 transport capacity of the simulated channel.The downstream water level is fixed at a constant value of 108.066 m. The porosity p of the bed material is assumed to equal to 40%, the sediment density ρ s to equal to 2600 kg/m 3 and the angle of internal friction of sediment ϕ to equal to 35 ∘ . For this application, a constant space step Δx of 100 m is used. The lag distance D char is assumed to equal to 50 m. The initial condition for sediment transport is Q s = 14.5 kg/s.The distribution of the boundary shear stress is by the Merged Perpendicular Method. The dimensionless shear tress θ c is assumed to equal to 0.047. The deformation ΔZ j of a “deposit” point j is assumed to be proportional to (1/τ j). Figure 4 shows the initial bed as well as the channel bed profiles at different times. The channel is in dynamic equilibrium 200 days after the start of the simulation. RubarBE is able to predict both the deposition heights and the advance of the deposition front. However,

the numerical results show an “inflection” in the longitudinal profile located at x= 910.9 m. This slight change in the bed profile could be due to the influence of the downstream boundary condition and the distribution of sheer stress at x= 910.9 m. The channel bed slope upstream from the “inflection point” is about 0.000175 m/m. Figure 5 shows the evolution of the cross-section at x= 1000 m. In a concave angle of a cross-section, computed shear stress by the Merged Perpendicular Method is lower than in a convex angle. Thus high deposition is observed in the concave angles of the channel.

Figure 4. Initial bed and computed channel bed profiles at

different times.

Figure 5. Cross-section deformation: x= 1000 m.

The evolution of the riverbed profile and the cross

sectional geometry is affected by the methods used to

compute the boundary shear stress. A numerical simu

lation is performed with the assumptions that the shear

stress distribution is calculated by τ= ρgRJ and the

boundary critical shear distribution computed from the

Shields curve (the (Ikeda 1982) relation is not used).

SIM-1 refers to the simulation with the Merged Per

pendicular Method and (Ikeda 1982) relation; SIM-2

refers to the simulation with τ= ρgRJ and critical

shear distribution from the Shields curve. Figure 6

shows the dynamic equilibrium beds resulting from

the simulation SIM-1 and SIM-2. SIM-2 shows less

deposition in the channel bed; the difference between

SIM-1 and SIM-2 is about 0.15 m. The equilibrium

bed profile computed by SIM-2 is not affected by the

boundary condition: a constant slope of 0.000175 m/m

is obtained.

3.2 Laboratory experiment

While theoretical cases deal with long-term behaviour,

the selected test case provides testing of very unsteady

flow during a short period.

This test case concerns an experimental small-scale

laboratory dam-break waves over movable beds. The

experiment was performed by (Spinewine & Zech Figure 6. Initial bed, computed equilibrium bed. X Reservoir h 0 h 1 Gate 0 Figure 7. Idealized dam-break problem, h 0 and h 1 are the initial depths upstream and downstream of the dam before failure. 2002) in the framework of the EC-funded IMPACT project at the Department of Civil and Environmental Engineering, Université Catholique de Louvain, Belgium. The objective is to investigate the geomorphic impacts induced by very rapid and transient floods such as those resulting from dam-breaks. A horizontal flume of rectangular cross-sectional geometry is used. The flume has the following dimensions: length= 2.5 m, width= 0.10 m and sidewall height= 0.35 m. The reservoir is assumed to be long and has the following dimensions: length= 10 m, width= 0.10 m and sidewall height= 0.35 m. The origin of the horizontal axis is located at the gate position. The initial water depths for this case are h 0 = 0.10 m if x< 0 and h 1 = 0 m if x≥ 0, where x is the distance along the flume (Fig. 7). Particles composing the bed are uniform in size: D 50 = 3.5 mm and σ= 1. The porosity p of the bed material is assumed to 36%, the sediment density p s to 1540 kg/m 3 and the angle of internal friction of sediment ϕ to 25 ∘ . The Strickler coefficient K was derived from the particle diameter through the classical Meyer-Peter and Müller formula: K = (21.1/D 1/6)= 54 (m 1/3 /s). Tests consisted in the sudden opening of a vertical gate that separated the initial water and sediments levels upstream and downstream of the gate. Due to highly unsteady nature of dam break flood propagation; the flume and the reservoir were described through a dense grid of cross-sections. Two constant space steps are

used: x= 5 cm and x= 20 cm. A smaller space

step allows obtaining the arrival of the flood wave in a more accurate way. A larger space step allows describing the transition between super and sub critical flow (hydraulic jump) more conveniently.

The initial condition for sediment transport is Q s = 0 kg/s. On the upstream side (x=-10 m), a constant depth of water h= 0.10 m is imposed. On the downstream side (x= 2.5 m), it is assumed that the flow acted like critical outflow.The upstream sediment condition is Q s = 0 kg/s. The time step is variable, but it is chosen so that the maximum Courant number of every cell does not exceed a limited value imposed by the model. The simulations were run for two values of maximum Courant numbers (noted CFL): 0.5 and 0.1.

The total time of the simulation is 2 second.

For this test case, the distribution of the boundary shear stress is calculated by τ= ρgRJ ; the dimensionless shear tress θ c is calculated by the Shields curve.

For all the runs, the results show that in the near field, rapid and intense erosion accompanies the development of the dam-break wave. In the far field, the solid transport remains intense but the dynamic role of the sediments decreases (Figs 8-9). The flow loses its capacity, the transported material is deposited.

Figure 8. Bottom level: ∆x= 5 cm, D char = 1 m, t= 2s.

Figure 9. Bottom level: ∆x= 20 cm, D char = 1 m, t= 2s.
Instabilities of calculations were observed during the numerical tests. Results of simulations depend on the grid spacing, the CFL (Figs 8-9) and D char values (Fig. 10). Instabilities are more marked in the case of CFL= 0.1. The difference of accuracy between the numerical results increases in the far field (Fig. 11). The numerical simulations take in account only the bedload transport. This assumption may be restrictive in the modelling of flood or dam break events, where suspended load is important. Added numerical tests were carried out, in which the dimensionless critical shear stress θ c was supposed nil. Similar behaviour is obtained with non-nil critical shear stress (Fig. 12). Experimental data are compared to the numerical results. CEM-1 refers to the simulation with a space step of 20 cm, D char = 1 m and CFL= 0.5; CEM-2 to the simulation with a space step of 20 cm, D char = 1 cm and CFL= 0.5 and CEM-3 to the simulation with a space step of 5 cm, D char = 1 m and CFL= 0.5. Figure 13 shows the comparison concerning the front characteristics: the time of front wave arrival is smaller with the RubarBE model. This behaviour can be explained by influence of the hypothesis and approaches used by RubarBE (average velocity, hydrostatic pressure …) (El Kadi & Paquier 2003, Spinewine & Zech 2003). Figure 10. Bottom level evolution with spatial lag D char : ∆x= 20 cm, CFL= 0.5, t= 2s.
Figure 11. Bottom level evolution: D char = 1m, CFL= 0.5, t= 2s.

Figure 12. Bottom level evolution with nil or non nil critical

shear stress: ∆x= 20 cm, D char = 1 m, CFL= 0.5, t= 2s.

Figure 13. Front characteristics.

However, it must be noticed that the closest approx

imations to the experimental data seem to be for the

numerical CEM-3, i.e. space step of 5 cm, D char = 1 m

and CFL= 0.5. At the same cross-section the differ

ence between the arrival times is around 0.15 s. The

shape of the experimental wave front is quite similar

to the numerical profiles and small grid space step pro

vides better estimate of arrival time of the flood wave.

The channel friction could affect significantly the

propagation of the front wave. A Manning friction

coefficient of 0.0185 m 1/3 /s, derived from the diame

ter of the riverbed material, was selected.The influence

of the wall friction was neglected. Then, a sensitiv

ity analysis was carried out. Two different Manning

coefficients are tested with the simulation CEM-3.

Figure 14 shows that the celerity is quite dependent

on the friction coefficient introduced in the numerical

model. The agreement between experimental data and

RubarBE simulation (CEM-3) is quite improved with

a roughness of 0.02 m 1/3 /s instead of 0.0185 m 1/3 /s in

the previous simulations.

Figures 15a, b, c show the water levels evolu

tion at three cross-sections: x=-0.25 m, x= 0.00 m

and x= 0.25 m. Computed water levels agree with

experimental data except slight differences observed

upstream from the gate. In the reservoir, the closest
Figure 14. CEM3: front characteristics with different values of roughness. approximations to the experimental data seem to be for the numerical simulation CEM-3. The simulation CEM-1 provides accurate approximations to the experimental data upstream from the gate. At gate location, the water levels evolution is underestimated. Flow is critical at the gate; decoupled model is inherently less stable than the coupled model in the case of Froude numbers vary close to unity, and they may need a special treatment of time step (Cui et al. 1996). Beyond the high concentrations of sediment that invalidate the hypothesis

of one single phase (see here below), the differences between calculation and experimental results are due to the highly 3-D nature of the dam-break wave for which some of the St. Venant hypothesis (small bottom slopes and curvatures, hydrostatic pressure and uniform velocity distribution in the cross section) are certainly not verified. Figures 16a, b, c show the bottom position at three cross-sections: x=-0.25 m, x= 0.00 m and x= 0.25 m. Significant discrepancies between numerical and experimental results are observed through the reservoir and the channel. The use of the Exner equation and of a maximum sediment transport capacity does not integrate the presence of a mixture of water and sediments in high concentration. This assumption but may be restrictive in the modelling of flood or dam break events. The use of another method for calculating the sediment transport seems to be necessary to take into account high concentration transport. 3.2.1 Field application: Miribel channel This field application consists of sediment transport and morphologic changes in the Miribel channel. This channel is located north from Lyon in France. A geomorphologic survey was carried out in the Miribel channel by Malavoi 2000. This case schematises the sediment transport in the channel after closing a former excavation in 1990.This pitch of about 400 000 m 3 is located in the upstream

Figure 15. Water levels evolution: a) x=-0.25 m, b)

x= 0.00 m, c) x= 0.25 m.

reach of the channel near the “Thil” village. Since sed

iments are trapped in this pitch, materials cannot be

carried away from the upstream reach to the down

stream one. As a consequence, important erosion was

observed in the surrounding reaches.

The Miribel channel has a nearly rectangular sec

tion, is 16 km long and 85 m wide. The pitch is

approximately 2 km long and the channel slope is

about 0.00065 m/m. The bed material and sediment Figure 16. Bottom levels changes: a) x=-0.25 m, b) x= 0.00 m, c) x= 0.25 m. Table 3. Characteristics of the simulation. Water Manning Sediment Standard Sediment discharge coefficient

Figure 17. Miribel channel: initial bed, computed equilib

rium bed and water surface.

specified as the sediment transport capacity of the

upstream and downstream reaches. On the downstream

side, it was assumed that the flow acted like uniform

outflow.

The porosity p of the bed material is assumed

to equal to 30%, the sediment density p s to equal

to 2650 kg/m 3 and the angle of internal friction of

sediment ϕ to be 35 ∘ .

The channel is described through a grid of cross

sections: a constant grid spacing x= 100 m is

used. The lag distance D char is assumed to equal

to 1 m. The initial condition for sediment transport

is Q s = 144.7 kg/s. The distribution of the boundary

shear stress is calculated by τ= ρgRJ .The dimension

less shear stress θ c is assumed to 0.047. In the case

of sedimentation, deposited sediment in one cross

section is distributed in horizontal layers across the

channel width.

Figure 17 shows the evolution of the bed profile

and free surface with time. The model predicts the

progression of scour as well as deposition in the exca
vation. The evolution of the Miribel bed is controlled
by the deposition of sediments in the pitch. The natural
passage of sediments through the channel is inter
rupted by the pitch: sediments are washed into the
excavation causing the bed upstream to erode. Down
stream of the excavation the bed is lowered as the flow
picks up energy on leaving the hole. At the end of the
simulation, the deposition rate in the pitch is about 3 m.

4 CONCLUSIONS

RubarBE is designed to simulate single flood event and
long-term scour and/or deposition. RubarBE assumes
that equilibrium conditions are not necessary reached
within each time step; the influence of unsteady con
ditions during flood events is taken in account through
a loading equation.

Gravel river widening by bank erosion in a straight stretch of river –

investigations on a numerical model

M. Schmautz

SKI GmbH + Co. KG Consulting Engineers, Munich, Germany

ABSTRACT: Removing existing bank protection works allows a lateral erosion and thus widening of a regulated

stretch of river. Based on an extensive parameter study, a method was developed to estimate the maximum river

width which has to be expected during the widening process – which is the main question while planning a

measure of river widening. The controlling parameters and boundary conditions have been identified and the

structural evolution of the process was investigated.The research work focuses on straight rivers with cohesionless

bed and bank material which play a major role in the alpine region.

1 INTRODUCTION

Nowadays, numerous European rivers are in the stage

of erosion with the well known consequences of

decreasing water and groundwater levels. One alterna

tive (taken into consideration at several Alpine rivers)

for an ecological and hydraulic engineering feasible

solution of these problems is to allow a lateral ero

sion of the river by removing existing bank-protection

works. The widening of the river would decrease the bed load transport capacity; the eroded bank material would serve as an additional sediment influx. Existing knowledge about the processes and planning tools for such measures are partially insufficient.

At the Laboratory of Hydraulic and Water Resources Engineering of the Technische Universität München in Obernach fundamental model tests have been carried out by order of the Bavarian State Ministry for Regional Development and Environmental Affairs (fully mobile bed, model length up to 100 m) since the year 2000 to prepare extensive measures of river engineering at the lower courses of the Alpine rivers Iller and Isar which are tributaries of the Danube. The focus of the research is especially on the interaction between degradation, lateral erosion and the hydraulic influence of weirs or ramps which stabilise the river bed in well-defined distances. The conception of the study and the results of several model runs were illustrated in Schmautz & Aufleger (2002) and Aufleger et al. (2003).

The numerical modelling of the processes of bank erosion was subject to an additional research project which was financed by the Deutsche Forschungsgemeinschaft. Herein, a method was developed to estimate the maximum river width which has to be expected during the

widening process – which is the main question while planning a measure of river widening. The controlling parameters and boundary conditions have been identified and the structural evolution of the process was investigated. The research work focused on straight rivers with cohesionless bed and bank material which play a major role in the alpine region. The investigations were carried out on a hydrodynamic numerical model which had to be extended by appropriate equations to reproduce the main sedimentologic processes during river widening. The development and verification of the numerical model were presented in Schmautz & Aufleger (2002) and in Schmautz (2003). Chapter 2 summarises the main features of the model. In this paper, the widening process and the developed method to estimate the maximum river width will be illustrated. 2 NUMERICAL MODEL 2.1 General In principle, the procedure of the numerical simulation of gravel river widening is illustrated in Figure 1. For any time step n the computations of the hydrodynamic, morphological and bank stability modules result in a new bed topography which is the basis for the computations in the next time step n+ 1. For calculating the bed load transport capacity q B * , a threshold formulation according to the Meyer-Peter/

Müller formula is used:

where ρ ′ = (ρ S – ρ)/ρ; ρ S = mass density of bed

particle; ρ=mass density of water; g= gravitational

acceleration; d m =mean diameter of grain; k 1 , k 2 =

constants to be determined by calibration; θ= τ/

(ρ S – ρ)gd= dimensionless shear stress (Shields

parameter); and θ crit = critical Shields-parameter.

2.2 Development works and verification

In addition to typical numerical ‘bed load models’,

special attention is to be paid to the challenges in the

bank regions which are the distribution of the flow

and the shear stress as well as the beginning and the

direction of the bed load transport.

The hydraulic verification of the applied depth

integrated 2D hydrodynamic model has shown that

the main flow processes concerning the lateral ero

sion and thus the bed shear stresses can be reproduced

adequately after calibrating the parameters of the

turbulence model.

Before extending the morphological module to

simulate the erosion process at the banks, extensive

theoretical preparatory work had to be done. The

inception and the direction of the bed load transport

on an arbitrarily inclined geometry which are affected

by fluid and gravitational forces simultaneously were

investigated.

Bank stability and bank failure are included by a

functional approach based on the angle of repose. The

research work focused on bankfull or nearly bankfull

Figure 1. Flow chart for simulating gravel river widening.
discharge where the erosion by the flow is dominant. Bank failure is of inferior importance. The enhanced model was verified and calibrated by ‘recalculating’ several physical model tests and comparing the results of the numerical simulation with the measurements. At this, the fundamental large scale model tests (carried out at the Laboratory of Hydraulic and Water Resources Engineering of the Technische Universität München) served as an essential data basis. The results of the numerical simulation are in very good agreement with the experiments concerning the evolution over time as well as the spatial development and the formation of the profiles. Among the parameters, only the formulation for the direction of the bed load transport was subject to the calibration. The other parameters could be defined by means of preliminary investigations. 3 EVOLUTION OF THE WIDENING PROCESS – RESULTS OF THE PROCESS STUDY 3.1 General The process study aimed at improving the understanding of the widening process (evolution over time and spatial development) and systemising the influence of a few relevant parameters. To this end, simulation runs with well defined parameters were carried out which show the interaction between the changes of the bed level and the river width as well as the development of the water levels, the energy line and the bed load transport in idealised stretches of rivers (Schmautz, 2003). Figure 2 illustrates the basic possibilities to weave a stretch of river with removed bank protection works into the upand downstream river reaches. In the case of coinciding parameters, (a) and (b) just differ in the downstream hydraulic boundary condition. Ways of weaving a stretch of river with removed protection works into the upand downstream river reaches.

3.2 Definition of the river width and the median bed level

To evaluate the simulation runs, characteristic geo

metric parameters had to be defined. As is shown

in Figure 3, parameters that are geometrically well

defined and hydraulically significant, are determined

independently of the initial geometry.

To evaluate the widening, two measures are used.

The width b m characterises a hydraulically relevant

parameter which depends on the actual discharge

among other things. The width b b/2 is hydraulically initial profile h bank /2 widened profile width b b/2 in h bank /2 beneath the oberbank h bank width b m in h m /2 above the median bed level median bed level within b bed z m bed region, width b bed h m 4 h m h m /2 bank region

The flow Q is constant and nearly bankfull in the beginning. As a hydraulic boundary condition, a constant downstream water level was defined so that the flow depth at the downstream end corresponds with the flow depth h normal in the initial state. The reaches A and B only differ in the length L UU which is 832 m in the ‘short’ reach A and 4000 m in the ‘long’ reach B. In both reaches the bed load influx varies between 0 kg/s and 42 kg/s. The transport capacity in the initial geometry is about 120 kg/s. Consequently, the rivers suffer from an influx deficit. In the Figures 6, 7 and 9 percent numbers are given in brackets behind the

influx rates. The meaning of these numbers is explained in chapter 4.4.2. In this paper, only the evolution of the river width and the bed level are illustrated. 3.4 Process and state of equilibrium in river reach A 3.4.1 Development without bed load influx (Figure 5) In the first two days, a degradation of the bed can be observed in the upstream part of the reach. In the downstream part, the bed aggradates due to the influx from 45 55 65 75 0 100 200 300 400 500 600 700 800 length x [m] w i d t h b b / 2 [m] 0.00 0.50 1.00 1.50 b e d l e v e l z m [m] begin 1 d 2 d 5 d 15 d 25 d bed load influx 21 kg/s (50 %)

Figure 6. River reach A, evolution of river width and bed level, bed load influx= 21 kg/s.

the eroding stretch and the simultaneous widening.

Following, the bed load deficit affects the entire reach

and the bed is eroding nearly parallel. The erosion pro

ceeds until the bed load transport comes to rest in the

whole stretch of river (after 100 days).

Within the first days, the widening takes place

evenly within the bigger part of the reach. Already

after 5 days, the widening has finished. The widening

process is controlled by the strong erosion of the bed

and the resulting reduction of the energy slope and

the shear stress which prevents further erosion in the

banks. The process between 5 and 25 days can be char

acterised by a stable bank line (driving shear stress

below critical shear stress) and simultaneous bed load

transport in the bed.

3.4.2 Development with bed load influx= 21 kg/s (Figure 6)

In the upstream third of the reach, an erosion of the bed

can be observed, in the downstream part a durable

aggradation. After 25 days, the bed has reached a sta

ble final state which has a higher level and higher slope

compared to the case without bed load influx.

The widening process lasts considerably longer than

in the case without bed load influx and ceases after 25

days. The greater duration of the widening process and

the greater maximum widening are due to the higher

and stable bed level which prevents a rapid descent of

the bed shear stress in the bank region (like in the first

case).

Thus, the bed load influx exerts strong influence on

the widening process as well as the resulting maximum width. The bed level and the river width after 25 days describe a stable final state of the evolution. The fed bed load moves through the reach without deor aggradation. 3.4.3 Comparison after 25 days depending on the bed load influx (Figure 7) A direct comparison of four simulations runs shows again clearly the influence of the bed load influx. After 25 days a stable state concerning the river width and the bed level is reached in all rivers (except the bed level in the river without bed load influx). The bed level as well as the maximum river width and the maximum widening are significantly affected by the bed load influx. 3.5 Process and state of equilibrium in river reach B 3.5.1 Development without bed load influx (Figure 8) In the entire presented time frame, the reach B degradates in the upper part of the stretch due to the bed load deficit; in the downstream part the river aggradates due to the influx from the eroding stretch and the simultaneous widening. The erosion front is proceeding continuously downstream but does not reach the last third of the stretch during the widening process. The erosion of the bed is not yet finished after the presented 35 days. During the first 5 days, the river widens completely evenly while the bed level rises largely parallel to the 45 55 65 75 0 100 200 300 400 500 600 700 800 length x [m] w i d t h b b / 2 [m] 0.00 0.50 1.00 1.50 b e d l e v e l z m [m] begin 0 kg/s 10,5 kg/s (25 %) 21 kg/s (50 %) 31,5 kg/s (75 %) 42

kg/s (100 %) after 25 days

Figure 8. River reach B, evolution of river width and bed level, bed load influx= 0 kg/s.

initial bed level. At the end of the reach, a marginal

greater widening can be determined which is due to a

higher energy slope as a result of the fixed downstream

boundary condition.

Following, the river width increases until a max

imum widening after 35 days is attained. Between

3000 m and 3500 m the widening reaches a constant

value which exceeds the maximum value in river reach A clearly. The longer duration of the widening of 35 days compared to 25 days in reach A also originates from the greater maximum widening. 3.5.2 Comparison after 35 days depending on the bed load influx (Figure 9) A direct confrontation of the final state in dependence on the influx rates reveals the small influence of the

bed load influx on the process compared to the ‘short’

river reach A.

After reaching the final state (after 35 days), differ

ences in the bed level and the river width are evident

in more than half of the stretch of river. Higher bed

load influx leads to higher bed level and river width.

In the last third of the reach however, only negligible

deviations can be determined. Apparently, the stretch

of river with a length of 4000 m is long enough to satu

rate the bed load transport capacity in the downstream

third during the relevant period of widening. Thus, an

erosion of the bed is prevented independent of the bed

load influx.

3.5.3 Evolution of the profile at x= 3200 m (Figure 10)

At the station x= 3200 m, the widening and the defor

mation of the profile proceed approximately under

saturation of the bed load transport capacity. The

advancing widening comes along with a progressing

raising of the bed level. The transfer of the bank mate

rial to the bed region takes place under conservation of

mass during the first days. The final state can be char

acterised by a stable bank line (driving shear stress

below critical shear stress, vanishing bed load trans

port) and simultaneous bed load transport in the bed

region.

3.6 Main conclusions

The summarised conclusions go beyond the illus

trations herein and include the findings made in

Schmautz (2003). The parameters ‘bed load influx’, 45 55 65 75 0 500 1000 1500 2000 2500 3000 3500 4000 length x [m] w i d t h b b / 2 [m] 0.00 1.00 2.00 3.00 4.00 5.00 6.00 b e d l e v e l z m [m] begin 0 kg/s 10,5 kg/s (25 %) 21 kg/s (50 %) 31,5 kg /s (75 %) 42 kg /s (100 %) after 35 days

Figure 9. River reach B, river width and bed level after 35 days depending on the bed load influx. ‘length of the stretch’and ‘downstream boundary condition’ affect the

widening process and thus also the final conditions significantly. Among other things, the following fundamental findings can be formulated: – The resulting maximum river width is increasing with the length of the stretch until a maximum possible value is reached. – With rising bed load influx, higher bed and water levels as well as greater river width result. For a sufficient length of the stretch, the maximum final width is independent of the given influx. – If the water level at the end of the stretch is raised by a tailback from the downstream reach or by a weir or ramp, higher bed levels result compared with the case without tail-back. The maximum final width is smaller. – During the widening process and also in a possible state of equilibrium, the water levels can lie significantly above those in the initial situation. 0 2 4 6 051015202530 35 4045 width y [m] h e i g h t z [m] begin 1 d 2 d 5 d 15 d 25 d 35 d S A water level after 35 d Figure 10. 4 PARAMETER STUDY – METHOD TO ESTIMATE THE MAXIMUM RIVER WIDTH

4.1 General

4.1.1 Overview

On the basis of the qualitative insights into the widen

ing process and the influence of relevant parameters

summarised in chapter 3, a method was developed

to quantify the maximum river width that has to be

expected in a river reach during the widening process.

The basic idea and the scheme of the method are

illustrated in Figure 11. The calculation is based

exclusively on well known geometric, hydraulic and

morphologic input variables and is executed in three

steps. In the first two steps, the ‘regime width’ and

the ‘regime length’ – two characteristic reference

values – are computed from the initial geometry,

a constant, dominant discharge and a median grain

diameter. In the third step, the actual width which is

reached in a stretch of river can be determined with

the aid of dimensionless diagrams depending on fur

ther parameters (length of the stretch, bed load influx

and downstream hydraulic conditions).

4.1.2 Premises for the applicability of the method

The method is limited to rivers without distinctive

morphological structures (bars or braiding). The bed

load influx may not exceed the transport capacity in

a river with regime conditions. The impact of river

bends is not taken into account. The hydrology has to

be idealised by a constant dominant discharge. I 0 L UU

Figure 11. Flow chart to determine the maximum river

width. 4.1.3 Underlying parameters The following ranges of
the parameters form the basis of the parameter study: –
initial slope I 0 0,5% to 2,0% – initial bed width b bed,0
12 m to 80 m – initial bank height h bank 1 m to 4 m – med.
grain diameter d m 12 mm to 63 mm 4.2 Regime width b ∗ eq
By definition, b ∗ eq names the width b m (for the
definition of b m see Figure 3) that is reached in a ‘very
long’ river reach (so called ‘equilibrium stretch’).
Thereby, ‘very long’means that the development in the
observed part of the reach is not affected by the upand

downstream boundary conditions. By dimensional analysis and analytic derivations (Schmautz, 2003), the following dependency of b ∗ eq on the parameters could be found: where Q= discharge; I 0 = initial bed slope; k Str = Strickler-value; ρ ′ = (ρ S − ρ)/ρ; ρ S =mass density of bed particle; ρ=mass density of water; and d m =mean diameter of grain. As a new parameter, θ m,U has been introduced and identified, which characterises the end of the widening process in the ‘equilibrium stretch’. The final stable state can be characterised by a stable bank line (driving shear stress below critical shear stress, vanishing bed load transport) and simultaneous bed load transport in the bed region. For this stable state, θ m,U is evaluated as the median Shields-parameter in the bed region. Figure 12 shows the parameters and their evaluation at the example of the geometry used in chapter 3 (see Figure 4). f U defines a further parameter which describes the relation of θ m,U and the critical Shields-parameter: 0 2 4 -5051015202530354045 width y [m] 0 0.02 0.04 0.06 0.08 θ 1/2 b bed q B θ m,U geometry inflated by factor 2 1/2 b∗ eq S A S h i e l d s p a r a m e t e r θ [ ] h e i g h t z [m] t r a n s p o r t q B [k g / (m s)] Figure 12. where k 2 = constant in Meyer-Peter/Müller formula;

and θ crit = critical Shields-parameter.

The realised parameter study has shown f U to be mainly a function of the width to depth ratio b ∗ eq /h m as is depicted in Figure 13. The dependence on the angle of repose is negligible.

The determination of the regime width b ∗ eq by the equations (2) and (3) and by Figure 13 requires an iterative computation.

The so called ‘regime bed load transport’ Q B,b*eq in the ‘equilibrium stretch’can be computed e.g. with the aid of the Meyer-Peter/Müller formula:

where b bed ≈ b ∗ eq – 6h m .

4.3 Regime length L b ∗ eq

In the process study, a relevant influence of the length L UU on the resulting river width has been identified. With L b ∗ eq , a characteristic length of the widening process is introduced.

The determination of the regime length L b ∗ eq is illustrated exemplary in Figure 14 again on basis of the geometry, morphology and hydrology used in the process study (see Figure 4). The ordinate describes

the ratio of the maximum widening (b ′ – b 0) to the widening to the regime width (b ∗ eq – b 0). An ordinate value of 1.0 means a resulting width of b ∗ eq . Every point in Figure 14 represents a simulation run for a river reach with a defined length and without bed load influx. Greater length leads to greater river width until a maximum value above b ∗ eq is reached. The widening to a value greater than b ∗ eq is due to a higher energy slope as a result of the fixed downstream boundary condition (constant downstream water level so that in the beginning, the flow depth at the downstream

Figure 16. Maximum widening of the river depending on the length of the river reach. definition of L b ∗ eq , the region of the linear increase is utilised. Within the parameter study, the dependence of the regime length on the parameters could be identified and depicted in a dimensionless diagram (Figure 15). 4.4 Width b ∗ With the regime width b ∗ eq and the regime length L b ∗ eq , characteristic parameters of a river reach have been defined and determined. It remains to quantify the actual maximum width b ∗ which results during the widening process depending on the reach length and the bed load influx. The effect of the downstream

= 25 % Q B,% = 0 % Q B,% = 100 % Q B,% = Q B,in / Q B,b∗eq [%] in parameter study

Figure 17. Maximum widening of the river depending on the length and the bed load influx.

hydraulic boundary conditions is not illustrated herein.

The downstream water level is constant so that in

the beginning, the flow depth at the downstream end

corresponds with the flow depth h normal .

4.4.1 Width b ∗ without bed load influx

The maximum width b ′ which results in a river reach

without bed load influx was already used to determine

the regime length. The results of all simulation runs

are illustrated in Figure 16 in dimensionless form. The

ordinate represents the ratio of the maximum widening

(b ∗ -b 0) to the widening to the regime width (b ∗ eq -b 0).

On the abscissa, the length L UU is scaled by the regime

length L b ∗ eq .

The interrelationship can be approximated by a

straight line running from (0/0) to (1/1) (except

L UU /L b ∗ eq > 0, 75).

4.4.2 Width b ∗ with bed load influx

Besides the reach length, also the bed load influx

influences the maximum widening relevantly (see

chapter 3). To formulate a relationship between the

reach length, the bed load influx and the widening, the

influx rates have to be made comparable. As a refer

ence value, the regime bed load transport Q B,b * eq is

dedicated analog to the regime width and the regime

length. The bed load influx can thus be expressed

in dimensionless form and in percent Q B,in /Q B,b * eq ,

respectively.

Within the parameter study, influx rates of 25%,

50%, 75% and 100% were investigated.The results are

plotted in Figure 17, again in the well-known way. The

regression lines run parallel to the line of no influx.The

Flow in meandering bends

D. Termini

Dipartimento di Idraulica ed Applicazioni Ambientali,
Universitã di Palermo, Palermo, Italy

ABSTRACT: The analysis of flow in bends may be considered as one of the key problems in studying river

morphology. In this paper the first results of an experimental investigation of flow around a meandering bend have

been reported.The experiments have been carried out in a laboratory meandering channel of large amplitude, both

over an immobile flat bed and over an erodible bed.The analysis of the collected data confirm that when the aspect

ratio is small the cross-circulation assumes a great importance. In particular, in the case of deformed bed, it seems

that a second counter rotating secondary flow cell appears along the bend near the outer bank. When the aspect

ratio is large the convective acceleration terms associated with downstream changing channel curvature cannot

be neglected in the force balance equation. The stream-wise

acceleration of the downstream velocity component is important throughout the bend assuming greater significance when the radius of curvature decreases.

1 INTRODUCTION

Accurate specification of the spatial distribution of bottom stress and flow velocity is of crucial importance in calculation of erosion and deposition zones along the channel. Erosion and deposition, in fact, depend on the divergence of sediment flux (Nelson and Smith, 1989), that is, in turn, related to the characteristics of the flow which erodes the channel itself (Schumm, 1963; Schumm et al., 1972; Hooke, 1975; Jackson, 1975; Chang, 1988; Renz and Jun, 1989). A natural meandering stream represents one of the most complex flow situations: not only it is turbulent and strongly three dimensional, but its irregular topography is continuously changing as results of erosion and deposition processes. In studying such a complex problem, it is necessary to identify the aspects that mainly affect the characteristics of flow and to focus the attention only to their analysis.

Meandering channels are characterized by a downstream changing curvature that strongly affects the hydrodynamic processes along the channel itself. When the flow enters in the bend, a secondary motion is produced by the interaction of the forces associated

with centrifugal acceleration, transverse water sur

face slope and shear stress (Yen 1972). In accordance

with Yalin (1992), in a sinuous channel the secondary

motion can be considered as the combination of two

motions: the elicoidal motion, that consists in a paral

lel longitudinal motion upon which cross-circulation is

superimposed, and the so-called convective accelera

tion. The first component, to which corresponds a zero

specific cross-flow rate, is inducted by the channel curvature; the second component is indeed due to the stream-wise changing curvature. Thus, because of the variable curvature of the channel, the distribution of velocity vectors on the bed is not uniform and convective accelerations occur. Clearly the channel plane shape affects significantly the magnitude of the aforementioned components. A large amount of research on flow in bends has been performed. In most of the experimental investigations a fixed rectangular cross-section with flat bed has been considered and, thus, different hydraulic conditions from the flow over a deformed bed have been analyzed. Furthermore, constant curved channels have often been used for the experiments (Rozovski, 1965; de Vriend, 1979; Odgaard and Bergs, 1988) and only fully developed channel regions have been examined. On the basis of the experimental observations, some authors (Yen, 1972; Engelund, 1974; Kikkawa et al., 1976; Francis and Asfari, 1978; Zimmerman and Kennedy, 1978) have emphasized the effect of cross-circulation on bed deformation, neglecting the convective accelerations associated to the channel changing curvature. Other experimental works carried out in meandering channels (Hooke, 1975; Whiting and Dietrich, 1991;Whiting and Dietrich, 1993 a, b), apart from field observations (Lewin, 1972; Jackson, 1975; Bridge and Jarvis, 1976; Thompson, 1986), have highlighted the effect of the flow convective accelerations due to the downstream changing topography and the contribution to the total force balance for a meandering stream. Recently, Blanckaert and Graf (2001) performed a series of experiments in a constant curved channel with

small aspect ratio (B/h= 3.6, where B= channel width

and h=water depth). The authors analysed the inter
action between the stream-wise flow velocity and the
secondary flow and established that the cross-sectional
motion is composed by two cells of circulation: a
center-region cell (related to the classical elicoidal
motion) and a second counter-rotating cell appearing
near the outer bank. The counter-rotating cell acts as
a stabilising region between the center region and the
outer bank.

On the other hand, some results previously obtained
by the author of the present work (Termini, 1999 a, b),
in a large amplitude meandering channel, have high
lighted that, for large values of the aspect ratio, the
convective accelerations due only to changing channel
curvature (over flat bed), play the most important rule
on the force balance. Thus, in this case, the changing
channel curvature is considered the key effect in order
to predict the localization of erosion and deposition
zones along the channel itself.

In this work the attention is focused to evaluate the
importance of cross-circulation and convective flow
acceleration on bed deformation and channel migra
tion, for different aspect ratios. The paper gives a
description of some recent experiments conducted,
in order to analyze the hydrodynamic characteristics

of the flow along the bend, in the laboratory meandering channel constructed at D.I.I.A. (Dipartimento di Ingegneria Idraulica ed Applicazioni Ambientali) of Palermo's University (Italy).

Intensive study has been devoted to the erosion zone that develops along the outer bank of the meandering bend. Here, in fact, multiple pools, that can be associated with features called "shingle bars" (Lewin, 1972; Whiting and Dietrich, 1993 a, b), have been observed. These features migrate downstream into the straight reaches connecting the meandering bends. Some authors (Parker and Joanneson, 1989) interpreted them as member of a family of alternating periodic responses to the impulsive forcing by the change in curvature at the bend entrance.

In order to isolate the effect of the channel changing curvature from the effect of the bed topography on flow pattern, the experiments have been conducted both over a flat bed and over an erodible bed. In both cases, the local flow velocity components have been measured along the meandering bend, in order to evaluate the cross-circulation significance and the forcing effect of the bed topography.

2 EXPERIMENTAL INSTALLATION

The experiments were performed in a meandering

laboratory channel that follows the sine-generated

curve with a deflection angle of 110 ∘ . The chan

nel cross section was rectangular with width, B, of 0.50 m. The channel axis was 23,46 m long and the channel banks were of clear 0.2 cm thick plexiglas strips. The bed of the channel was of quarts sand (D 50 = 0.65 mm, D 16 = 0.55 mm and D 84 = 0.90 mm), with longitudinal bed slope of channel axis equal to S= 0.371%. The plan view of the meandering laboratory channel is reported in Figure 1. Water entered the channel by the return pipe C connecting the pumping tankA to the head divergent D.Then, the water flowed in the straight channel (inflow channel) until to reach the meandering channel reach. In the erodible bed experiments, both the water and the sediment were recycled. They were discharged from the channel into the pumping tank A. Two runs, called Run 1 and Run 2, characterized respectively by a “small” aspect ratio (B/h= 9.6< 10) and a large aspect ratio (B/h= 16.6> 10), have been carried out both over the flat immobile bed and over the erodible bed. For the flat bed runs, the sand on the bed was impregnated with spray paint which preserved the grain roughness and did not allowed the bed deformation. Table 1 presents the hydraulic conditions for each run: Q indicates the flow rate, h is the water depth, Re∗ is the roughness Reynolds number, Fr is the Froude number. During each run, the flow velocity components and the water depths were measured. Intensive study was made especially along the channel reach between section 7 and section 31 (see Figure 1); some other sections (“control sections” 37, 43) have also been Return pipe pump Meandering channel Regulation valve 25 19 31 37 43 D 0.75 3.00m 0.50 V 6.60 6.50 0 1.00m 5.14 2.00 P V 1 A O B 13 C Concrete basement 7 7 Figure 1. analyzed in order to check the periodicity both of the

water depth and of the flow velocity. The local flow

velocities were measured in nine verticals of the mea

surement sections both by using a 2D side-looking

probe Acoustic Doppler Velocimeter (ADV) and by

using an Ultrasonic Doppler Velocimeter (DOP2000), that allows to measure instantaneous flow velocity pro files. The DOP2000 was especially used for deformed bed runs, where very small water depths occurred along the inner bank of the curved reaches and the ADV did not provide accurate measured data.

Furthermore, both the flow velocity components and the bed topography measured during previous experiments carried out in the same meandering labo ratory channel (Termini, 1999 a, b, c) have also been used in this work (Run 3 of Table 1); the local flow velocity components were measured along the chan nel reach between section 19 and section 31, by using a propeller.

During each experiment, the water depth was also measured by using a point gage, opportunely attached to a portable carriage that traversed the channel.

3 ANALYSIS OF MEASURED DATA

3.1 Flat bed experiments

Flat bed experiments have been carried out in order to isolate the effect of the downstream changing channel curvature and, thus, to analyze how it influences the kinematic characteristics of the flow.

The velocity measurements were made in 17 sec tions (measurement sections), distant each either

50 cm or so, along the channel reach between section 7 and section 31 (Figure 1). The data have been analyzed assuming a local reference system with longitudinal axis (s) pointing downstream, transverse axis (r) pointing to the inner bank and vertical axis (z) pointing upward.

The analyses of the vertical profiles of the measured longitudinal velocity components (v s) highlights that when the aspect ratio B/h is less than 10 (Run 1), v s assumes the maximum value at a water level z= δ< h; when B/h> 10 (Run 2), v s has the maximum occurring at a water level z= h. This is in accordance with Blanckaert and Graf 's (2001) findings (B/h< 10), where the maximum of longitudinal flow velocity was found close to the outer bank and below the water surface.

As an example, in Figures 2a-2b the vertical profiles of the longitudinal velocity component measured near the channel axis, during Run 1, respectively at the inflection section (section 19) and at the apex section (section 25), are reported. Analogously, in Figures 2c-2d the corresponding vertical profiles measured during Run 2 are also shown. The measured data of the longitudinal flow velocity component have been interpolated with the logarithmic velocity distribution law: where v ∗ is the shear flow velocity, κ is the Von Karman's constant, ν is the water viscosity, k s is the representative roughness height and is a function vs (cm/s)

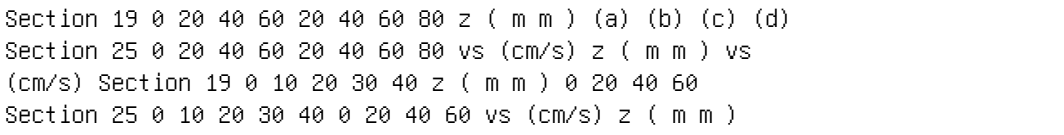

Figure 2. Longitudinal velocity profiles.

that for smooth wall is equal to 5.5 and for absolutely

rough wall is estimated as:

The value of the local shear velocity, that is a param

eter of the logarithm laws (1), has been estimated by

data-fitting.

Figures 2a-2d clearly show that in the case of

B/h< 10 (Run 1), the logarithmic law can be fitted

to data measured in the range 0< z<δ; in the case of

B/h> 10 (Run 2), the logarithmic law can be applied

over the entire flow depth.

Furthermore, Figures 3a-3b present the spatial dis

tributions of the velocity vectors measured, during

Run 1, along the channel reach between section 19 and

section 31, respectively near the bed (z= 0.8 cm)

and near the free surface (z= 4.0 cm); Figures 3c-3d

present the corresponding distributions measured, dur

ing Run 2, respectively at z= 0.8 cm (near the bed) and

at z= 2.0 cm (near the free surface).

The plane distributions of the measured veloc

ity vectors highlight that in both cases (Run 1 and

Run 2), the maximum of flow velocity lies, at the bend

entrance, at the inner bank. Along the bend, it crosses

the channel and, at the downstream inflection section, it is at the outer bank. At the apex of the bend the plane distribution of flow velocity is almost uniform.

Previous experiments carried out by Leschziner and Rodi (1979) in a constant strongly curved channel (R/B= 1, where R is the radius of curvature of the channel centerline) have shown that the maximum of longitudinal velocity, v s , occurred always near the inner bank. Blanckaert and Graf (2001) observed, in a constant curved channel with R/B= 5, the maximum velocity component v s occurring close to the outer bank and in the lower part of the flow depth.

The meandering channel considered in the present work is characterized by a variable ratio R/B passing from a very large value at the inflection section to a small value at the apex section. The spatial distribution of the flow velocity vectors highlights an intermediate behavior: the maximum is found near the inner bank where the ratio R/B is large; then, decreasing the ratio R/B, it moves toward the outer bank, that is reached at the inflection section downstream, where the ratio R/B is large but with negative sign. In the inflection section one wave-length distant, the maximum of flow velocity is found again at the inner bank.

The described pattern of flow velocity vectors high

lights the convective behavior of the flow. The flow, in

fact, passing from section 19 to section 31 (Figures 3a-

3d) accelerates at the outer bank and decelerates at the

inner bank. Thus, it can be concluded that because of

the acceleration in the upstream bend, flow enters in (a) (b) (c) (d) Figure 3. Plane distribution of velocity vectors. the reach starting from section 31 with highest velocity near the outer bank. Moreover, Figures 3a-3b show that, when B/h< 10, the cross-circulation is significant: the velocity vectors near the free surface are oriented in the opposite direction (outward) to the velocity vectors near the bed, that are oriented inward. When B/h> 10 (Figure 3c-3d) the velocity vectors near the bed and those near the free surface are almost oriented in the same direction. Figure 4. Measured vertical transverse distributions.

The magnitude of the cross-circulation has been

also observed by the vertical profiles of the measured

transverse flow velocity components (v r). As an exam

ple, Figures 4a-4d present the vertical profiles of v r

measured, both during Run 1 (Figures 4a-4b) and dur

ing Run 2 (Figures 4c-4d), at section 25 (apex section)

and at section 19 (inflection section). As it is shown,

when B/h< 10 (Run 1), the vertical distributions of

the transverse velocity component show a change of

sign passing from the bed to the free surface and

the cross-circulation is significant. Anyway, because

of the convective component is not null, the trans

verse velocity distributions cannot be approximated by theoretical laws (Rozovski, 1965) estimated in fully developed regions, where the convective terms have been neglected. When B/h> 10 (Run 2), the vertical distributions of the transverse velocity component (Figures 4c-4d) do not show a clear change of sign passing from the bed to the free surface. The crosscirculation is very small and the convective velocity component becomes significant. 3.2 Deformed bed experiments During the deformed bed experiments, the bed surface, visible by the clear Plexiglas walls, was intermittently monitored at the outer bank and at the inner bank of the channel by tracing the bed surface on the clear channel walls. Furthermore, the evolution of the bed deformation in time and the variation of the bed surface at the banks were filmed during the experiment. The flow velocity measurements were carried out only after the equilibrium bed configuration was reached. It was reached when, as described in previous works (Termini, 1999 a, b, c), both the water-surface slope and the gross bed geometry did not change in time. Along the curved reach, the stable average bed topography presented a front of deposit near the inner bank and a global erosion zone near the outer bank. Furthermore, a series of pools (distant each either almost 1 m) appeared at the outer bank. Each pool is considered as part of a bed-form that is similar to the bar unit developing in straight channels, but with front of deposition occurring always at the inner bank of the bend. These bars, superimposed on the average pattern of the bed, migrated along the bend and the bed levels at the outer bank varied continuously in time. Details of the stable bed topography estimated at the end of Run3 can be found in previous works (Termini, 1999a; Franco et al., 1997). In deformed bed experiments, the local flow velocity components have been measured only during Run 1. The measurements have been carried out by

using DOP2000, because very small flow depths appeared at the inner bank, where the global front of deposition occurred. The same measurement sections selected for the flat bed experiments were considered. For the analysis of data collected in deformed bed experiment, particular attention has been focused to the half cross-section near the outer bank (erosion zone), where the series of pools appeared. In Figure 5 the vertical distributions of the transverse velocity components measured at the transverse abscissas r= 8.5 cm, r= 14 cm and r= 25 cm of section 25 are reported. In Figure 6 the vertical distributions of the vertical velocity components measured at the same transverse abscissas are also reported. As Figure 5 shows, the vertical distributions of the transverse velocity confirm the formation of a significant r = 8.5 0 10 20 30 40 50

Figure 7. Horizontal profiles at different water depths of the time averaged velocity components: (a) transverse component; (b) vertical component. Furthermore, the distributions of the vertical velocity component, showed in Figure 6, highlight that at the transverse abscissa r= 8.5, i.e. near the outer bank, the vertical velocity has a negative sign in the higher part of the cross-section. This could reveal the existence of a counter-rotating secondary flow cell, in accordance with previous findings (deVriend, 1981; Blanckert and Graf, 2001; Booij, 2002) obtained in constant strongly curved channels. Blanckert and Graf (2001) attached a great importance to the counter-rotating formation that exerts a protective effect on the bank and reduces the level of the flow turbulent activity. The aforementioned second flow circulation cell can be also examined in Figures 7a-7b, where the horizontal profiles of the transverse velocity component and of the vertical velocity component are reported, respectively. Both the negative values (vector pointing to the outer bank) of the transverse velocity component, v s , and the negative values of the vertical velocity component, v r , appearing near the free surface and at the outside part of the cross-section could confirm the existence of the second counter-rotating circulation flow cell (the first is the cross-circulation, related to the classical elicodal motion), that develops near the outer bank. Figures 8 and 9, where the isocontours of the transverse velocity component and of the vertical velocity component are reported respectively, show clearly the

aforementioned trend and the presence of a rotating cell at the upper outside riverbank.

In Figure 10 the isocontours of the transverse velocity component measured over the flat bed have also been reported. The comparison between Figure 8 (over deformed bed) and Figure 10 (over flat bed) highlights that the second flow circulation cell, forming at the outer bank (erosion zone along the channel), is produced as result of the bed deformation: it does not appear when the bed is flat. In this last case, in fact, Figure 10 suggests that an unique cell of circulating secondary flow develops along the bend: the contour 5 10 15 20 25 30 35 40 45 Figure 10. cross-section. Furthermore, Figures 8 and 9 highlight the presence of a third isolate circulation cell, that forms near the bed, where the pools occur. Figures 11 and 12 show the isocontours of the transverse velocity component measured at the inflection section (section 31), respectively over the deformed bed and over the flat bed; the isocontours of the vertical velocity component measured at the same section with deformed bed are reported in Figure 13. It can be observed that also at the inflection section the bed topography affects the transverse velocity distribution producing a circulating zone at the outer bank, both

near the bed and near the free surface. This circulation is less evident than that produced at the apex section.

4 CONCLUSION

Experimental investigations in a meandering laboratory channel of large amplitude have been carried out in order to analyse the secondary motion characteristics. The experiments conducted with flat bed have mainly shown that: (1) when the aspect ratio B/h is less than 10 (Run 1) the maximum value of the longitudinal flow velocity component occurs at a water level

On the validity of analytical approach to river regime

B. Mengoni & E. Paris

Department of Civil Engineering, University of Firenze, Italy

R. Bettess

HR Wallingford, Howbery Park, Wallingford, Oxfordshire, UK

ABSTRACT: The analytical approach to river regime of White et al. (1982) has been analyzed and the validity

of the extremal hypothesis has been verified. A modified version of the original method is here proposed in order

to improve prediction capability. To this aim, the original trapezoidal cross section has been changed, employing

the analytical geometry for stable channel proposed by Cao & Knight (1998). The modified method appears to be

still coherent with the extremal hypothesis, and provides better agreement if compared with field and laboratory

tests on stable non cohesive straight channels.

1 INTRODUCTION

The shape and the dimension of the cross section of a

self formed channel is the result of the complex inter

action between flowing water and mobile particles that

compose bed and banks.

Despite numerous contributes, the prediction of the stable channel configuration is still an active field of research, where yet no clear agreement about the methods is achieved.

Firstly, simple empirical methods were developed using data from field and laboratory observations, obtaining regime equations (Lindley 1919, Simon & Albertson 1963, Blench 1969) that have been used for long time. However, the typical shortcomings of the empirical methods, have induced many researchers to investigate the processes involved and formulate new approaches.

A more rational approach, known as tractive force method was developed on the assumption that in a stable configuration all the particles were in incipi ent motion condition (Glover & Florey 1951, Lane 1955). Nevertheless, experiments on straight stable channel with coarse non cohesive sediments (Wolman & Brush 1961), have showed that the concept of static equilibrium is not realistic and instead is possible the existence of a dynamic equilibrium, for which the sedi ments are actively transported in the central bed region and bed load vanished in sidebank regions.

Later, more physically based approaches were pro posed by several Authors in an attempt to describe the

regime conditions using the basic equations for water

and sediment transport. In particular, the extremal hypothesis combined the friction factor equation and sediment transport equation with an extra one, based on the maximization or minimization of a certain parameter (Chang 1980, Yang et al. 1981, White et al. 1982, Yang 1992, Millar & Quick 1997, Cao & Knight 1997, Millar & Quick 1998). Even if the predictions based on this approach are generally in agreement with large range of observations, the theoretical justifications for such hypotheses are still not clear, and suggests a further investigation. More recently, approaches based on the employment of basic laws of mechanics have been proposed. Parker (1978b) noticed that the tractive force theory could not be able to describe the case of an activebed gravel river; in fact, as long as bed load exists in the central region some grains on the banks must also be in motion causing bank erosion and indefinitely widening of the cross section. Parker termed this the “stable-channel paradox” and solved the problem introducing lateral momentum transfer due to the turbulence, obtaining in this way, a lateral redistribution of bed shear stresses. Parker (1978a) introduced also the case of straight sand river, where sediments are actively transported as bed load and as suspended load, considering a balance of lateral bedload and lateral diffusive transport of suspended sediments. Ikeda et al. (1988) introduced the effects of heterogeneous bed material on gravel river, Ikeda & Izumi (1991) formulated a more rigorous approach for sand rivers, Diplas & Vigilar (1992) reformulated the problem of threshold channel where the shape of the banks is not assumed but become part of the solution;

Cao & Knight (1998) considered the contribution of

the secondary currents.

Other contributions considered the time evolution

of an initially trapezoidal channel toward a steady

stead configuration: experimental data for uniform

sediments were collected by Ikeda (1981) and Diplas

(1990), for heterogeneous material by Ikeda & Izumi

(1991), for bankfull and overbank flow by Valentine

et al. (2001) and Valentine & Ershadi (2003).

Straight channel time evolution has been formu
lated in analytical and numerical way: Pizzuto (1990)
presented a numerical method for gravel channel in
case of bed load transport. He predicted the shear stress
distribution employing the modified area method of
Lundgren & Jonsson (1964), then calculated the evo
lution of bed topography and the bank failure in case
of side slope steeper than repose angle. Schippa (1991)
presented an analogous numerical model considering
suspended load and lateral flux of sediment com
ing from collapsed banks. Kovacs & Parker (1994)
developed a fully mechanistic mathematical model to
simulate the evolution process due to bank erosion in
case of bedload only.

In this paper, a review of the validity of the extremal
hypothesis is carried out by analyzing the White et al.
(1982) method. A modified version of the method is
proposed by adopting a new cross section geometry.
Comparisons of predicted values with experimental
results (Valentine et al. 2001) and with field data of
non-cohesive gravel and sand streams (Parker 1978b,
Parker 1995) have been performed.

2 FORMULATION OF THE PROPOSED METHOD

In the approach of White et al. (1982), in the following cited as WBP method, the determination of the stable cross section was achieved analytically by employing the flow and sediment transport equations, and assuming the minimization of the slope. The calculations were performed considering a rectangular shape, then adjusted to a trapezoidal one of the same cross sectional area. The bed and bank material have been assumed uniform and homogeneous.

However, several experimental observations (Ikeda 1981, Ikeda et al. 1988, Diplas 1990, Valentine et al. 2001) and numerical simulations (Kovacs & Parker 1994) have demonstrated that the trapezoidal configuration is not stable and always evolves toward a smoother shape. Moreover Valentine et al. (2001), obtained laboratory cross section clearly wider and shallower than that predicted by the WBP method, even if characterized by the same hydraulic area. For this reason, the cross section geometry of the WBP method has been modified, employing a new shape more similar to the one observed in laboratory test.

According to different theories, several shape of bank zones have been proposed in the last years: a cosine curve profile was obtained by Parker (1978a,b), Ikeda et al. (1988) and Pizzuto (1990); an exponential function was obtained from the regression on the experimental data by Ikeda (1981) and by Diplas (1990); a fifth-degree polynomial came from the numerical approach of Diplas & Vigilar (1992); a parabolic profile has been also proposed by several researchers (Chow 1959, Cao & Knight 1998a,b).

Cao & Knight (1998) obtained an analytical expression of the cross section profile on the basis of entropy maximization principle. This geometry has been chosen to modify the WBP method and it is characterized by the following equations (Fig. 1): where L= bank zone width; b= central bed width; W = total surface width; Y c = central channel depth; Ω= flow area; P=wet perimeter; φ= repose angle; μ= tang φ coefficient of static friction. The regime cross section corresponding to a set of given values of water discharge Q, sediment concentration X and sediment size Ds, is obtained by combining the above expressions of geometry (1, 2, 3) and the following flow resistance formula (White et al. 1980) and sediment transport formula (Ackers & White 1973): b LL W Y c Figure 1. New employed geometry characterized by flat central region and parabolic banks (proposed by Cao & Knight 1998).

follow:

2.1 Analysis of the proposed method

Results of several numerical runs using the new geom

etry still confirm the existence of a minimum of the

slope.A comparison between data obtained employing

the original WBP method and the method modi

fied with the Cao & Knight (1998) geometry (in the

following cited as WBP-M method) has been carried

out for different sets of Q, X , D. The comparison is presented in terms of the dimensionless variables defined as follow: As shown in Figure 2, the WBP-M cross sections are constantly wider than the predicted by the original WBP method, while depth values (Fig. 3) do not seem to change

significantly. A further investigation on the variability of the hydraulic parameters in the vicinity of the stable configuration has been carried out to explore the presence of extremal values other than the minimum of slope. A range of width-surface variation within the 60% of the regime value has been considered. Figures 4 and 5 show the hydraulic variables (made dimensionless with the corresponding regime values) for a set of given data (Q= 200 m 3 /s, X = 100 p.p.m., D= 0.4 mm). It can be observed that, except the slope, no other variable presents an extreme value: all the functions are monotonous respect to width variation. Only the Chezy coefficient C seems to have a roughly constant value for any cross section (Fig. 5). The coherence of the modified method has been also tested analyzing the condition of vanishing sediment transport. In this case the cross section cannot self adjust and therefore no minimum value of slope is not expected. In Figure 6, the hydraulic variables Y c , 0.0E+00 5.0E+04 1.0E+05 1.5E+05 2.0E+05 0.0E+00 5.0E+04 1.0E+05 1.5E+05 2.0E+05 W dim WBP W d i m W B P M Q = 10 m³/s Q = 20 m³/s Q = 50 m³/s Q = 100 m³/s Q = 200 m³/s Figure 2. Slope and Chezy coefficient for a set of cross sections (Q= 200 m 3 /s, X = 0 p.p.m., D= 0.4 mm, φ= 29 ∘). R, U , , τ have been shown for the case of

X = 0, Q= 200 m 3 /s, and D= 0.4 mm. It is still present a monotonous pattern of the hydraulic variables, including slope (Fig. 7). The above analysis refers to the hydraulic parameters in terms of the cross section averaged values.A further investigation has been carried out in terms of local depth averaged values using a numerical model based on the depth-integration of the Reynolds-averaged Navier-Stokes equations in the form proposed by Shiono & Knight (1989): where ρ= fluid density; H = local depth normal to the bed; h=water level; x= streamwise direction; y= transversal direction; U = streamwise velocity; V = lateral velocity; τ b = bed shear stress; τ xy =Reynolds stress;β= coefficient for the influence of lateral bedslope on bed shear stress.

(Q= 200 m 3 /s, X = 100 p.p.m., D= 0.4 mm, φ= 29 ∘). Crit

ical shear stress τ cr and cross section averaged value τ av are

also shown.

All terms of (14) are developed as function of unit

flow rate q, in order to obtain a second order, non

linear, non homogeneous, elliptic, partial differential

equation that is solved employing a numerical tech

nique based on a finite element method (Defra et al. 2003).

The numerical model, for a given geometry, slope and water depth, provides the corresponding depth averaged hydraulic variables along the transversal coordinate. As example, referring to the regime cross section corresponding to the set of data Q= 200 m 3 /s, X = 100 p.p.m, D= 0.4 mm, the results of the numer ical model in terms of bed shear stress distribution are shown in Figure 8.

It can be observed that the local shear stresses are higher than the critical value in the major part of the bank zone. This disagrees with the Cao and Knight stable cross section hypothesis, according to which the banks should be everywhere in threshold conditions with active sediment transport only in the central bed zone.

2.2 Comparison with laboratory and field data

The WBP-M approach has been tested using both field (Parker 1978b, Parker 1995) and experimental data (Valentine et al. 2001).

Valentine et al. (2001) performed experiments in a large laboratory-scale straight non cohesive chan nel, observing that cross sections predicted with the original WBP approach were too narrow and deep if

compared with laboratory results.

Using the WBP-M method, prediction reliability

has been improved: stable sections have become wider

and shallower and thus in better agreement with exper

imental data. In Table 1 and 2 are summarized the two

considered runs byValentine et al. (2001) together with

the results of the proposed method where the input data

for WBP-M method were assumed Q, D 35 , S, φ. Table 1. Laboratory data (Run 300695, Valentine et al. 2001) and WBP-M results. Experimental WBP-M Q [l/s] 25.0 25.0 D 35 [mm] 0.74 0.74 S [%] 1.83 1.83 [∘] 11.5 11.5 W [m] 1.76 1.39 d [m] 0.045 0.07 L/W [%] 15 49 U [m/s] – 0.39 X [ppm] – 49.9 τ [N/m 2] – 0.84 τ cr [N/m 2] 0.46 0.46 Table 2. Laboratory data (Run 110595, Valentine et al. 2001) and WBP-M results. Experimental WBP-M Q [l/s] 45.0 45.0 D 35 [mm] 0.74 0.74 S [%] 1.83 1.83 [∘] 11.5 11.5 W [m] 1.96 1.85 d [m] 0.068 0.084 L/W [%] 15 49 U [m/s] – 0.41 X [ppm] – 85.4 τ [N/m 2] – 1.06 τ cr [N/m 2] 0.456 0.46 The results are satisfactory, even if for Test 1 the geometry still remains slightly deeper and narrower, and bank zone is too large if compared with surface width (L/W = 49% instead of 15%). Field data coming from English and American noncohesive gravel and sand river (Parker 1978, Parker 1995), cover a wide range of discharges, sediment sizes and sediment concentrations. The WBP-M has been used to predict stable cross section geometry using Q, S and D 50 as input data. In Figures 9–12 comparisons between predicted and observed values are presented for both field and laboratory data in term of dimensionless quantities. In particular, Figure 9 and 10 show good agreement in terms of depth and width predicted values even if width cross section appears slightly under estimate. Moreover Figure 11 and 12 show dimensionless width and depth as a function of dimensionless discharge Q dim . General agreement of the WBP-M predicted values can be noted either for width and depth data. Finally, data appear to be quite distinct in two groups: one refers to gravel rivers data, for Q dim < 10 7 and one

3 CONCLUSIONS

Several recent experiments and numerical simulations

have demonstrated that the trapezoidal shape, as used

in the White et al. (1982), appears to be not a stable

configuration.

A WBP-M modified method of the WBP analytical

approach to river regime is here proposed.

To this aim the trapezoidal cross section geom

etry has been modified, employing a new shape

more similar to the one observed in laboratory tests. 1E+01 1E+02 1E+03 1E+04 1E+05 1E+06 1E+01 1E+03 1E+05 1E+07 1E+09 1E+11 Q dim W d i m Field data Lab data WBP-M Figure 11. W dim as function of Q dim : comparison between predicted and observed values. 1E+00 1E+01 1E+02 1E+03 1E+04 1E+05 1E+01 1E+03 1E+05 1E+07 1E+09 1E+11 Q dim Y d i m Field data Lab data WBP-M Figure 12. Y dim as function of Q dim : comparison between predicted and observed values. Particularly the Cao & Knight (1998) geometry has been assumed as the new stable cross section shape in the WBP-M proposed method. Firstly, the coherence of the extremal hypothesis, which the original method was based on, has been verified: the WBP-M method confirms the existence of a minimum of the slope where river geometry is assumed to be in stable condition. However WBP-M method provides wider cross sections than those predicted by the WBP method, while depth values are roughly the same. On the other hand, a further investigation reveals that the other hydraulic variables show a monotonous behavior in the proximity of the river regime condition. Moreover in the case of vanishing sediment transport river cross section cannot adjust its geometry and therefore no minimum value of slope is found. By using a two-dimensional numerical model the analysis of local depth-averaged hydraulic variables of the stable cross section shows non coherent results with hypothesis formulated by other authors. Particularly the

shear stresses distribution along the section does not reveal any critical value in the proximity of the bank zone, as vice versa postulated by Parker (1978b) and Cao and Knight (1998).

The validity of the WBP-M method has been tested employing both large scale experimental data of Valentine et al. (2001) and field data coming from sand and gravel non cohesive streams (Parker 1978b, Parker 1995).

The proposed method shows significantly improvement of the WBP method in terms of width and depth cross section geometry even if an underestimation in width values is still present.

Mobile-bed experiments on the exchange of sediment between main channel and groyne fields

Mohamed F.M. Yossef & Huib J. de Vriend

Faculty of Civil Engineering and Geosciences, Delft
University of Technology, Delft, Netherlands

ABSTRACT: The estimates of the sediment balance for the Rhine branches in the Netherlands during the last

three decades and particularly during the high water period of 1995 shows that erosion/sedimentation in the

groyne fields plays a major role in the total sediment balance of the river (ten Brinke et al., 2001). In the present

modelling practice, this role is not included in morphological predictions. To include the contribution of the

groyne fields in the total sediment balance of the river, we need to further understand the sediment exchange

process between the main channel and the groyne fields. For this reason, experiments have been conducted in a

mobile-bed flume. The flume represents half the width of a schematised river reach with groynes at the left side.

The geometrical scale is 1:100, based on typical dimensions of the River Waal. The bed material was scaled to

have bed load as well as suspended sediment transport. The flow conditions covered one situation with emerged

groynes and three with submerged groynes. Bed level changes, suspended sediment concentrations, and flow

velocities were measured. The results show that there is sediment deposition in the groyne fields under emerged

as well as submerged conditions. Furthermore, the results demonstrate the differences between the erosion and

deposition patterns in the groyne fields for the different flow conditions.

1 INTRODUCTION

1.1 Background

Groyne fields are a central element in the river Waal

and other Dutch branches of the river Rhine. They

form a zone of sediment storage with a significant

contribution to the overall sediment budget. Moreover, erosion of the groyne fields may affect the stability of the groynes. Finally, groyne fields provide the sand for the natural formation of wind-blown dunes on the floodplains that are a valuable habitat for riverine flora and fauna.

From the analysis of the findings of ten Brinke et al. (2001) see Table 1, one can conclude that during high water conditions sedimentation in the groyne fields plays a major role in the total sediment balance of the river. However, in the long run there is no net erosion or deposition from/to the groyne fields. Thus, the amount of sediment that is deposited during floods must be released during normal and low flow conditions. The release of sediment from the groyne fields is probably due to the navigation-induced sediment transport. This result emphasises the role that groyne fields play in the total sediment balance of the river.

It is therefore surprising that the existing rou tine modelling practices ignore the morphologi cal interaction between the main channel and the groyne fields. This is due to a gap in our knowledge concerning the sediment exchange mechanisms. With the present modelling capabilities, even the smallscale sedimentation/erosion in the groyne fields is not reproduced adequately. Recent attempts to reproduce these morphological processes have revealed important shortcomings in the present process knowledge and modelling

capabilities (Yossef & Klaassen, 2002). This was the reason of carrying out the present experiments. Table 1. Sediment balance for the main channel of the Waal River during the last three decades (after ten Brinke et al. 2001). Volume× 1000 (m 3 /year) Sediment source/sink 1970–1990 1990–2000 Year 1995 Input sediment from +682 +507 +250 upstream Output sediment to −761 −578 −270 downstream Bed degradation +489 +264 +573 Groyne fields – – −373 erosion/deposition Floodplain deposition −53 −53 −180 Dredging −357 −140 0 ± signs refer to gains and losses of sediment transported in the main channel.

1.2 Objective of the experiments

The aim of the experiments is to gain insight into the mechanism governing the sediment exchange pro cess between the main channel and the groyne fields mainly under different flow conditions. The experi ment described below is expected to fill in part of our knowledge gap.

2 LABORATORY EXPERIMENTS

2.1 Dimensions

The experiments were carried out in a specially built facility in the Laboratory for Fluid Mechanics of Delft University of Technology. The dimensions of the model were based on those of the River Waal and the space available in the laboratory. Figure 1 presents a schematic drawing of the model.

The model consisted of a schematised straight river reach, with a geometrically undistorted scale of 1:100 with respect to the Waal River. The working length of the model was 26.85 m, and the width 2 m. In the

lateral direction, the model represents half of the river

width. The model included nine identical groynes.

The first groyne was placed at 4.0 m from the model

Experimental set-up; schematic drawing not to scale. entrance following three wooden pseudo groynes that were installed to let the inflow of water and sand adjust before reaching the first groyne. The groynes were equally spaced at S = 2.0 m, they had a crest length L= 0.65 m and a crest height H g = 0.25 m, measured from the concrete bottom. The side slopes were 1:3 in all directions. The dimensions of the model are summarised in Table 2. 2.2 Experimental conditions Uniform quartz sand was used in all test cases. The sand had a median grain size D 50 = 0.164 mm, and a geometric standard deviation σ g = 1.23 (σ g is defined in Eq. 1). The thickness of the sand layer was varied from 0.125 m (case G1) to 0.175 m (case G3) to simulate a relative lowering of the groyne's crest height. However, in this paper we will present only one of the tested groynes geometries (case G1). For all test cases the Shields parameter θ (defined in Eq. 2), was set at a value of 0.23, and the suspension

number Z (defined in Eq. 3), was set at 1.87, so as to

guarantee a suspended sediment profile over the whole

water column (van Rijn, 1984).

Number of Measurement type Measuring equipment Instruments Locations Times Bed profile electronic bed followers 3 between gr. 5 & 8 4 @ 10, 20, 30 and 40 hrs Suspended sediment transverse suction system (TSS) 4 2 sections 1 @ 10 hrs Velocity electromagnetic flow meters (EMF) 2 2 sections 1 @ 10 hrs Water level wave gauges & static devices 2+ 2 4 points variable Video imaging video camera 1 between gr. 5 & 6 continuous a constant ≥1.0. Here we have D 50 = 0.164 mm, κ= 0.4; and β= 1. The hydraulic

conditions were chosen to fulfil the sediment transport requirements i.e. constant mobility and suspension in all test cases. Furthermore, for all the test cases Froude number (F r) small enough (maximum= 0.28), and the Reynolds number (R e) high enough to ensure subcritical fully-developed turbulent flow in both the main channel (R e ~ = 1.8× 10 4) and the groyne fields (R e ~ = 0.5× 10 4). 2.3 Measurements and data acquisition system Several parameters were measured during every test; namely: bed profiles, suspended sediment concentration, flow-velocity, water level, and bed-form movement via video recording.Table 4 provides an overview of the measurements and equipment used during the experiment. In this paper, we will focus on results obtained from the bed profilers. The bed level development was measured by means of three bed profile followers mounted on a movable carriage. The carriage could move on two rails to scan the area between groynes 5 and 8 i.e. a length of 6.0 m. The speed of the carriage was always set at its minimum value of 0.0315 m/s to obtain the highest spatial resolution of bed measurements. The sampling rate was 10 Hz. This means that the spatial resolution of the bed readings in the longitudinal direction was 3.15× 10 −3 m. The measured longitudinal profiles were spaced at 0.05 m, starting from 0.20 m from the model's sidewall, and ending at 0.20 m from the other wall, i.e. covering a total model width of 1.60 m.An initial reading was always taken before the start of every test, and measurements were taken after 10, 20, 30, and 40 hours. All the experiments started from an initially flat bed. 3 FLOW PATTERN 3.1 Emerged groynes During the first few hours of the test, the observed flow pattern did not differ much from what was previously

reported by e.g. Uijttewaal et al. (2001) and Yossef &

Uijttewaal (2003).

When the groynes are not submerged, the flow

inside the groyne fields shows an unsteady circulation

behaviour as shown in Figure 2 and characterised by:

- a primary circulation cell that forms in the down

stream part of the groyne field and covers nearly two

thirds of its spacing, the velocity of which is nor

mally about 30 to 40% of the main channel mean

velocity.

- a secondary circulation cell driven by the primary one with an opposite rotating direction and much smaller flow velocity.

- a dynamic eddy that frequently sheds from the tip of the upstream groyne. This eddy migrates in down stream direction and merges with the primary one, which in return changes in size due to the interac tion with the migrating eddy. After this eddy has disappeared, another eddy has room to form.

The whole circulation is driven by the main stream via exchange of momentum through the interfacial mixing layer.

Along with the morphological development, the flow pattern changes. With the development of the scour hole, the intensity of the dynamic eddy decreases while stretching in the vertical direction following the newly formed scour hole. After the development of the deposition region, the interaction between the groyne fields and the main channel is hindered and the primary eddy gets slower, which ultimately leads to the disappearance of the secondary circulation cell.

3.2 Submerged groynes

If the groynes are submerged, the flow in the groyne fields does not show the circulation pattern as observed

in the emerged condition.Yet, the groyne fields can be characterised as slow velocity region. The momentum transfer by the water flowing over the groynes is suf ficient to balance the momentum transfer through the mixing layer. The mixing layer in this situation has a constant width. The total turbulence intensity across the mixing layer decreases with the increase level of submergence.

Figure 2. Flow pattern in a groyne field during emerged condition. In the case of very shallow submergence (case G1a), the flow pattern showed some of the characteristics of the flow in the emerged situation. However, It should be noted, however that the flow over the groynes hinders the horizontal recirculation, ultimately causing it to disappear when reaching a high enough submergence level (cases G1b & G1c). Generally speaking, the flow in the submerged state shows an alternate accelerating and decelerating pattern between flow over and around the groynes; also see Yossef & Uijttewaal (2003). Another significant feature for the flow pattern in the case of submerged groynes is the secondary flow structure. This secondary flow occurs along the interfacial line connecting the tips of the groynes and is strongest near the groynes. The flow is directed towards the groyne fields near the bed and towards the main channel near the water surface; also see Peng et al. (1997) and Krebs et al. (1999). Except for a decrease in turbulence intensity near the tip of the groynes, no significant changes in the flow pattern were observed in response to the bed changes. 4 MORPHOLOGICAL DEVELOPMENT For all the tested cases, two typical features were observed. The first was the development of a scour hole near the tip of each groyne; the second was the sediment deposition inside the groyne fields. The morphological time-scale for the development of the scour holes was rather short compared to the total running time of the experiment. For each of the tested cases, both scour and deposition patterns looked similar near all groynes except near the first and the last ones. Nevertheless, there were significant differences between the emerged and submerged cases. In the following two sections, we will

describe the results from in further details. 4.1 Emerged situation During the emerged situation, the footprint of the flow pattern was clearly visible in the morphology, as shown in Figure 3. Both the scour hole and the deposition pattern follow the flow pattern as described in Section 3.1. The scour hole alignment follows the direction of the dynamic eddy. It is oblique to the flow direction and makes an angle of about 30 ◦ with the normal line (the imaginary line that connects the tips of the groynes). In a later stage, the scour causes a feedback to the flow by elongating the dynamic eddy in its direction. The sediment deposition inside the groyne fields takes place through its downstream part (Figure 3).The sediment is transported from the main channel towards the groyne field following the direction of the primary

circulation cell.Along with the drop of the velocity, the

sediment settles.The asymmetry of the ripples near the

wall deep inside the groyne field is opposite to the main

flow direction, but complies with the flow direction

inside the groyne fields. This indicates that the effect

of the primary circulation cell is extending through

the width of the groyne field. The area in the middle

of the groyne field, which coincides with the centre of

the circulation cell, is free from any bedforms.

Subtracting the final bed level from the initial bed

level yields the erosion/deposition pattern at the end

of the test. The result is shown in Figure 4, where we

can see that the pattern is recurring in all three groyne

fields.

4.2 Submerged situation

During the submerged situation, the effect of the flow

pattern is not explicitly visible on the morphology.

Figure 4. Deposition/erosion pattern after 40 hours for case G1i, ▯z= bed level after 40 hours – initial bed level. The sediment deposition inside the groyne fields takes place across the normal line, see Figure 5. The sediment is transported from the main channel towards the groyne through the mixing layer. From the dye visualisation, we were able to observe the effect of the secondary circulation. As described in Section 3.2, near the bed the flow in the mixing layer is towards the groyne field, transporting the sediment from the main channel into the groyne field. Moreover, due to the high turbulence intensity, the sediment concentration in the mixing layer is kept at a high value (compared to the concentration in the main channel). Consequently, significant sediment transfer took place though the mixing layer. The volume of sand deposited in the groyne fields decreased with the increase of the water level (Figure 7). Moreover, the location of the deposition moved further inside the groyne fields as the water level increased (Figure 7a, b & c, lower panels). sediment supply scour hole 5 th groyne 6 th groyne Figure 5. Figure 8. Deposition volume inside groyne fields for case G1i; upper panel per unit width, lower panel per unit length.

Both the depth and the alignment of the scour hole depended on the water level. The scour depth decreased with the increase of the water level, and in all submerged cases the depth of the scour depth was less than in the emerged situation. The alignment of the scour hole also changed with the water level. The scour hole moved towards the groyne fields as the submergence level increased (see, for example, Figure 6).

5 CONCLUSIONS

The mechanism of sediment transport into the groyne fields differs according to the flow situation. In the emerged situation, the sediment is mainly advected towards the groyne fields by the primary circulation cell. In the submerged situation, the sediment is trans ported to the groyne fields across the whole length of the normal line. The mechanism in this case is a mixture of advection by the secondary circulation and diffusion through the mixing layer.

The results from these experiments showed a decrease in the total deposition volume inside groyne fields as the submergence level increases; compare Figure 8, Figure 7 a, b & c (upper panels). Never theless, the experiments were conducted for constant

Impact of hydropower schemes at bedload regime and channel morphology of the Danube River

K. Holubová, Z. Capeková & J. Szolgay

Water Research Institute, Bratislava, Slovakia

ABSTRACT: Construction and operation of hydropower plants (HPP) including engineering works to maintain navigation conditions at the Danube River essentially changed flow dynamics and transport capacity of the river. As a consequence significant changes of the river bed morphology have occurred creating reaches with aggradation upstream and degradation downstream of the structures. The results of broad research programme

(1996–2002) focused at the changes of bedload transport regime and the river bed morphology of the Danube

affected by operation of hydropower schemes Gabcikovo constructed downstream of Bratislava and Freudenau

situated in Vienna, are presented. Bedload rating curves based on bedload measurements were developed for two

river sections: the Slovak–Austrian Danube upstream of Bratislava and Slovak–Hungarian Danube downstream

of Gabcikovo HPP. Increased bedload transport capacity is documented by the results of bedload measurements

realised during the period 1997–2002 and supported by analyses of the bed material composition, development

of the river bed morphology at both river sections. Bedload transport equations frequently applied in engineering

practice (Meyer-Peter & Müller, Ackers & White, Schoklitsch, etc.) to estimate transport rates are compared with

the relations developed on the basis of bedload measurements at the Danube. The main attention concentrates

at the river section downstream of Gabcikovo HPP, which indicates the most significant morphology changes

induced by unsteady flow conditions, deficit in sediment supply and engineering maintenance of the river channel

for navigation purposes.

1 INTRODUCTION

Since nineteenth century the Danube River has been

influenced by engineering maintenance of the river

channel mainly for navigation purposes. After World

War II a series of hydropower schemes designed for

electricity production and also for improving naviga

tion conditions were constructed upstream of Vienna.

During the recent years the last two hydropower plants were put into operation – in Vienna (Freudenau, 1997) and downstream of Bratislava (Gabcikovo, 1992).

Some years ago plans were made to construct a power plant at Hainburg, which was supposed to fill the gap between Vienna and Bratislava but national and inter national protests finally prevented this scheme being realised and forests in the remnant floodplain were protected (Jeaggi, 1992).

Operation of both hydropower plants Freudenau and Gabcikovo including increased degree of the Danube regulation to maintain navigation conditions (dredg ing, groynes, deflectors) induced higher dynamics of morphology changes. Problems of intensive river bed erosion have occurred downstream of Freudenau and

Gabcikovo and more intense deposition influenced Slovak-Austrian Danube upstream of Gabcikovo impoundment. Present morphological changes of the Danube caused evident decrease of low flow water levels in the sections with river bed degradation. Analyses of morphological development of the Danube river at the section that flows through the Slovak territory arise from a consideration of various opposite tendencies in the river bed development, which is important for understanding of the present river processes.Alternation of longer periods of aggradation and degradation always dominantly affected surface and ground water level regime in this territory. Since 1960s natural aggradation of the river bed that prevailed at the Danube downstream of Devin (km 1880) over a long period, was replaced by successive degradation. Commercial dredging of excessive amounts of gravel induced dramatic changes of the river bed resulting in a progressive fall of water levels upstream and downstream of Bratislava. Water levels decreased by two meters in Bratislava and elsewhere they dropped by one meter during period 1957–1992 (Holubova et

al. 1998). Process of river bed aggradation has been re-established again since the Danube was dammed downstream of Bratislava.

Figure 1. Bedload measurements at the Danube (1997–2002).

Dynamic equilibrium between local transport capacity and sediment supply was seriously affected and significant changes of flow dynamics and sediment regime connected with the operation of hydropower schemes linked to this dramatically eroded river bed.

The impact of hydropower schemes at river processes along the Slovak–Austrian and Slovak–Hungarian Danube was analysed in the frame of the bedload research programme that consisted of two main parts. The first one: Sediment transport at the Danube river under the changed flow conditions in the reach of the Slovak capital (1996–1998) and the second one: Changes in sediment transport regime in the Danube, downstream of Gabcikovo HPP (1999–2002). Both parts of the research programme were based on a broad range of bedload measurements (Fig. 1) to identify changes in bedload transport regime and connected changes of river bed morphology, bed material composition and water level changes. The most important results completed by actualised morphological development and water level changes of

low flow (Q~ 1000 m 3 ·s −1), are presented.

2 THE SLOVAK–AUSTRIAN DANUBE

The Danube River between Vienna and Devîn (km 1880) is one of the last free-flowing river sections in Austria. Since hydropower plant Freudenau was put into operation (1997) this river section that includes ecologically very rare forest area has been affected by higher morphological dynamics that resulted in the river bed erosion and problems of navigation mainte nance during the low flow.Therefore a strong emphasis has been given to the development of strategies for improvement and management of this stretch, which is declared as an Alluvial Zone National Park (Schiemer et al. 2003).

In order to decrease deficit of sediment supply downstream of Freudenau an artificial supply of coarsely sorted sediments (300,000 t · year −1) were designed to stabilise the river bed (Zottl 1998). After a few years large amounts of sediments were reduced (160,000 t·year −1) but the expected effect – development of river bed armouring – has not been fully achieved yet. Monitoring results of Austrian engineers indicated successive degradation of the river bed (1 cm/year) downstream of Vienna (Kordina et al. 2003). This trend was also proved by practical experience. Unstable conditions downstream of Vienna that induced increased sediment supply also influenced the Danube section upstream of Bratislava. Higher intensity of the riverbed aggradation occurred at the Slovak–Austrian Danube above the edge of impoundment particularly during the recent years.Therefore the main objectives of the first part of research programme (Holubova et al. 1998) were focused at identification of bedload transport regime and morphological changes of the

river bed in the section upstream of Bratislava. 2.1 Changes in bedload regime at the Slovak-Austrian Danube Broad research of bedload regime was realised during 60's at Slovak section of the Danube (Szolgay 1960). Bedload measurements at the Slovak-Austrian Danube (km 1870) were re-established in 1997 after 40 years under the changed flow conditions. Twentythree complete bedload discharge measurements were carried out at km 1878.15. Discharges ranged from 1050 m 3 ·s -1 to 4350 m 3 ·s -1 during field works (1997- 1998). Complete cross section measurements in five verticals realised by basket sampler (Fig. 1) included continual flow velocity measurements to analyse flow conditions (Holubová 2000). The results were used for evaluation of the bedload rating curve that is given by following regression type of relationship: where G s = bedload discharge; Q=water discharge. Figure 2 shows bedload rating curves developed on the basis of field measurements for periods 1997-1998 and 1954-1957. Comparison of both curves indicates that larger amounts of bedload are transported during higher water discharges under the present conditions. Recent experience showed that the beginning of bedload movement is connected with lower discharges (880 m 3 ·s -1) compared with situation in the past (2000 m 3 ·s -1). Bedload regime also indicates further changes in characteristics of movement due to unsteady flow conditions and engineering measures mentioned above. 2.2 Bedload equations appropriate for Slovak-Austrian Danube Sediment discharge equations of Meyer-Peter & Müller, Ackers & White, Jaeggi & Smart and Schoklitsch were tested using the field Danube data. 2 3 4 6 7 8 9 2 3 4 6 7 8 9 1000 10000 WATER DISCHARGE Q [m 3 /s] 2 3 4 5 6 7 8 9 2 3 4 5 6 7 8 9 2 1

Ackers & White* 377

Meyer Peter & Müller* 670

* with fractions.

For each equation the mean normalised error (MNE)

was estimated (Holubova 2000). The best results were

achieved by Schoklitsch equation (with fractions). At the next level Jaeggi & Smart and original form of Schoklitsch equation have comparable errors – both overestimated the results. Meyer-Peter & Müller (with fractions) and Ackers & White (with fractions) equations significantly overestimate calculated values of bedload discharge (Table 1).

Good results were obtained by Meyer-Peter & Müller equation with modified values of constants $A' = 0.039$ and $B' = 0.39$ that were obtained on the basis of bedload measurements at the Danube (km 1878.15). This modified equation enables to spread the range of its applicability for higher discharges compared with equation (1) that should be used for limited discharge range (1050 $m^3 \cdot s^{-1}$ –4350 $m^3 \cdot s^{-1}$).

2.3 Morphology development of the river bed

Aggradation of the Danube river bed was expected in the reach of impounded water levels and predicted by numerical models. Prediction of morphology development could not match the actual situation as the model calibration did not include the effects of an

 Figure 3. Development of morphological changes of the river bed at the Slovak–Austrian Danube during 1992–2002. 2 0 0 2 2 0 0

1 2 0 0 0 1 9 9 9 1 9 9 8 1 9 9 7 1 9 9 6 1 9 9 5 1 9 9 4 1 9 9 3 0 100 000 200 000 300 000 400 000 D R E D G E D M A T E R I A L (m 3) YEAR km 1880-1877 km 1862-1866 Figure 4. Bed material dredging in the Danube at the sections between km 1880 to km 1877 and km 1862 to km 1864. sediment supply) and further engineering measures recently implemented in the river channel (groynes modification and construction of new ones, dredging, restoration measures, etc). The results of morphology analyses at common Slovak–Austrian Danube proved previous assumptions of a more intense process of deposition that has occurred downstream of km 1877 (Fig. 3), which is influenced particularly by backwater effect. Increased transport capacity of the river and higher amounts of bedload transported from Austrian Danube also support aggradation process. Tendency of river bed aggradation is observed during the recent years also at the section upstream of backwater effect (km 1880–1877) even if over the longer period (1992–2002) erosion prevailed at this section. Since 1998 a navigation dredging is required to maintain navigation conditions. Extracted amounts of a bed material have increased successively (Fig. 4) as more intense deposition has caused navigation problems. Bed material extractions had to be spread upstream of impounded section where

navigation dredging was never required before. Even

if total amount of dredging is comparable with bed

load transport capacity, the river bed aggradation can

be observed particularly during the recent years.

Analyses of a bed material composition indicate

changes of physical characteristics that reflect actual

river processes.

Larger part of bed material samples that were taken

in 1997 proved a higher percentage of coarser frac

tions compared with situation in the past, while smaller

fractions did not exhibit any considerable differences.

Grain size distribution of the bed material samples

taken from the river channel in the section between

km 1880 to km 1866 during 2003 (57 samples) indi
cates that bed material coarsening evident in 1997 can
not be observed yet. Higher volumes of coarser frac
tions in the samples observed in 1997 (115 samples)
upstream of Gabcikovo impoundment could be caused
by erosion prevailed at this locality in the past.
At present the bed material composition is almost
identical as it was in 1950s (Fig. 5) particularly in the
central part of the river channel. Specific flow con
ditions resulting in local scouring around a head of
groynes induced higher sorting of bed material. There
fore coarser gravel is observed at localities close to
left and right river banks at the sections with groynes.
Reversal trend of bed material composition could be
caused by increased volume of bedload from Austrian
Danube and deposition re-established at this river sec
tion during the recent years (Fig. 3). Downstream of
km 1874 only slight increase of finer grains in bed
material composition has occurred due to backwater
effect.
Conditions for an occurrence of armour layer on the
riverbed were assessed by Raudkivi (1981) armouring
criteria:

where D 84 = grain diameter (84% finer by weight). 1 8 6 6

Figure 5. Changes in grain size distribution of the bed

material at the Danube upstream of Bratislava. While in 1997 conditions for bed armouring occurred only very rarely, at present they are identified almost at whole Slovak-Austrian Danube even if practical experience during field measurements did not prove creation of a compact armour layer. Analyses of bedload and bed material properties indicate that grain size of both is comparable. Bedload grain size characterised by D 50 ranged from 25 mm to 30 mm and bed material D 50 from 15 mm to 36 mm (average value 20 mm). Lower amount of finer fractions in bedload samples was caused by coarser mesh (3 mm) of bedload sampler, which did not enable to retain fine gravel and sand in the basket sampler. 3 DANUBE DOWNSTREAM OF

GABCIKOVO HYDROPOWER PLANT Gabcikovo hydropower plant that is built on bypass canal dominantly influenced flow conditions and sediment regime along the common Slovak-Hungarian Danube. Deficit in sediment supply and changed flow dynamics has caused significant degradation of the river bed downstream the old Danube and tailrace canal confluence. Original version of the common Slovak-Hungarian project included construction of lower HPPNagymaros (km 1694.6) that would have provided protection of the river bed by created impoundment. As the completion of hydropower plant in Nagymaros was stopped due to protests of public and ecologists in Hungary the river bed is exposed to a strong erosion. Evaluation of river bed development is rather complicated with regard to high variability of flow dynamics downstream of the old Danube and tailrace canal confluence. Therefore the second part of the research programme (Holubova et al. 2002) was focused at the problems of sediment transport and morphology changes downstream of Gabcikovo. Project included field measurements of bedload discharges, analyses of morphology development, water levels changes and analyses of the river bed composition. 3.1 Impact of Gabcikovo HPP at river bed morphology and low flow water levels Two important phases of the river bed development since Gabcikovo was put into operation are documented at Figure 6. The most intensive degradation of river bed downstream of the old Danube and tailrace canal confluence occurred during the first two years of Gabcikovo operation. During this period the river bed incision reached maximum values in shorter reach (km 1811-1810.5). During next years the maximum value of the river bed incision was slightly reduced but degradation still propagates downstream getting through the bridge Medvedov profile that was stable

over long period. Large amounts of eroded material

are transported downstream and deposited at lower

reaches. Present situation indicates that dynamic equi

librium has not been achieved yet and process of the

river bed erosion still continues (Fig. 6) with negative

impacts at water levels (Fig. 7).

Changes of low flow water levels reflect morpho

logical development of the river bed downstream of

Gabcikovo. Maximum decrease of a minimum nav

igation water level (Q~ 1010 m 3 ·s −1) reached value

71 cm during the first years of HPP operation (1992–

1996) just downstream of the old Danube and tail

race canal confluence. Decrease of water occurred at

shorter reach during this period but successive degra

dation of the river bed induced further decrease of

water level that propagates downstream. At present a

maximum decrease of low flow water level reached 1 7 9 4 1 7 9 5 1 7 9 6 1 7 9 7 1 7 9 8 1 7 9 9 1 8 0 0 1 8 0 1 1 8 0 2 1 8 0 3 1 8 0 4 1 8 0 5 1 8 0 6 1 8 0 7 1 8 0 8 1 8 0 9 1 8 1 0 1 8 1 1 1 8 1 2 1 8 1 3 DANUBE DOWNSTREAM OF GABCIKOVO (km)

Figure 7. Low flow water levels (Q ~ 1010 m 3 ·s −1 ; min.

navigation water level) under the pre-dam and post-dam

conditions. 1.29 m (km 1811) compared with pre-dam conditions (Fig. 7). Evident decrease of low flow water level was spread downstream. Significant change of the river bed slope occurs close to Zlatna na Ostrove (Fig. 7). Here the Danube is changing its character from submontane to lowland river. The river slope is changing from i= 0.232% (km 1811–km 1794) to i= 0.04% (km 1794–km 1766). Bed material eroded and transported from the steeper parts of the Danube is deposited at the reaches with lower gradient causing problems with maintenance of navigation conditions. Analyses of 57 bed material samples along investigated section (km 1811–km 1792) involved samples from central part and also from left and right parts of the river channel. The main characteristics of bedload samples and bed material samples are very similar. Bedload grain size characterised by D 50 ranged from 7 mm to 10 mm at locality of field measurements (km 1795.58) and bed material size also given by D 50 ranged from 8 mm to 14 mm (average value 10 mm). Composition of the river bed material is rather uniform (Fig. 8) along the whole investigated river section. Bed material characteristics D 35 , D 50 , D 80 showed changes only at lower part of the Danube. Higher volume of coarser fractions in bed material occurred only locally close to groynes heads and also at the left and right side of the channel influenced by dredging (downstream of km 1794). Possibilities for creation of armour layer evaluated by Raudkivi criteria (2) did not

indicate conditions for creation of river bed armouring. Investigation of the river bed topography by ATLAS ultrasonic equipment proved creation of bed forms – mostly dunes with variable size (dune length L d = 0.2 m–0.6 m; dune height H d = 0.6 m–2 m). 1 7 9 2 1 7 9 4 1 7 9 6 1 7 9 8 1 8 0 0 1 8 0 2 1 8 0 4 1 8 0 6 1 8 0 8 1 8 1 0 1 8 1 2 DANUBE (km) 0 10 20 30 40 50 60 70 80 90 100 110 D (m m) 1 7 9 2 1 7 9 4 1 7 9 6 1 7 9 8 0 20 40 60 80 D (m m) D35 CENTRAL PART D50 CENTRAL PART D80 CENTRAL PART D35 RIGHT SIDE D50 RIGHT SIDE D80 RIGHT SIDE D35 LEFT SIDE D50 LEFT SIDE D80 LEFT SIDE Figure 8. Grain size distribution of the bed material along the Danube section downstream of Gabcikovo.

3.2 Bedload regime downstream of Gabcikovo

In order to define bedload regime at present conditions

and quantify volumes of bedload transported through

the reach, series of field measurements were realised

at the locality just above significant change of the river

bed slope. This locality (km 1795.58) was selected not

only with regard to the significant change of the river

bed slope but also with the aim to avoid further impacts

that could locally influence bedload regime. During

the period 2000–2002 broad series of bedload mea

surements were done under the discharge conditions

reaching from 972 m 3 ·s –1 to 4745 m 3 ·s –1 . Complete

seventy-one bedload measurements in six verticals

were realised in cross section by the same method

and technical equipment as it was done at Slovak–

Austrian Danube. Fluctuation in bedload movement

was considered by 10 times repeated measurements

at each of verticals (time of each measurement varied

from 2 to 5 minutes depending on intensity of bed load movement) and final value in the vertical was obtained as average value. Extent of field works that also included measurements of velocity distribution realised continually with bedload measurements, per manent recording of water level fluctuations, sampling of bedload and bed material, represent data, which are unique at the Danube.

On the basis of bedload measurements realised in the section of the Slovak-Hungarian Danube down stream of Gabcikovo the following regression type of relationship was developed:

This relationship (3) represents bedload rating curve for the Slovak-Hungarian Danube downstream of Gabcikovo (Fig. 9) recommended for given discharge range.Total amount of bedload transported through the investigated section of the Danube for an average year 2 4 5 6 7 8 9 2 4 5 6 7 8 1000 WATER DISCHARGE Q (m 3 /s) 2 3 4 5 6 7 8 9 2 3 4 5 6 7 8 9

Figure 9. Bedload rating curve based on field measure

ments at the Danube downstream of Gabcikovo (km 1795.58). is about 252,000 m 3 .The total amounts of bedload estimated for period 1992-2000 varied from 165,000 m 3 (1998) to maximum value 412,000 m 3 (1999). Intensity of bedload movement is comparable with the Slovak-Austrian Danube (i= 0.342%) even if the river bed slope at the Slovak-Hungarian Danube is lower (i= 0.232%). Deficit in sediment supply, higher flow dynamics and bed material that consists of fine gravel, support transport of large amounts of bed material. Increased dynamics of bedload regime influenced topography changes along the investigated section. Changes of channel geometry in the cross section varied in the range from a few centimetres to one meter during two years of field measurements. 3.3 Bedload equations for the Danube downstream of Gabcikovo HPP Some bedload equations were tested also for the Slovak-Hungarian Danube at the section downstream of Gabcikovo.The same method of testing was used for bedload equations mentioned above except of Jaeggi & Smart equations that were replaced by Rottner ones. Equation of Meyer Peter & Müller was tested with modified values of constants, which were estimated on the basis of bedload measurements as follows: A ′ = 0.0378 and B ′ = 0.1552. Similarly as it was for the Slovak-Austrian Danube relatively good results were achieved by Schoklitsch equation but in this case, the form with constant sediment size provided better results.

Comparable results were obtained by Meyer Peter & Müller equation with constants derived from field measurements, Ackers & White equation with constant size of D 35 and Schoklitsch equation (with fractions). Extremely high values of mean normalised error (MNE) for both versions of Rottner equations indicate that these equations are inappropriate for the Danube conditions. Ackers & White equation with fractions provides rather high deviation from measured values. Table 2. The results of the bedload equations testing. Flow dynamics influenced by operation at

Gabcikovo HPP and engineering works implemented

in the river channel at the Slovak-Hungarian Danube

downstream of Gabcikovo create complicated condi

tions for bedload regime and quantification of bed

load discharges. The results of bedload equation tests

proved that these equations frequently used in an engi

neering practice and also in numerical models would

not provide reliable prediction of morphology devel

opment at the Danube. Bedload rating curves (1), (2),

developed for considered river sections and specific

flow conditions of the Danube created necessary back

ground for reliable and physically correct predictions

of morphology development.

4 CONCLUSIONS

River processes at the Slovak-Austrian and Slovak-

Hungarian Danube are significantly influenced by

operation of hydropower schemes Gabcikovo and

Freudenau.

Sediment regime at upper part of Slovak-Austrian Danube is affected by increased sediment supply as a result of engineering works and protective measures implemented downstream of Freudenau HPP (artificial bedload supply, restoration measures, navigation dredging, etc). Bedload rating curve based on the results of bedload measurements (1997-1998) proved higher intensity of bedload movement. Total amounts of bedload for average year increased under the present conditions by about 30% compared with situation in 1950s. Higher volumes of sediment supply induced river bed aggradation at the section that is not influenced by backwater effect causing navigation problems. Successive deposition of the river channel would also reduce flood capacity with negative impacts at flood protection in the vicinity of Bratislava.

Present knowledge of bedload regime and morphology development at the Slovak-Austrian Danube indicates the need to formulate common Slovak-Austrian project that should include analyses of the whole Danube section between both hydropower schemes Freudenau and Gabcikovo. This approach would enable the application of all relevant research

results, knowledge and experiences achieved in both

countries to solve the present problems including sta

bilisation of the river bed downstream of Freudanau

more effectively.

Gabcikovo HPP significantly influenced dynamic

equilibrium between sediment supply to the reach

Investigation of Lithuanian river-channels classification

Z. Rimkus

Lithuanian University of Agriculture, Kaunas-Akademija, Lithuania

ABSTRACT: The paper reviews the development of river-channels classification (river-channel processes

type). A description of the degree of investigation of this point is presented. The importance of river-channels

classification to the investigation of subsequent theoretical river bed processes and practical purposes of hydraulic

engineering is emphasized.

According to the research of river-channel stability criterion / Grishanin invariant channels of Lithuanian rivers

are suggested to be classified into straight channels with alternating bars, adapted type and highly meandering

channels. It has been proved that the most important parameters of different type river-channels - mean depth,

width and yield - have different interdependencies. The type helps to evaluate river-channel stability and trend

of deformations: highly meandering channels have the highest transporting capacity, straight channels with

alternating bars - the lowest one.

1 INTRODUCTION

Various river channel forming factors, their complex interrelation, geographical environment of the river, different genetic zones of river basin geomorphologi cal formations create preconditions for the diversity of river channel and floodplain morphological develop ment. Attempts have been made to work out a certain system in this natural diversity i.e. to classify river channels to separate types based on variety and pecu liarities of river bed processes. River channel (their macroforms) classification to separate types of their development is useful to designers and builders of hydrotechnical constructions.This makes easier devel opment and application of hydraulic project standards, helps to avoid mistakes in selecting construction site, to evaluate objectively impact on the environment, contributes to efficient application of river channeling devices. Grouping of river bed macroforms enables prognosis of river bed processes, e.g. course of river bed deformation (trend, volume, rate). River-channels classification is necessary for the development of gen eralized theory of river bed processes (Stream 1998). In this respect many issues are related to the evaluation of the impact on the environment. Recently, evalu ation of the impact of hydraulic engineering on the

environment has been regulated by the Environmental

Impact Estimation law and supplementing norma

tive documents. Environmental impact evaluation is

indispensable for the implementation of any hydraulic

project. Objective establishment of essential changes

in river bed process indices is the basis for correcting the project or providing special environmental measures, related to hydraulic engineering of inland water bodies. Aim of this work – on the basis of river-channel stability criterion/Grishanin invariant research to propose a river-channel classification methodics, to reason its scientific and practical use. 2 BACKGROUND OF THE PROBLEM AND OBJECT OF THE RESEARCH 2.1 Short history of river-channel classification The first classification of river-channels was suggested by Russian scientists K.I. Rosinskij & I.A. Kuzmin (1947). Their idea was to classify rivers into three types: of direct, meandering and branched out channels. Lack of quantitative connections among different types did not derogate the importance of this classification. In the world practice three types of channels are known as the main ones. After ten years L. Leopold & M. Wolman (1957) divide river-channels into the same types – direct, meandering and branched out. Later this classification was improved by a number of scientists, working in different regions of the world: N.I. Makkavejev, N.A. Rzanycin, N.E. Kondratjev, I.V. Popov, S. Chitale, D. Saimons, I.F. Karasiov, R.S. Tshalov and others (Makkavajev 1955, Rzanycin 1961, Chitale 1970, Shen 1971, Karasiov 1975, Tshalov 1979, Chanson 2001).Types of river-channels strongly depend on the particular conditions of river formation and physical-geographical conditions in the river

region. Practical hydraulic engineering highly valu

ates those methodics of channel classification, which

are based on quantitative indices of morphological

elements of river-channel macroforms. Usually these

indices are not complex and do not require expensive

initial investigations. One example of such method

ics is the method, suggested by B.F. Sniscenko (1980)

where river-channels are classifies according to the criterion:

where I 0 =mean slope of the bottomland; B 0 =mean width of the bottomland; I =mean stream slope; and B=mean width of the channel at the level of water overflow.

All parameters can be easily determined by using cartographic maps of the scale 1 : 1000 – 1 : 25,000.

B.F. Sniscenko proposed distribution of river-channels into six types: highly meandering, unfinished mean dering, flat branching out, limited meandering, straight channels with alternating bars and channels with islands (braided channel).

Research of the Lithuanian river-channel classifi cation is poor. The final disappearance of glaciers in Europe should be considered the last phase of the Lithuanian river valley and river-channel network for mation. River-channels of present shape were formed by the glacier melting or the so called fluvioglacial water. In the post-glacial period rivers in west Lithua nia did not cut into their valleys significantly, while in east Lithuania this cut reached 3–5 meters. After the process of cutting into the rivers started formation of bottomlands. The post-glacial period is characterized by strong warming of climate and significant increase

in precipitation, which contributed to the formation of modern river-channels (Lietuvos 1958).

In 1960 a Russian scientist S.N. Pinkovskij classi fied river-channels of Lithuanian and other Euroasian rivers on the basis of big scale map and analy sis of geomorphological, geological and hydrological material of North-West part of the former USSR (Pinkovskij 1960). Here river-channels of the main Lithuanian rivers were divided into two groups: highly meandering and not meandering (straight lined and one-branched). The presented scheme is laconic, the classification is relatively old and includes only big Lithuanian rivers, therefore, it is of no significant theoretical and practical importance.

At the same time M. Beconis emphasises that according to the forms of their manifestation the run-of-river processes are geomorphological; mor phological formations are distinctly expressed in river channels and their bottomlands, these processes result in formation of valleys (Beconis 1960). River val ley, i.e. the river-channel formation environment, is important to the formation, therefore, successful investigations of run-of-river processes requires knowledge of the regularities of this environment formation. According to M. Beconis side-erosion is very important for river-channel development processes. Under the influence of this erosion high banks of some rivers are destroyed and annual move is 10–20 cm. Slope of the valley is also

influenced by mechanical suffusion (wash out of rocks, fine particles and soluble materials through water filtration) and landslip processes. They are often observed in river-channels of South-East Lithuania basin. Recently interesting and useful investigations of run-of-river processes are being carried out by the scientists of Vilnius University and Lithuanian Institute of Geography: A. Cesnulevicius, A. Baubiniene, T. Kovera, M. Paukste, D. Veteikis, J. Volungevicius, etc. They have distinguished and described genetical and dynamical segments of the big Lithuanian rivers, analyzed state of the banks, established the accumulated and eroded sections (Baubiniene 1999, Cesnulevicius et al. 1999, Cesnulevicius 2000). Author of this paper on the basis of B.F. Siniscenko methodics suggests to divide river-channels of the Nemunas basin in Lithuanian territory into straight channels with alterating bars, forced meandering, limited meandering and high meandering (Rimkus 1988). In comparison with the described methodics of B.F. Sniscenko, here a new type of rivers has been distinguished – forced meandering, while no river-channels of unfinished meandering and flat branching out types have been found in Lithuania. Values of A criterion and their average standard deviations have been established for each class of river-channels. Although the suggested classification of river-channels seemed to be not only of theoretical importance but important in practical engineering it has not become widely used in Lithuania. The lack of motivation of hydraulic engineering specialists concerning the importance of riverchannel type determination is considered to be the main reason. Changes of run-of-river processes under the influence of waterworks or negative influence of these processes on the constructions are observed only after a certain period of time. They are not inert and cause no problems in the case of superficial evaluation of this process. Run-of-river processes have not been evaluated because of the following reasons: the traditions existing in the environment of hydraulic engineering specialists, gaps in education of engineers, relatively small rivers in Lithuania (the dominating opinion states that small rivers have no problems), small number of scientists, lack of coordination and financing of their activity, etc. Political and economical orientation to the European Union, increasing attention to ecological problems and rational use of natural resources, development of science encourage searching for attractive ways to deal with the described problem. Effective

use of natural resources requires good understanding

of the regularities of natural phenomena, finding the most effective criteria that are closely related with fundamental essence of the phenomenon and ability to evaluate the impact of economical activity on the environment.

2.2 Object of the research

Small streamlets (3–10 km length) dominate in Lithua nia by number and total length. Their number reaches 3.6 thousand and they make 50% of the total length of all rivers that are longer than 3 km. The number of medium (10.1–100 km) rivers is 755 and their total length makes 41.5% and the number of big rivers (longer than 100 km) – 17 and total length makes 8.4% of the total length of all measured rivers (37.6 thou sand km). The longest and biggest rivers the Nemunas, the Neris, the Sesupe, etc. do not fit the Lithuanian territory or go along the border (Fig. 1 & Tab. 1). Average density of river network in the country is 1.18 km/km 2 . River-channels of most rivers, espe cially smaller ones, have undergone channelization; according to the length the regulated river-channels

Figure 1. Scheme, hydrological zones and location of water observation stations on the main Lithuanian rivers: A – West

Lithuania: B – Middle Lithuania: C – East Lithuania: – water observation stations. make 82.6%, natural ones – only 17.4% (Gailiusis et al. 2001). 3 METHODICS The criterion of rivers, canals and other natural and artificial waterways

channels stability M that has been used in this work is described in literature sources and is also called Grishanin's invariant (Grishanin 1990): where R= hydraulic radius of the canal; g= acceleration due to gravity; χ=wetted perimeter of the canal; and Q= discharge. According to K.V. Grishanin the medium M value for the sections of river-channels with fine bed load/sediments is close to the constant M value M = 0.92 ± 0.12, for the gravelled and stony riverchannels M = 0.5 ÷ 0.6. Some data shows that invariant M remains constant only for the river-channels of certain type. According to V.I. Antropovskij (1972) M = 0.9 ÷ 1.1 for the channels of unfinished meandering, and M = 0.4 ÷ 0.5 for the channels with

Note: Str – straight channels with alternating bars; For.m – forced meandering channels; Lim.m – limited meandering

channels; Fr.m – highly meandering channels; Adap – adapted channels

islands. A.N. Lepin & N.K. Aleksandrova (1980) have

established that invariant of highly meandering chan

nels is M = 1.2÷ 1.3. Other works also present some

useful knowledge on this issue (Zelezniakov 1976,

Kondratjev et al. 1982, Muchamedov et al. 1970).

As river-channels are relatively wide so having

accepted that R≈ h and χ≈B the Grishanin invariant

obtains the following expression:

where h=medium depth of flow in the channel;

B=medium width of flow.

The Grishanin invariant has been calculated in

44 Lithuanian rivers for the cross-sections at which hydrological stations are located and stream velocity, water discharges and main parameters of the chan nel – depths and widths – are measured at different time (Fig. 1 & Tab. 1). To reduce the influence of antropogenetics on the investigation results hydro metrical, hydrological and hydraulic data of earlier years (not later than 1960) is used. Water discharges and corresponding water depths are selected for the period the most intensive run-of-river processes: 0.75Q f . <.Q cal < 1.25Q f (Q cal – calculated water dis charge, Q f – formative water discharge). Formative discharges are calculated according to the empiri cal expressions proposed by the author of this paper (Rimkus & Darbutas 1999):

(a) Rivers in hydrological regions of Middle and West Lithuania

(b) Hydrological region of East Lithuania and bigger rivers – the Nemunas and the Neris

where Q a = average water discharge of the river of many years; F = area of the basin km 2 .

Types of river-channels and corresponding Sni scenko criteria A have been selected on the basis of earlier investigations (Rimkus 1988).

For the analysis of the dependency of the main chan nel parameters – depth, width and water discharge –

on the type of river-channel three rivers of different

channel type have been selected at random; the Neris at

Vilnius (No 11, straight channel with alternating bars),

the Merkys at Puvociai (No 6, adapted type) and the

Sesupe at Kalvarija (No 25, highly meandering). 4 RESULTS
In order to the Grishanin invariant for the classification of Lithuanian river-channels the mean values of invariants, the biggest values of their deviation and empirical averages (S) of the deviation module have been calculated for the rivers presented in the Table 1. The mean values of the invariant vary within 0.85- 1.81. Empirical averages of deviation module for most of mean values of invariants are below 0.1, and only highly urbanized rivers have value of this coefficient above 0.1. The highest empirical coefficient of deviation module is 0.26. Wider variation of the invariant can be determined by channel deformations, local flow backups, sudden increase of the channel width, bigger tributaries, etc. (Grishanin 1990). Generally, different mean values of the invariants, calculated for different river-channels or their sections, and slight absolute values of average empiric values of deviation module corroborate the statement that Grishanin channel stability criterion is quasiconstant (equations 2 and 3) only for certain sections of rivers and can be used as river-channel classification index. Dependency analysis (Fig. 2) and results of investigations (Channel type= f(A)) earlier conducted by the author of this paper (Rimkus 1988) show that the following three types of river-channels can be distinguished from the whole of points on the basis of identity of mean values of Grishanin invariant: (1) straight channels with alternating bars; (2) forced and limited meandering; (3) highly meandering. Thus, according to Grishanin invariant and considering development of river-channel types classification in other regions (Tshalov et al. 1998) the earlier proposed types of channels – forced and limited meandering – are attributed to one type of river-channels and are called 0.6 1.1 1.6 2.1 1 10 100 A M 1 2 3 4 Figure 2. Dependences of river-channel types on Sniscenko criteria A and Grisanin’s criteria M : 1 – straight channels with alternating bars; 2 and 3 – adapted meandering channels ((according to former classification (Rimkus 1988); 2 – forced meandering channels and 3 – limited meandering channels)); 4 – highly meandering channels. 0 2 4 6 0 4 h m Medium depth m a) b) c) 2 6

Figure 3. Interrelation of the parameters of the river-channels in different types of beds: (a) the Neris at Vilnius, straight channel with alternating bars; (b) the Merkys at Puvociai, adapted channel & (c) the Sesupe at Kalvarija, highly meandering channel.

channels of adapted type. Calculations show that straight channels with alternating bars have the mean value of the invariant M= 0.91 (0.74<M < 1.07), empiric average of deviation module of mean values of Grishanin invariant S= 0.09, the corresponding values of adapted type channels are M = 0.99 (0.9<M < 1.09), S= 0.06; of highly meandering channels – M = 1.36 (1.17<M < 1.81), S= 0.18.

Graphic interpretation of Grishanin invariant (Fig. 3) illustrates regular interrelation of the main parameters of river-bed – depth, width and water discharge. The invariant equation (3) is expressed with respect to depth:

where h med =medium depth of flow in the channel according to Grishanin invariant.

After that calculations, graphical and statistical analysis are performed according to randomly selected hydrometrical data of different type river-channels. The analysed relation is relatively close in the rivers of the same type of channel, while comparison shows

significant differences. Figure 3 shows the relations,

expressed by the following equations:

(a) the Neris at Vilnius (straight channel with alternat

ing bars)

(b) the Merkys at Puvociai (adapted channel) (c) the Sesupe at Kalvarija (highly meandering channel) Different interrelations of the main parameters of the channel are characteristic the river-channels of different type. This should particularly be taken into consideration in the case of reforming of sections of river-channels, e.g. construction of bridges and waterworks, reforming river-channels in lower steps of waterworks, other regulation or renaturalization of river-channels. Tendency to deformations can be determined on the basis of Grishanin criterion and type of river-channel. According to K.V. Grishanin if M > 1.05 (channels with tendency to meandering), the river flow does not have full transporting capacity and mud silting of the channel is probable. On the contrary, if M < 0.90, the river-channel has an increased transporting capacity and deepening is probable. Thus value of the index M helps to determine not only type of the channel, interrelation of the main parameters, but also channel stability and tendencies to deformations: the lowest transporting capacity is characteristic to highly meandering channels, the highest one – to straight channels with alternating bars (relatively straight channels). This conception is confirmed by famous supporter of hydromorphology theory – B.F. Sniscenko, who states that “...transition from highly meandering channels to straight channels with alternating bars can be related with gradually growing amount of bed and suspended load, and increase of total amount of stream sediments and transporting capacity” (Kondratjev et al. 1982, p.88). 5 CONCLUSIONS 1. Analysis of river-channel classification shows the lack of attention to this problem in Lithuania. Theoretical and practical necessity of river-channel distribution to types is reasoned. 2. Distribution of Lithuanian river-channels to straight channels with alternating bars, adapted channels and highly meandering channels is suggested on the basis of the analysis of river-bed stability criterion/ Grishanin invariant. 3. The interdependancy of the most important parameters of different type river-channels – mean depth, width and discharge – is based on the regularities, characteristic to separate types of channels. Type of the river-channel

determines the channel stability and tendencies to deformations: the lowest transporting capacity is characteristic to highly meandering channels, the highest one – to straight channels with alternating bars (relatively straight channels).

3D numerical modelling of morphological bed changes in the Danube River

T. Fischer-Antze & D. Gutknecht

Institute of Hydraulics, Hydrology and Water Resources Management, Vienna University of Technology, Austria

N.R.B. Olsen

Department of Hydraulic and Environmental Engineering, The Norwegian University of Science and Technology,

Norway

ABSTRACT: This paper describes numerical modelling of morphological bed changes in the Danube River.

The reach modelled in this study has a length of 4 km and is located between Vienna and the Austrian-Slovakian

border. The Danube River in this reach is characterised by a great width-to-depth ratio leading to an alternate bar

configuration. The August 2002 flood event with a peak of 10,000 m 3 /s was modelled. The numerical code is

based on a finite volume approach solving the Navier-Stokes equations to obtain the water velocity and the bed

shear stress, and the sediment transport is computed by an empirical formula. In the present study, the model

was modified by introducing a new sediment transport formula by Wu et al. (2000). Results show a fairly good

agreement between measured and calculated bed changes.

1 INTRODUCTION

The Danube River reach between Vienna and the Austrian-Slovakian border has a length of 40 km and is one of two remaining free flowing reaches in Aus tria. At the upstream end, a hydropower station acts as a barrier to the sediment transport which disturbs the natural sediment dynamics. The reach is significantly influenced by river engineering works in particular by groynes and fixed banks. In regions of minor engineer ing influence, the development of alternate bars can be observed.

As a consequence of significant manmade encroach ments, the reach is in a stage of erosion with an average erosion rate of approximately 2 cm per year; the lack of sediments held back from the upstream dam require compensation by the operator of the hydropower station.

In August 2002, a 100 years flood with a peak dis charge of 10,000 m 3 passed the Danube and caused significant bed changes. In this study the bed changes were modelled using the three dimensional model SSIIM on a chosen reach of 4 km. The quality of the results is assessed by comparing measured with calculated bed changes.

2 RIVER MORPHOLOGY

In nature, rivers are exposed to morphological bed

changes caused by interaction between flow and sediment transport. Depending on the flow situation and geometrical features of the river, different bed structures can emerge. The Danube River reach in this study is characterised by a width-to-depth ratio of approximately 60 and a depth-to-grain-size ratio of 200. According to literature, the before mentioned values should lead to a dominant alternate bar configuration (Yalin & da Silva, 2001). With a mean grain diameter d m of 26 mm, (d 16 = 6 mm, d 84 = 48 mm, d 90 = 58 mm) (Zottl & Erber, 1987) the Danube in this reach is classified as a gravel bed river with a wide sieve curve. 3 DATA ANALYSIS On behalf of the Austrian Waterway Authority bi-annual bed level measurements from a boat are performed to monitor the development of the river bed. The boat position was measured by a differential GPS technology, and the bed levels were determined using single beam echo sounder in combination with water levelling. The system measured the bed levels on pre determined cross-sectional profiles to enable comparisons of different measurement campaigns. The data used for this study have a longitudinal spacing and a cross-sectional distance of 100 m and approximately 0.5 m, respectively. Pre and post flood surveys performed in spring and autumn 2002 are used in this study. The measured cross-sectional data was processed with

an interpolation software. The river beds from the two

surveys were rastered onto a grid with a mesh size

of 10 m in both directions. The grid positions for both

surveys were kept identical for enabling the creation of

differential plots. This methodology allowed to detect

the spatial distribution of erosion and deposition pat

terns which evolved during the period between the two

surveys.

Additionally, approximately 30 bed samples dug

from the river bed using a grab dredger with a volume

of 0.3 m 3 evenly distributed over the whole study reach

were taken to achieve a mean grain size distribution of the river bed. The modelled reach was chosen because it was not influenced by engineering work during the measurement interval and because it was within the alternate bar reach.

4 SEDIMENT TRANSPORT

The sediment transport in this study was computed by incorporating a sediment formula for bed load by Wu et al. (2000) to the three-dimensional numerical model. A correction factor accounts for hiding and exposure mechanisms assuming to be a function of the hidden and exposed probabilities, which are stochas tically related to the size and gradation of the bed material. The probability of particles d j staying in the front of particles d i can be assumed to be the percent age of particles d j in the bed material, p bj . Therefore, the probabilities of particles d i hidden and exposed by particles d j can be obtained as:

where N is the total number of particle size fractions of nonuniform sediment mixtures, p bi and d i are the percentage and the diameter of the ith fraction, respec tively, η i is the correction factor and m is a constant determined to be −0.6.

The hiding and exposure factor is then used to mod ify the criterion for sediment incipient motion for each

fraction, where τ ci is the critical shear stress for particle d i in nonuniform sediment mixtures, γ s and γ are the specific weights of sediment and water, respectively and θ c is a constant determined to be 0.03. The non-dimensional fractional bed-load transport rate φ bi is defined as where q bi is the transport rate of the ith fraction of bed-load per unit width. Laboratory and field data was used to establish the formula for the fractional bed-load transport rate. By a regression analysis using least square curve fitting, the following relationship is obtained, where n ′ is Manning's coefficient corresponding to grain roughness, here calculated with n ′ = d 1/6 50 /20, n is Manning's coefficient for channel bed which was calibrated here and τ b is the bed shear stress. 5 NUMERICAL MODELLING OF SEDIMENT TRANSPORT To compute bed changes over time the semi-implicit numerical model SSIIM (Olsen, 2002) was applied. A finite volume method with a non-orthogonal, structured, and adaptive grid in the vertical direction was used for spatial discretisation. The model solved the Reynolds averaged Navier-Stokes equations in the three directions. The k-ε turbulence closure scheme (Rodi, 1980) computed the stress term and the SIMPLE method (Patankar, 1980) the pressure term. In SSIIM there are several options to calculate sediment transport. The most tested approach is represented by the formulas of van Rijn (1984, a, b, c). Due to the fact that this formula has a limited range of applicability – it was tested for grain diameters up to 2 mm – the recently published transport formula presented by Wu et al. was incorporated into the model for this study. The two-dimensional distribution of the shear stress is computed from the turbulence model. The vertical bed changes in the centre of a cell in the bed geometry are calculated from the Exner equation where the difference between sediment inflow and outflow in one cell is multiplied with the time step and the result is divided by the area of the cell seen from above. The average bed movement in each cell must be transferred to the corners of the cell, where the vertical levels of the bed are defined (Olsen, 2000). A two

layer concept with an active upper layer and a lower

inactive layer enables to model armouring processes.

In this study, sediment transport computations were

performed on the 4 km reach. In order to compute the

flow with a maximum precision in this reach, a pre test

with a length of 8 km was chosen to serve as an input for the initial flow field and to assure a developed flow field at the inflow boundary of the smaller study reach. The discharge and the water surface elevation in this study were kept constant at the level of the 100 year's flood assuming that most of the transport and bed changes between the two surveys happened during the peak.

6 RESULTS

In figure 1, the 4 km long reach of the Danube River is shown. Figure 1a displays water depths below a pre defined fixed low water level. The water is flowing from the left to the right, the numbers along the reach indicate the stream-km decreasing in flow direction towards the Black Sea. Typical morphological features of a natural river in a bend with a mobile bed can be observed being a bar formation in the inner bend and scour at the outer bend. The studied river reach is situ

ated in an environment of alternate bars. Illustrated in
1902 1902 1904 1904 1906 1906 Depth below low water level [m] 1902 1903 1903 1903 1904 1905 1905 1905 1906 -1012345 Erosion [m] Deposition [m] -1-0.75-0.5-0.2500.250.50.751 b) a) c)

Figure 1. a) Water depths of the Danube River in spring 2002, b) measured bed changes between spring and autumn 2002,

c) computed bed changes. figure 1a, one bar ends at the upstream end and another bar is formed at the downstream end of the reach. Figure 1b shows a differential plot of the pre and post flood bed topography survey. The plot was

generated by subtracting the interpolated grid of the pre flood measurement from the post flood grid. This processing allows detection of areas with erosion and deposition together with the amount of bed changes during this period. Several morphological processes can be derived from this figure. The local bed changes remained mostly in the range of ±1 m. An area of deposition can be observed at the upstream bar, which indicates a bar movement. Furthermore, the point bar dynamics are characterised by an increase of bar height and an erosion of the scour in the outer bend. In a distance of 300 m from the downstream end, a deep hole-like area occurred in the bed levels of spring 2002, which was filled by sediment due to the flood event. Figure 1c represents the bed changes computed by the numerical model. The above mentioned characteristic features of the bed changes can be reproduced by the model with a fairly good quality. The height of modelled local bed changes coincides well with the measured bed changes. Regions of strong bed changes as the deposition of the upstream bar, the deposition at the second part of the point bar and the deposition due to the filled up hole near the downstream boundary are represented well by the model. Results show, that

both the position and the amount of bed changes are

predicted correctly.

The band of erosion in the scour region and the

deposition area in the bar region are modelled with

less accuracy. The bed changes in the bend show the

correct tendency of erosion and deposition patterns,

though the locations and amounts of changes show

some deviations. The scour near the outflow of the

reach is over predicted by the model.

Generally, the numerical model is capable to pre

dict bed changes caused by a storm water event, both

the deposition and erosion patterns and the amounts

of changes are predicted reasonably correct for the

overall reach.

The deviations from the natural development may be caused by some simplifications in the model which were necessary due to a lack of dense spatial information. For simplification, a constant initial sediment distribution at the bed was assumed, so that pre existing armouring and sorting processes were not accounted for. The water leaving the main channel into the floodplains was neglected, since slow flow velocities in the shallow areas are assumed to be of minor importance for bed changes. The assumption of a constant discharge will probably be a source of less accurate results. Furthermore, the sediment input into the model had to be estimated, since for such extraordinary floods reliable bed-load measurements are not practicable.

7 CONCLUSIONS

The aim of the present study was to modify an existing three-dimensional numerical code with a new sediment transport formula and test it on the Danube River. The Wu et al. formula was incorporated, which enabled to compute nonuniform sediment transport by accounting for exposure and hiding effects.

The model was tested for a 4 km long reach of the Danube River and was compared against bed level

measurements. This study was a first step towards three dimensional modelling of the Danube river. The preliminary results indicate that the model can repre

Using a 1D steady flow model to compare field determination methods of bank-full stage

O. Navratil, M.-B. Albert, C. Boudard & J.-M. Grésillon

Cemagref, Lyon, France

ABSTRACT: Existing methods to determine bank-full stage and then bank-full discharge from field measurements give very diverging results. With the aim of clarifying this question, we use a 1D steady flow hydraulic model as reference in order to compare the main existing methods, applied on height case studies. We present here our methodology for one of these cases, the Ardour River at Folles, in the Loire river basin, France. Consistency of bank-full definitions is tested with the help of the hydraulic model. Thus, the evolution of flooded area with discharge at river reach scale allows us to define the hydraulic significance of the different elevations and discuss the validity of each method on the basis of hydraulic definition.

1 INTRODUCTION

Bank-full discharge is an interesting parameter to summarize channel morphology at reach scale and to study morphology – hydrology relationships. But identifying bank-full flow conditions for natural rivers is a heavy challenge. The indepth comparative analysis published by Williams (1978) evidenced that exist

ing methods generally used lead to very diverging results. He wrote that “ideally, the various methods should all be compared with the ‘true’ bank-full dis charge for each station. However, the chances of being present to measure a flow just at bank-full, however defined, are extremely small, and the true bank-full discharges are unknown for the stations of this study. So the different methods are simply compared with one another”. Other works aimed to compare different esti mations of bank-full discharge (e.g. Radecki-Pawlik 2002). Therefore, we try to follow up these studies, using hydraulic model results, in order to define the hydraulic significance of each stage definition.

2 STUDIED RIVER REACH

Ardour River at Folles is situated in the Loire river basin, France.

The stream reach surveyed is an alluvial river with perennial flow (figure 1). No significant upstream reg ulation or diversion occurs. Its associated river basin is a 131 km 2 drainage area underlying by a granitic bed rock. The studied reach is 230 meters long, i.e., about 25 times the mean bank-full channel width (Wb= 9 m), with a mean slope of about 0.0047. Figure 1. Upstream view of the Ardour river reach with main channel and floodplain. The channel has low sinuosity (1.03) with a well developed floodplain. It is a C3 channel type, according to Rosgen classification (Rosgen 1994). The reach includes a gauging station with 30 years of records and a

well-known stage-discharge relationship available from the Regional Environmental Department. A bridge situated at the middle of the river reach does not constrain the main channel flow. Water surface profile starts to be disturbed only for discharge greatly above bank-full conditions (discharge exceeding 20 m 3 /s). 3 TOPOGRAPHIC MEASUREMENTS Topographic measurements were practiced in the stream channel and adjacent floodplain (figure 2) and linked to staff gage elevation using an electronic, digital, total-station theodolite. Nineteen cross-sections were surveyed to describe the main morphological variations and water surface profile at the reach scale. Along the river reach, eleven morphological features were systematically surveyed at each crosssection to describe the main breaks in the cross section

geometry (figure 3): five features on each side of the

channel in addition to the thalweg elevation.

The intersection between water surface and channel

banks on the left and right sides are also surveyed,

to characterize the hydraulic conditions at the time

of survey. These measurements have been led at two

different flow conditions.

Topographic measurements will be used 1/ to define

bank-full elevation all along the river reach on the basis

of different definitions and 2/ to build an hydraulic

model.

4 BANK-FULL STAGE DEFINITIONS

Two different ways exist to define bank-full stage

based on morphological criteria (Williams 1978):

1. On site estimations of the elevation of incipi

ent flooding at different cross-sections, all along

the stream survey, using morphological breaks as

fields indicators (Leopold et al. 1994, Osterkamp &

Hedman 1982).

2. Geometric criteria requiring measured cross

sections (Wolman 1955, Riley 1972, Pickup 1976,

Williams 1978, Harrelson et al. 1994). 4.1 Geomorphic definitions Topographic measurements provide two geomorphic indicators at cross-section scale to characterize the transitional area between main channel and floodplain surface: the Bank Inflection and Top of Bank elevations (figure 3). The Bank Inflection feature corresponds to the upper limit of the main channel. It is the end of the near vertical channel bank. Many authors used to detect this feature on field. Leopold and Wolman define this break as

the active floodplain elevation for near straight channel or river reaches that have a low sinuosity (Leopold et al. 1994). It also corresponds to the limit of the active channel (Osterkamp & Hedman 1982). The Top of Bank feature corresponds to the elevation of the Valley Flat (Williams 1978; Leopold et al., 1994), the flood stage (Emmett 1972) or the predominant bench (Kilpatrick & Barnes 1964). It can be defined as the end of the transitional area between main channel and floodplain, and in this way, the beginning of a near flat surface (figure 3). This morphological feature has been already used for an other study on this river reach (Navratil 2002). At each cross-section, we retain the mean elevation between left and right side. These geomorphic definitions of bank-full stage are therefore highly dependent on operator expertise and channel difficulties to detect such features (Wahl 1976). However, these measurements provide, rather than a single elevation, a range of bank-full elevation all along the river reach. 4.2 Geometric definitions Using topographic measurements available at crosssections, we applied three classical methods analyzed by Williams (1978). Wolman's definition is the elevation corresponding to the minimum in the width to mean depth ratio function of the elevation. It was first introduced by Wolman (Wolman 1955) and used by many authors (Harvey 1969, Pickup & Warner 1976, Richards 1982, Carling 1988, Radecki-Pawlik 2002). Figure 4 shows an example of such a relationship at one cross-section. Riley's definition is the stage corresponding to the first maximum of the bench index (Riley 1972). This index characterizes the evolution of bank slope versus elevation (from upper to lower elevation). Figure 5 shows such relationship and the bank-full stage defined at a cross section. Different maxima appear, corresponding to other break in bank slope (Radecki-Pawlik 2002). Williams's definition (Williams 1978) is the elevation corresponding to a change in the relation between wetted area to top width (figure 6). As evidence in figure 7, the three methods lead to different bank-full elevation values. Williams and 0 50 100 150 200 250 300 350 400 10 11 12 13 14 15 16 17 Elevation (in meter)

Other hydraulic parameters as width, wetted perimeter, mean water depth, wetted area and maximum water depth can be derived from this computed elevation. A one dimensional code of simulation for steady and sub-critical flow is used (Baume & Poirson 1984). The water surface profile is calculated with good accuracy with the equations used into this code (Nicollet & Uan 1979). But, basics hypothesis have first to be verified. The sinuosity of the station being low (see study area), the one dimensional hypothesis is admitted. As we characterize the morphology of the main channel in term of capacity, the steady flow is then justified. As the mean slope is very small for all the station studied, the flow is subcritical. Afterwards, the good accuracy of the river modeling depends on quality of the topographical model, calibration data and method used. In addition to longitudinal variability of the current cross sections, the topographic measurements 9

included the description of possible hydraulic controls (bridges, weirs). A relationship between water level and discharge at the downstream cross-section was developed using a uniform flow model, in accordance with on field measurements at two different flows.

To calibrate our model, we used water surface profiles measured for two different discharges, one at low flow (Q= 2.26 m 3 /s), the other one at near bank-full flow (Q= 7.43 m 3 /s). A rating curve is also available by the Regional Environmental Department, with its range of validity. We fitted our model by using the Single Channel Method (Lyness et al. 1997), i.e., a single roughness coefficient for the main chan nel and the floodplain. A single Manning's "n" value for the entire reach is accepted with a mean error of 5 cm. Figure 9 shows an example of calibration for Q= 7.43 m 3 /s.Then, it allows us to calibrate our model for other discharges with the rating curve available at one cross-section and to extrapolate these results for

the entire reach. Such a calibration provides a good estimation of water profile for in-bank and over-bank flows within the range of validity of the rating curve.

6 A SYNTHETIC REPRESENTATION OF OVERFLOWING DEVELOPMENT

For the purpose of this study, bank-full stage was defined according to morphological indicators. We consider that bank-full flow occurs at a break in slope, above which small increases in depth are accompanied by disproportionately large increases in width.

To characterize the hydraulic meaning of bank-full definition, we use the hydraulic model to estimate the evolution of flooded area for a large range of flows, at the reach scale. Figures 10a-c shows the flooded area, calculated with the hydraulic model at three dif ferent discharges: (a) in-bank flow (Q= 3.5 m 3 /s), (b) intermediate flow (Q= 7 m 3 /s) and (c) over-bank flow (Q= 14 m 3 /s).

For Q= 3.5 m 3 /s, the flow is contained in the main channel. For Q= 7 m 3 /s, local area are flooded, due

Figure 10a-c. Over view of the flooded area at the reach scale for tree discharges from upstream (right side) to downstream (left side): Q= 3.5 m 3 /s; Q= 7 m 3 /s; Q= 14 m 3 /s.

to vegetation interact with bank morphology and local sedimentation. For Q= 14 m 3 /s, the flow is well developed in the floodplain. For this flow conditions, the flooded area is relatively homogeneous, excepted a local area corresponding to bridge's embanked crosssections at the middle of the reach and a downstream morphological singularity. With the aim to study overflowing increase at reach scale and to compare different definitions of

bank-full elevations, we use the relationship between the flooded area versus discharge (figure 11). From low flow to about 15 m 3 /s, the flooded area is significant at the reach scale. For upper flow, variability increases largely.

(k m

2) in-bank flow intermediate range of flow over-bank flow

Figure 11. Evolution of the mean flooded area versus

discharge (solid line).

At low flow, flooded area increases rapidly for a

little rise of discharge (flows of about 0 to 0.5 m 3 /s).

Next, different ranges of discharge can be character

ized when studying the relative increase of flooded area with a constant step of discharge (figure 11):

1. A smooth evolution of the flooded area with a constant rise of discharge: flows from 0.5 to 5 m 3 /s.

2. The intermediate range of discharge where local over-bank areas occur, can be associated to the transition between main channel and floodplain flows: flows from 5 to 7.5 m 3 /s. Its low bound is characterized by a sudden rise in flooded area.

3. The third range of discharge called the over-bank flow describes the floodplain evolution flow: from 7.5 to about 15–20 m 3 /s. Its low bound corresponds to the beginning of a relatively constant increase of flooded area and ended at the limit of the floodplain.

At upper discharge, a smooth evolution of the flooded area versus discharge can be detected, cor responding to valley margin (flows upper than 15–20 m 3 /s). Such a relationship will help us to find the hydraulic significance of each of the five bank-full definitions (see bank-full stage definitions).

7 CONSISTENCY OF BANK-FULL DEFINITIONS AT RIVER REACH SCALE

Bank-full stage has been computed at each cross section all along the site survey, for each definition (table 1). The range of bank-full discharge can be up to a factor 4, showing the great variability for each

definition. Bank-full discharge can’t be considered at

a single cross-section, but rather at a reach scale.These

results demonstrate and complete further analysis that

concept of bank-full discharge has no significance at

a single cross-section (Riley 1972, Williams 1978).

Assumption that bank-full discharge concept is

significant at a larger scale, i.e., that water surface

profiles corresponds, on the average, to morphological features all along a stream reach, for characteristic discharges is now tested. Water surface profiles are computed for different discharges. The least square method is used to determine the discharge that minimizes, at the reach scale, the mean absolute difference between water surface levels modeled and morphological levels previously defined. For example, figure 12 shows the Williams’s bank-full elevation and the adjusted water surface profile for Q= 7.2 m 3 /s (table 1). Table 1 gives the main results of this test for other bank-full definitions. It allows us to appreciate the consistency, at reach scale, of these different bank-full elevations. For all definitions retained, bank-full elevations are normally distributed around water surface profiles with a 95% confidence interval. The mean difference is less than 0.002 m for each definition. All definitions are then consistent at river reach scale. Characteristic discharges corresponding to morphological features have physical significant at this scale (table 1).

However, each definition of bank-full is more or

less consistent all along the site. Mean differences

between Top of Bank or the Bank Inflection elevations with water profiles are respectively 0.17 and 0.12 m. Wolman's and Williams's definitions are consistent too but with a mean error a little bit greater than geomor phic definitions (0.15 and 0.18 m). Riley's definition seems to be less consistent than others, with a mean difference of about 0.26 meter. The calibration uncer tainty of water level modeled can explain about 20% of variability between water level and morphological features (calibration uncertainties are about 0.05 m). Then we can assess that Wolman and Williams's defi nition, Top of Bank and Bank Inflection are consistent all along the reach. The Riley's Bench Index seems to be a poor definition of bank-full condition for this site survey.

Bank-full discharge expressed at a cross-section has no significance, but, on the opposite, this metric well describes the main channel morphology averaged at the reach scale. A test of robustness of bank-full dis charge value with the length of the survey shows that this length must be about 20 times bank-full width to converge to bank-full discharge estimated using the all studied reach (test lead with the Bank Inflection elevation with an accepted error less than 5%). This test is in accordance with literature recommendations

(Harrelson et al. 1994, Leopold et al. 1994).

8 HYDRAULIC SIGNIFICANCE OF BANK FULL DEFINITIONS AND CONCLUSIONS

Bank-full discharge estimated with the hydraulic model for each definition (table 1) are now associated with its corresponding flooded area (figure 11).We can locate these values on the flooding evolution curve to determine their hydraulic significance (figure 13).

Large scale tests for gravel-bed river widening

M. Aufleger & A. Niedermayr

Institute for Hydraulic and Water Resources Engineering, Technische Universität München, Germany

ABSTRACT: Numerous gravel-bed rivers are affected by unceasing degradation problems, mostly caused or

increased by technical measures upstream. In Germany removing the bank fixations is regarded as a concept

to dissolve the problem. By allowing lateral erosion and in consequence river widening the bed load transport

capacity will be decreased. Additionally the eroded bank material will serve as an auxiliary sediment influx. To

determine this process of gravel river widening and estimate the possible changes in river morphology, large

scale tests are carried out at the Technische Universität München since 1999. In addition to a straight model

flume, with a total width of 8 m and a length of 100 m, a double curved model flume with a total width of 10 m

and a length of 90 m was constructed to investigate the erosion effects in meandering channels.

1 INTRODUCTION

Incising gravel-bed rivers are one of the main concerns

in German river engineering. For the sake of flood pro
tection, energy production with hydropower, land gain
for agriculture or improved shipment of rivers, many
rivers were changed fundamentally. Like the Bavar
ian alpine rivers Iller and Isar, which are tributaries of
Danube, they were regulated, their width was restricted
and the banks fixated. Thus, the bottom shear stress
and erosivity increased. As a consequence of the con
tinuing degradation, the water level and thereby the
ground water level decreased causing severe harms
to the river ecosystem and floodplain, as well as
endangering the stability of hydraulic structures.

2 REMOVAL OF BANK FIXATIONS

2.1 General

Actually, the removal of the bank fixations is taken into
account allowing lateral erosion. Thus, the river will
be able to adjust its width, bed elevation and profile to
the given constraints. The river bed widening leads to
a reduction of the shear stresses and consequently to a
reduction of the degradation tendency. In addition, the
eroded bank material will serve as an additional sed
iment influx and will prevent bed level from erosion
in the meantime. Though there exist much research
work about river regime and stable channel design
(e.g. Ackers & White (1973), Bray (1980), Chang

(1980), White & Bettess & Paris (1982)), convenient

experiences about the process of river widening and the final geometry of a river for given constraints are missing, especially if there is no sediment input from an upstream reach and the free adjustable reach length is restricted. Considering this lack of suitable research work the improvement of planning tools for river rehabilitation measures basing on the removal of bank fixations was necessary. Preliminary test were carried out in small model flumes (Schmautz & Aufleger (2002)) and simultaneous extensive analytical investigations were undertaken (Schmautz (2003) and Schmautz (2004)). To minimise the influence of model effects or necessary simplifications, it was necessary of using large model tests. 2.2 The structure of investigations Simultaneous to the physical investigations, a numerical model has been developed to investigate gravel river widening by bank erosion in a straight stretch of river. The physical model hence serves additionally as a perfect method to calibrate and verificate the numerical model (Figure 1). In return the calibrated model simulates a multiplicity of model runs in short time and aids to interpret the test results. 3 FUNDAMENTALS 3.1 Scale The choice of the geometrical scale is essential for the transferability of model test results in prototype data. Gravel-Bed River Widening Research Program Physical Model Large Scale Tests Straight Laboratory Flume Straight Double Curve Numerical Model Interpretation and Extrapolation of test results Calibration and Verification Data

Figure 1. Organisation of the gravel-bed river widening research program.

Regarding bed load transport investigations, for the

sake of a good reproduction the model has to be large,

which is usually in contradiction to economical aspects

and feasibility. In our case, the scale was chosen as

large as possible, to reduce side effects on transport in

consequence of viscosity.

3.2 Simplifications

The model tests are mainly carried out for the sake of

investigating the fundamentals in morphological pro
cesses, e.g. interaction between river bed widening and
bed level erosion or lateral erosion mechanisms. Thus,
the intention of the model tests can’t be to reproduce
the nature in every possible aspect. Adequate simpli
fications must be chosen for economic reasons and
terms of feasibility:

- The influence of vegetation on lateral erosion mech
anisms is neglected.
- Identical model sand material is used for the con
struction of the river banks and the river bed. In
nature, the river banks consist of finer gravel than
the river bed, but a construction in layers would
be much more difficult and the whole model sand
should be exchanged due to mixing after each
model run.
- The initial state is approximated by an trapezoidal
cross-section and either an absolutely straight chan
nel (4.1) or an ideal double curved river reach (4.2).

4 THE TEST CHANNELS

4.1 The straight channel

The main focus of the first model tests was to concen
trate on the basic principles of the widening process
and the interaction between bank erosion and degra
dation resp. aggradation.Therefore side-effects caused

by meandering flow were disregarded, mainly because

the regarded Bavarian alpine river Iller is only slightly

meandering. Figure 2. Straight test channel (M= 1:20). The straight test channel was constructed in 1999 and consists of a 100 m long and 8 m wide flume, supplying sufficient place for lateral erosion. The tests were mainly carried out in the geometrical scale M= 1:20. Since 2000 a total number of eight model series, some of them consisting of several model runs, were performed regarding different boundary conditions like upstream sediment influx, model sand diameter, initial channel width or the initial longitudinal slope. The results of one model series concerning the river Iller are described in Aufleger & Niedermayr & Strobl (2003). 4.2 The double curve In addition to the straight model flume a double curved model flume with a total width of 10 m and a length of 90 m was constructed in 2002 to investigate the erosion effects in meandering channels. This model test is required by the need for an investigation of the Bavarian alpine river Isar, which is contrary to the river Iller distinctly meandering.

Figure 3. Double curved test channel (M= 1:20).

The construction of the whole model test was con

ducted in one year, including the development of an

adequate measurement device, the build-up of the nec

essary roofing to protect the cohesionless river bed

against rain, the preparation of the initial trapezoidal

river bed and the performance of the first model run.

A second model run could be performed in 2003.

4.2.1 General about the hydraulic in river bends

There exist much research work about the hydraulic in

river bends, especially about the degree of the transver

sal water slope, the cross-sectional motions, i.e. the

helical motion resp. secondary flow, and the occurring

shear stresses. Measurements were either achieved in natural rivers (e.g. Bathurst & Thorne & Hey (1979)) or rectangular model flumes (e.g. de Vriend (1981) or Blanckaert & Graf (2001)).

General, in river curves secondary flow occurs resulting in motion towards the outside curve near the water surface and towards the inner curve near the bot tom. This helical motion increases the shear stress on the outer river bend and causes besides the centrifugal force a transversal bottom slope.

Our model tests concentrate on morphology changes.To minimise the necessary work, in particular concerning the measurement, we abandon expensive and detaily flow velocity measurements. Such highly accurate measurements are intended for the next year. For that matter only general statements concerning the influence of the secondary flow could be made within this paper.

4.2.2 Test conditions of the double curved model

The model dimensions are designed appropriate to the situation at the river Isar near the estuary to Danube.The initial profile is approximated to be trape zoidal and two curves representing the meandering river. Radius and angles are corresponding to one river section intended for the realisation of the removal of

bank fixations. Figure 4. Model dimensions of the double curved test channel. The model tests were conducted under the following test conditions: - geometrical scale M= 1:20 - initial longitudinal slope J= 0.85% - model dimensions according to Figure 4 - Parameters R/B= 7.7; R/H= 188, B/H= 24.4 with R: radius of the curves, B: initial river width and H: initial river depth - model sand diameter d m = 1.2 mm, identical material for bank region and river bottom - bankfull discharge about Q= 435 m 3 /s which is corresponding to a return period of two till five years - constant downstream water level corresponding to normal water depth in a downstream straight channel with bank fixations - Total model run of 50 days in nature, divided into several time steps to record river changes - in case of the first model test in 2002 no sediment feeding - in case of the second model test in 2003 sediment feeding about 50% of the transport rate of the upstream initial channel. The transport rate of the initial channel at the given discharge is about Q S,Nature = 42.4 kg/s resp. Q S,Model = 23.7 g/s, thus the performed sediment feed amounts Q S,Nature = 21.1 kg/s resp. Q S,Model = 11.85 g/s. In the river Isar, especially at the location corresponding to the investigated double curve, there is a general lack of sediment feed from upstream. By feeding 50% of the transport rate in the model, two different situations in nature could be investigated. First of all, as a technical measure, sediment is deposited upstream hence the transport capacity is saturated partially. Secondly, an equivalent curve situation downstream, where an adequate bed load influx from upstream occurs, could be reproduced.

Figure 5. Measurement device and coordinates

transformation.

4.2.3 Measuring and evaluation technology

The quality of a large model test of such dimensions

is definitively affected by the utilised measurement

device and furthermore the accuracy of the acquired

model data.

The used measurement system mounted on a manu

ally movable measurement wagon is driving automat

ically transversal to the channel at the rate of 1 m/s. Measurements were achieved either by an optical laser sensor in case of sand level or an ultrasonic sensor in case of water level. The actual position of the measure ment wagon is registered by the use of a theodolite and two prisms fixed to the measurement wagon. After wards via the use of a geographical information system (GIS), a digital terrain model is created and any section of the model can be evaluated, mainly cross-sections and longitudinal profiles.

4.2.4 Comment

Two model test runs in the double curved test channel were performed and are compared within this paper. Their test conditions are only differing in the amount of sediment feed. General the structural and chrono logical development of the model tests is interesting. Within the scope of this paper only the structural devel opment of the two different model tests after 50 days of model run at bankfull discharge (Q= 435 m 3 /s) will be compared in the results. At the end there will be also some conclusions about the time-dependent development.

5 RESULTS

5.1 General structural development

After 50 days of model run at bankfull discharge

(Q= 435 m 3 /s), the river morphology changes relative

to the initial state fundamentally (compare Figure 9).
Figure 6. Total river width after 50 days of model run at bankfull discharge (Q= 435 m 3 /s). Both the river width in the first and the second curve augments, while the second curve gets much wider than the first one. In the inner part of the curves material is deposited, particularly decreasing the flow velocity in the inner part of the curves. Explicitly the formation of aTalweg took place, resulting in conjunction with the widening tendency in a rearrangement of the flow towards the outside curves. 5.2 Widening of the double curve In preliminary tests investigating the river Isar in the straight model channel under the same test conditions except that meandering was not displayed, only a slight widening tendency of few meters could be recorded, according to the relative small shear stress value in bank region in case of a straight river reach. Of course, in a curved flow the stress on the outside banks increases due to the influence of secondary flow and the necessary flow deflection in the bends. In case of removing the bank fixations, the widening will clearly exceed the value of a corresponding straight reach. Identically in both model runs, the width of the second curve in flow direction exceeds distinctly the first one (Figure 6). Towards the first curve, the incoming flow is affected by the upstream straight reach, therefore the flow smoothly slides along the outside river bank. In contrast, the much steeper angle of flow approach into the second curve causes severe stress on the outside bank and hence increases river widening. In region of the crossover point from the first into the second curve the river width minimises. River width of the second model run (50% sediment feed) tops in both curves the particular width of the first model run (no sediment feed). This is based upon the sediment feed, which results in less degradation and a higher longitudinal slope (see 5.3). In case of the second curve based on the initial state the width almost doubled.

Figure 7. Talweg elevation after 50 days of model run at

bankfull discharge (Q= 435 m 3 /s).

Thus, widening is mainly depending on the angle

of approach flow, the degree of transport capacity sat

uration and secondary flow. Furthermore, the flow is

concentrated over the deeper outer part of the river sec

tions, resulting in an increasing boundary shear stress outside (compare 5.4).

Concerning the time-dependent development of the two model runs (not displayed), in both cases mainly the second curve is still not getting a dynamically sta ble state, i.e. for the given discharge and sediment influx the width still increases. Contrary to the model tests in the straight channel, where such a stable state occurs after a few days of model run (Aufleger & Niedermayr & Strobl (2003)), the width development still does not end after 50 days of model run at bankfull discharge, although the widening tendency declines. An explanation for this persistent widening tendency will be shown in 5.4.

5.3 Bed level

As the flow area resp. the flow depth and the longi tudinal slope affect directly the shear stress and thus the tendency to erode resp. deposit material, an inves tigation of the actual-state of bed level is fundamental for an evaluation of the morphological development. Within this paper, the Talweg elevation (Figure 7) is investigated.

In both model tests, the Talweg erodes. In the first model test, erosion is about one meter und much more than in the second model test, where sediment feed

prevents bed level from erosion and hence causes only

few decimeters of erosion.

5.4 Water level

Water level decreases about 10 cm during the model

run (Figure 8). At the end, the medium water level

slope in the second model test is about 0.85‰.

In the first curve almost no transversal slope occurs,

contrary to the second curve where water level aug

ments in the outer part of the curve. Figure 8. Water level in the second model at bankfull discharge (Q= 435 m 3 /s). 5.5 Cross-sectional development The cross-sectional development (Figure 10) displays perfectly the morphological changes in flow direction. In the region of the maximum river width in the first curve (s= 900 m) lateral erosion of the outer bank occurs in combination with a development of the Talweg. Together with the deposition of bed load in the inner curve due to secondary flow effects and the influence of the centrifugal force a rearrangement of the flow towards the outer curve results. The same tendency can be noticed in the second curve (s= 1200 m). As the second model run gets wider than the first model test, also the location of the Talweg moves farther to the outer curve. But in addition, the deposition of material in the inner curve is more pronounced. Thus, the effective flow area in both model tests is almost similar. Velocity measurements confirm that in the inner part of the curves, mainly above the deposited material, almost no flow takes place. The main flow is restricted to the outer part of the curve (Blanckaert & Graf (2001)). The flow velocities resp. shear stresses do not change in the same way as the river widens and as a result the widening tendency declines only in small steps. This fact is a wide difference to the results of the straight channel, where river widening leads to an increase of the flow area and fast to a reduction of flow velocities and thus to decreasing shear stresses. 5.6 Volume transport From the measured cross-sections resp. the generated surface model volume changes based on the initial state can be evaluated. The volume change is defined as being positive in case of eroded material, thus the volume discharge exceeds the bed load influx (Figure 11). In case of the first model test,

where no bed load influx was performed, the volume change corresponds

Figure 9. Meandering development after removing existing bank fixations (50 days of bankfull discharge, Q= 435 m 3 /s).

Figure 10. Comparison of cross sections after 50 days of model run at bankfull discharge (Q= 435 m 3 /s).

to the volume discharge. In case of the second model

test with 50% bed load influx, the volume discharge

can be calculated out of the volume change and the

totally feed of bed load which is about 50.000 m 3 . The total volume change of the first model run after 50 days of model run is approximately about 60.000 m 3 , in case of the second model test only about 35.000 m 3 which means circa 40% less eroded

Figure 11. Definition sketch.

Figure 12. Volume change and volume discharge after

50 days of model run at bankfull discharge (Q= 435 m 3 /s).

material. In contrast, the total volume discharge of the

second model run is approximately 85.000 m 3 , about

40% more transport than in case of no sediment feed.

In the first model run where no bed load influxwas

provided, transport capacity is decreasing due to the

morphological changes, mainly reduction of the longi

tudinal slope.The second model test behaves different,

sediment feeding prevents river bottom from erosion

and the transport capacity remains at a high level.

6 CONCLUSIONS

6.1 Interaction between sediment feed, bed level and bank erosion

Responsible for any mass transport thus erosion is the shear stress value. If the local shear stress τ(n) exceeds the critical value τ crit then mass transport will occur (see Figure 13).As the local shear stress τ(n) is depend ing on the position in the river profile and on the flow, bed erosion may appear even if there is no lateral ero sion (in deed bank material could slide due to local stability failure).

Due to lateral erosion and sediment influx from upstream or sediment feed (Figure 14), the total amount of incoming sediment can exceed the actual transport capacity and will provoke deposition of the surplus amount of sediment. If there occurs lateral erosion, bank material will move due to the gravity force towards the channel center, hence eroded bank material will be transported at the river bottom and will prevent temporary river bed from erosion. River

morphology is influenced by the interaction between Figure 13. Schematic shear stress distribution. Figure 14. Influence of sediment influx from upstream resp. lateral influx. lateral influx caused by bank erosion, sediment feed resp. bed load provided by upstream reaches and river bed erosion resp. deposition. 6.2 Morphology in river bends The hydraulic in river curves affects directly the morphology and in return morphological changes influence the hydraulic in bends. The hydraulic is characterised by the centrifugal force, resulting in a transversal water slope and secondary flow. The development of the channel width in river bends is absolutely contrary to comparable straight river reaches, both concerning structural and timedependent development of river morphology: - River width in curves exceeds considerably the value in identical

straight channels. In the case of the observed river bends a width of more than 140 m, i.e. a doubling of the initial width, has to be expected. – The river width is depending on the amount of sediment feed. With increasing sediment feed bed level augments resulting in higher longitudinal slope. This directly forces the widening process. – Additionally any geometrical change in the approach flow as the shifting of the upstream river bend affects the widening process. – The whole erosion and deposition process in the river bend is connected directly to the secondary flow.

– As a consequence, the widening occurs not only at the start of the morphology changes, as it could be observed in the straight model channel (Aufleger & Niedermayr & Strobl (2003)). In deed, the influence of the affecting parameters lasts much longer on the widening process and furthermore changes of these parameters could tend to an local increased bank erosion.

Influence of local scouring on natural step pool geometry

F. Comiti, A. Andreoli & M.A. Lenzi

Dept. Land and Agroforest Environments, University of Padova, Italy

ABSTRACT: Step pool morphology characterizes many high-gradient streams in a variety of natural settings,

but its formative processes and evolutionary dynamics are still poorly understood. In this paper step pool

geometry is investigated from the perspective of a comparison with steep alluvial channels where grade-control

structures such as check-dams and bed sills make the stream

profile resemble a natural stepped stream. Along these channels, local scouring phenomena due to falling jets form plunge pools under each structure, as natural steps determine the formation of pools. In order to test the hypothesis that natural pools and pools formed below grade-control works present analogies with respect to their dimensions, shape and formative dynamics, 37 natural pools and 79 artificial pools have been surveyed in 11 mountain streams of the Eastern Italian Alps. Pools below grade-control works featured a transition between the scour hole and the downstream sloping bed marked by depositional berms. When geometric features such as maximum pool depth, length and step/berm distances are normalized to the jet virtual energy, almost no statistically significant differences have been detected between natural and artificial systems. These results lend support to an upstream-forced cascade model for step pool formation, where falling jets energy controls the geometry of the system, hence representing the most important scaling independent variable.

1 INTRODUCTION

Step pool torrents have been under active research for two decades now, both for their apparent geometric regularity which stimulates hypothesis about its origin, and for the peculiar tumbling flow pattern (Peterson & Mohanty, 1960) they present, which leads to dissi pate energy in a different and more effective manner compared to that accounted for by traditional flow resistance formula (Lee & Ferguson, 2002).

An analogy can be found in the sequences of grade control structures such as check-dams and bed sills placed in alluvial mountain rivers in order to stabilize these channels by preventing bed incision and by reducing their longitudinal slope. The river beds of such trained channels show a stair-like profile, but for lower gradients a positive bed slope – a downward sloping tread – called either ultimate, compensation or equilibrium slope is usually achieved between two drops, because their spacing is large enough to allow the flow to establish a sort of “uniform” regime down stream of the scour pool. However, for steep streams, short spacings are usually assigned, so that the next drop structure locates just at the end of the upstream pool, thus making the profile very similar to a natural step pool sequence. What gives step pool systems its peculiarity is the hydraulic regime which is featured, that is the above mentioned tumbling flow. It alternates gravity-driven jets just below steps and jet diffusion in pools, in a more or less rhythmic way with critical flow conditions occurring somewhere before the step lips. The passage between supercritical (Fr> 1) falling nappes and subcritical (Fr< 1) pools is made through a hydraulic jump, where the jet diffuses generating a great deal of turbulence. Therefore flow resistance in step pool systems is dominated by turbulent mixing energy dissipation analogous to that of hydraulic jumps more than by grain or form drag, even though the latter may be significant if steps are very rough (Knighton, 1998). However, if a positive bed slope downstream of the pools is present, also “continuous” energy expenditures take place, but given the macroroughness characteristics of steep boulder beds no supercritical flow is generally established along this span even if it might be present for very short distances (Jarrett, 1984, Grant, 1997, Tinkler, 1997). Therefore at

the next downstream step the flow can achieve again critical (Fr≈ 1) conditions, thus allowing to treat each step and its related pool identically from a hydraulic standpoint notwithstanding different upstream bed slopes, albeit this procedure might neglect the effect of

different jet issuance angles and different degrees of

jet turbulence.

A scour hole – the pool – will be shaped by the

diffusing jet if bed material can be entrained and

removed by the flow. It is obvious that a pool due its

existence to the upstream step, less straightforward is

how the variables of the system are interrelated and

how they determine the ultimate system geometry.

In particular, it is still poorly understood the rela

tive importance between downstream versus upstream

boundary conditions, between sediment properties and

jet characteristics, and finally what are the physical

processes involved in the origin and disruption of

natural step pool sequences.

Since the earliest investigations on step pool, a neg

ative correlation between step spacing and channel

slope has been identified (Judd & Peterson, 1969;

Hayward, 1980; Whittaker, 1987; Grant et al., 1990;

Chin, 1999; Chartrand & Whiting, 2000; Weichert

et al., 2003) but the parameters of the best-fit power

law equation differ considerably among the authors.

All the other possible correlations among dimen

sional geometrical variables, i.e. step wavelength and height, and external factors as discharge, slope and sediment size have been examined and can be found in Wohl et al. (1997), Chin (1999) and Chartrand & Whiting (2000). However, a marked improvement towards the understanding of variations in step pool geometry has been achieved by the adoption of a non-dimensional approach focusing on the so-called steepness H/L – analogous to a relative wave ampli tude – and its normalization by the channel slope, to give the relative steepness factor (Abrahams et al., 1995). It is notable to point out that the ratio height to-spacing H/L resembles a loss of head per unit of channel length, thus bearing energetic implications (Knighton, 1998). The innovative yet controversial experimental work by Abrahams et al. (1995) demon strated by flume tests that maximum flow resistance occurs with evenly-spaced steps and within the range: Such conditions were found by the same authors to describe rather well real step pool streams, where on average was c= 1.5. Geometrically, this result shows the lack of significant down-sloping streambed lengths in a step pool reach, i.e. downstream of pools – where bed slope is reversed – only a short, roughly flat zone is generally present before the next step. From an

energetic perspective this means that the elevation

loss due to steps approximates the total elevation loss

along a reach, confirming the role of step-induced spill

resistance on the overall energy budget in step pool

channels. Subsequent field investigations (Wohl et al., 1997; Chartrand & Whiting, 2000; Zimmermann & Church, 2001) has somewhat narrowed the extent to which Abrahams et al.'s slope-normalized geometry is valid in real streams, because they have observed for channel slopes below 5–7% ratios c usually larger than 2, and a negative correlation with channel slope. In addition, data from step pool channels in the Italian Alps (Lenzi & D'Agostino, 2000; Lenzi, 2001) confirm its suitability only for streams which have experienced several "ordinary" floods after the step-forming one, otherwise the ratio c tends to be below the unity. Therefore they argued that Eq. 1 might represent a geometrical equilibrium condition requiring processes of bed armoring and localized erosion to occur, in order to scour fine sediment from pools and thus attain a reverse bed-slope between steps. In fact, following an extraordinary flood with unlimited sediment supply, the steepness factor can suddenly decrease as a result of sediment trapped in the pools and a lengthening of step spacing. To date, morphological studies on step pool streams have all neglected to shed light on scouring process leading to pool formation, apart from the early work by Whittaker (1987) and the more recent one Zimmermann & Church (2001). This paper aims at testing the hypothesis that natural step pool geometry is mostly determined by local scouring phenomena due to jet diffusion, by comparing dimensions of pools found below natural steps and grade-control structures. 2 FIELD SITES AND METHODS 73 scour holes downstream of grade-control structures and 37 pools below natural steps were surveyed in 11 mountain rivers of the Eastern Italian Alps (Fig. 1). Mean longitudinal gradients of the channels range between 0.02 and 0.16. All the streams are perennial and present a typical Alpine hydrologic regime, with two periods of high stages: in autumn (rainfall floods) and spring (snowmelt runoff). Six streams – whose watersheds are geologically different and very complex – provided data on "artificial" step pools (Fig. 2). For a detailed description of these rivers, see Comiti (2003) or Lenzi et al. (2003), where several analysis of scour pools' dimensions below check-dams and bed sills are presented in detail. Five channels were selected for the survey of "natural" pools'

dimensions (Fig. 3); all but one (Biois River) drain rather small catchments (<20 km 2) and represent typical natural step pool sequences. Natural pools in the Biois were measured in a trained reach between two check-dams. Geologically, the basins lie in the Dolomitical area and present very complex alternations of sedimentary and igneous rocks. An

exception is the Digon catchment, which features a

prevalent metamorphic substrate (Andreoli, 2002).

In natural systems, bankfull width at steps, at pools

and, most importantly, bankfull flow depth at steps Figure 3. Definition sketch of the geometric variables surveyed below natural steps. were also surveyed. The latter is hypothesized to correspond to the critical (i.e. Froude number of the flow ≈ 1) flow depth h c in order to allow a comparison with pools below artificial steps because discharge data in natural channels are available only for the Rio Cordon creek, where a recording station for flow and sediment rates is located just downstream of the surveyed reach (Lenzi, 2001). Therefore initial jet thickness h c for natural step pools – in contrast to the case of grade-control structures where it was evaluated from flood discharge data – is more roughly estimated from bankfull marks at steps, which of course present several difficulties as to their interpretation. However, Rio Cordon discharge data furnished a means to test this methodology, and proved its validity. Scour length l s and berm distance l b characterize the longitudinal extension of artificial pools, with the latter representing the downstream border of the pool region, because just after the berm the bed typically shows a positive slope. For

natural step pools, instead, the longitudinal dimension l step is the distance to next step downstream, since no similar berms were found in natural systems between the scour length location and the next step, and a positive bed slope was generally absent. More details about the field measurements can be found in Comiti (2003). 3 RESULTS The same dimensionless parameters have been used to analyze both scour holes below artificial steps (i.e. grade-control structures) and natural pool dimensions. Figure 4 shows the relationship between maximum scour depth normalized to critical flow depth and the drop ratio z/h c , as done in Lenzi et al. (2003) for artificial pools only. Natural and artificial pools are displayed together: their points delineate a similar linear trend, overlying considerably in the range having more measurements, i.e. for z/h c < 4. For larger drop ratios, natural pool data are totally lacking, whereas the two high check-dams points seem to follow the same trend. It is remarkable that such an accordance

is achieved with one parameter only, and no sediment

properties are taken into account.

The parameter z/L is now introduced to analyze

scour dimensions. It indicates the potential energy lost

by the falling jet in the span length between two fixed

points, i.e. represents a sort of local gradient relevant to

each pool. If berm distance l b for artificial pools and

step spacing l step for natural ones are used, with the

ratio y s /z – analogous to the relative steepness factor

c (eq. 1) – considered as the dependent variable, the

graph in Figure 5 turns out.

If the parameter in abscissa is regarded as a slope

and the y-axis as the relative steepness factor, both

referring to berms in the case of artificial pools,

Figure 5 becomes analogous to a graph where the 0 2 4 6 8

Figure 5. Dimensionless plot of maximum scour depth ver

sus the “local gradient” factor; for artificial pools the berm

distance l b is the reference L, whereas l step is used for natural

pools. The range 1< c< 2 for the steepness factor proposed

by Abrahams et al. (1995) is marked too. steepness factor c is plotted versus channel slope, as in Zimmermann & Church (2001), and a similar decreasing trend is shown. Compared to that graph where the mean channel slope is the independent variable, here the “slope” values are much higher because they derive from local measurements of drop heights and step/berm distances. However, the tendency towards a c or y s /z of approximately 1.5 is exhibited in both figures, as well as the “rise” up to values around 4 for the lower gradients. Figures 4 and 5 suggest strong similarities between natural pools and scour holes below grade-control structures; furthermore, a strong link seems to exists between natural steps and depositional berms found downstream of artificial pools. A statistical evaluation of these analogies is then needed. Jet virtual energy at the impingement E= z+H s (with H s = 1.5h c) appears to be the physical variable which best normalizes pool dimensions in artificial systems (Comiti, 2003; Lenzi et al., 2003) in the sense that it narrows the variability range of the dependent geometrical variables, leaving only a certain amount of variance due to the system geometry. Therefore if some analogies exist between natural and artificial pools, these are best sought comparing the geometrical variables scaled to this jet energy. The problem is to test statistically whether two independent groups, in this case natural (N) and artificial (A) pools, are significantly similar with respect to some of their features – namely maximum depth and its longitudinal location, length, berm distance/step spacing – when these are made nondimensional through the jet energy E. The underlying assumption is that similarities in shape reflect similarities in the formative process, even though this might not be always the case, as pointed out by Knighton (1998, p. 225) for meanders. Given the fairly large sample size available, the commonly-used Student’s t-test could be performed. However, this test requires the variances of the two groups to be similar, since their difference may alter test’s significance. Here, it was chosen first to verify if variance homogeneity was respected by applying the standard Fischer’s F test and the more powerful Levene’s test too (Statsoft, 2002). In the case it was not, non-parametric statistics were adopted instead of the t-test in order to decide whether to reject the null hypothesis H 0 “the two sample (groups) belong to the same population”. The non-parametric tests analogous to Student’s t performed for this analysis are the Mann-Whitney U , the Kolmogorov-Smirnov and the Wald-Wolfowitz. All the calculations were carried out using the software “Statistica 6.1” (Statsoft, 2002). Maximum scour depth y s and residual depth s (= y s – z) are the main vertical

dimensional characteristics of pools. Their normalization by the jet energy E led to the box-and-whisker graphs reported

in Figures 6a and 6b respectively, where the median

value is shown along with the 25–75 percentile range

and the overall variation range. The median value is

used instead of the mean value because the Student’s

t test was not reliable for the non-homogeneity of

groups’ variance, thus non-parametric tests – which

refer to the median value – were needed. All the three

tests (Table 1) did not allow to reject the null hypoth

esis of extraction from the same population, being

Figure 6. Pool maximum scour depth y s (a, above) and

residual depth s (b, below) normalized to jet energy E, below

natural steps (N) and grade-control structures (A). Table 1. Pool dimensions normalized to jet energy: descriptive statistics and significance level p for the three nonparametric tests used to compare natural (N) and artificial (A) pools. p-values smaller than 0.05 are highlighted, indicating a probable difference between the two groups. Mean Stand. Dev. Mann-Whitney Wald-Wolfowitz Kolmogorov-Smirnov N A N A p p p y s /E 0.95 0.92 0.27 0.18 >0.10 >0.10 >0.10 s/E 0.47 0.43 0.22 0.16 >0.10 >0.10 >0.10 l s /E 2.11 1.88 1.05 0.63 >0.10 >0.10 >0.10 l b /E 3.00 2.90 1.37 0.78 >0.10 <0.05 >0.10 l step /E p>> 0.10. The t-test would give the same result too (not shown in the table). These results indicate that the vertical extent of natural pool does not significantly differ from that characterizing pools created by gradecontrol strutures, when the forcing – i.e. upstream – energy conditions are taken into account. The normalization through the nominal jet energy for scour length produced l s /E frequency distributions which turned out to be non significantly different between natural and artificial pools, both using the t-test – but with non-homogenous variance – and the three non-parametric tests (see Table 1). In Figure 7 the graphical comparison is shown, where it can be seen a

fairly wider range for the 25–75 percentile region occurring for natural pools, as well as for the overall variation range. As regards the berm distance and downstream step distance, they were made non-dimensional in the same way, and the two distributions of l b /E for artificial pools and l step /E for natural pools were obtained. Their statistical comparison gave as result the nonrejection of the null hypothesis by two tests out of three, in fact the Wald-Wolfowitz's led to p< 0.05 (Table 1). Looking at their median points (Fig. 8) it Figure 7. Scour length normalized to jet energy E below natural steps (N) and grade-control structures (A).

Figure 8. Step and berm distance normalized to jet energy

E below natural steps (N) and grade-control structures (A),

respectively.

is apparent why their similarity – yet significant on

the whole – is less strong than that found for the pre

vious geometrical variables. The fact that normalized

berm and step distances on the whole probably belong

to the same population prompts to theorize a simi

lar formative process. Finally, pools' geometric ratios

such as l b /y s – l step /y s show significant similarities

(Comiti, 2003), thus confirming the results from the

energy-based approach reported above.

4 DISCUSSION AND CONCLUSIONS

The results of the statistical comparison between pools

at grade-control structure and below natural steps

lends support to an upstream-forced cascade model,

i.e. where falling jet characteristics – virtual energy E

given by the specific critical flow energy H s plus the

potential drop energy z – control the geometry of the

system, hence representing the most important scal
ing independent variable. Berms formed at the end of
the pools downstream of grade-control structures have
been found to be probably analogous both geometri
cally and sedimentologically (Comiti, 2003) to steps
in natural systems.

Field data (Tab. 1) indicate that step spacing L step
and berm distance l b are multiples of the jet energy E,
with on average:

The present model for step pool formation is valid
for all flows which energy E is large enough to cause
pool erosion and berm (step) deposition. In steep
boulder-bed streams, the availability of a wide range
of large clasts – relative to flow depths – allows the

Assaying historical maps and relict channel forms for the analysis of

channel processes (on example of the Spree River in Germany)

N. Nikolaevich, A. Sukhodolov & C. Engelhardt

Department of Ecohydrology, Institute of Freshwater Ecology and Inland Fisheries, Berlin, Germany

ABSTRACT: Comparative analysis of physical factors for the contemporary and preindustrial states of the

riverine ecosystems is a valuable approach in the development of river restoration projects. The present study

explores the applicability of advanced methods of hydromorphological analysis to extract detailed information

on channel processes from historical maps. Coupled with the modern techniques of infrared aerial photography

and field investigations of relict channel forms, these methods allow the determination of characteristic dimen

sions for preindustrial and paleo-channels. In this study the reliability of a XVIII century map was examined

by performing the analysis of contemporary maps and field observations. Sinuous pattern of the river course

from historical maps was then processed in the frame of modified sine-generated approach and validated against

theoretical relationships. Possibilities for gathering valuable parameters of the channel cross-section from empir

ical relationships, analysis of infrared and usual aerial photographs and field methods are also illustrated and

discussed.

1 INTRODUCTION

In the last three decades, intensive environmental research on rivers had led ecologists, river engineers, and practitioners to recognize the valuable role that physical characteristics of the environment, particu larly river flow and channel processes play in the sustainability of riverine ecosystems (Vannote et al. 1980, Cushing & Allan 2001). Valleys, floodplains, and river channels are the elements of landscape com prising the physical component of a riverine ecosys tem. Degradation of natural landscapes for intensive land use, urbanization, industrialization, and explo ration of natural resources therefore implicitly reflect the decreasing of the ecosystem's sustainability and biodiversity. Recognition for the necessity of reduction and improvements of landscape degradation already inspired many renaturalization projects (Brookes & Shields 1996). However, the efficiency of designing of such projects is presently precluded by the lack of solid theoretical and experimental knowledge on com plex relationships between components of a landscape and functioning of the ecosystem.

Most dramatic changes in the landscape of riverine ecosystems appeared in the period of industrializa tion – a period of the last 250–300 years. The duration

of the industrial period is relatively short compared to the characteristic scales of the global climate change, for instance to the past 11000 years of Holocene, or even to the smaller-scale time shifts in the climate as the “little ice age” between XII–XVII centuries (Mauquoy et al. 2002). Therefore preindustrial riverine landscapes were developed gradually in the natural conditions of dynamical equilibrium over long period of time and represented the products of self-organizing system “flow-sediment load-river channel” (Grishanin 1993). The late preindustrial state of river channels was also extensively documented in maps, geological profiles, and hydrological records as transition to the industrial stage required extended planning. These peculiarities of the latepreindustrial period make it a convenient template designed by nature and reflecting the fine balances between water runoff, solid transport, and local limiting factors (Kondratiev et al. 1982). Although historical maps provide valuable information on the “momentary” pattern of the river channel and therefore can be used as the source of information for advanced methods of channel process analysis, their quality is always of great concern. For example, on a historical map of XVIII century from the Berliner Hauptarchiv one can find channel patterns that look artificial (Fig. 1), especially taking into account the archaic style of the map. Since the channel of the river was straightened, the runoff regulated with in-channel reservoirs, and the solid transport completely transformed by weirs, there remained very few places that can be directly compared to evaluate the quality of the maps. This fact increases the value of indirect methods of evaluation and, above all, comparison with available theoretical approaches.

Our present study is thus aimed at: (1) critical assessment of historical maps and their suitability for quantitative characterization of channel processes; (2) extraction of quantitative information describing characteristics of the channel forms from maps and comparison of the obtained values with the theoretical

Figure 1. Example of the Spree River channel between Alt

Schadow and Kossenblatt from the map dated 1769.

Figure 2. Historical map of the Spree River, 1769. models; and (3) accomplishing the data set with the characteristics of the channel cross-section from the complex analysis of aerial photographs performed in normal and infrared lights as well as field drilling. The results reveal that the shape of individual meanders can be accurately described by the sinegenerated curve of Langbein & Leopold (1966) modified to account for asymmetry of natural meanders (Kondratiev et al. 1982). Scaling parameters for meanders can be computed from theoretical relationships developed from sine-generated approach (Zamishlyaev 1982, Yalin 1992). 2 ANALYSIS OF CARTOGRAPHIC MATERIALS 2.1 Direct comparative analysis A set of historical documents provided by the Berliner Hauptarchiv served as the factual basis for the present study. It consisted of a map “Lauf des Spree Strohms von Cossenblad über Beeskow und Fürstenwalde, und von Wusterhausen bis Berlin” dated 1769 (Fig. 2), 1 Inch : 500 Ruthen that corresponds to the scale of 1 : 69174, and of longitudinal profile “Nivellements Plan des Spree Strohms von Beeskow bis Fürstenwalde” dated 1791, 1Inch : 60 Ruthen or 1 : 13345.

The set also included contemporary topographical

maps of scale 1 : 10000 and 1 : 50000 dated 1985.

Although the preindustrial channel portrayed in the

1769 map was completely transformed in the last

century, there are still some distinctive elements of

the landscape that can be directly compared to those

displayed by the contemporary maps. Because the

runoff of river Spree after the Ice Age but long before

Holocene was many times greater than 1000 years ago,

the valley of the river preserves its history in the form

of fully filled with sediments oxbow lakes of huge

size: many times larger than present day oxbow lakes.

Such relict forms are clearly depicted in the present day maps and also in the historical maps (Fig. 2).

An example of large-scale oxbow lake is shown in Figure 3. Figure 3a displays the enlarged oxbow lake from the historical map (Fig. 2) and Figure 3b shows the corresponding piece of a contemporary map. The centerlines of the oxbow lakes were digitized and scaled for comparison and the resulting curves are pre sented in Figure 3b. A line of a small canal visible on both maps was used as the alignment line for digitized curves. A close correspondence for these two lines at the downstream part of the channel is evident, but the upstream parts indicate significant deviations. A possible reason for this deviation is the difference in contours of the agricultural land-use that served for determination of oxbow lake margins. Apart from the accuracy problem of this comparison we can conclude that large-scale structures can be measured from the historical map more or less reliably.

Fortunately, close examination of cartographic materials, field trips, and field measurements provided the possibility for a direct comparison of the chan nel form of the smaller scale pertaining undoubtedly to the preindustrial period (Fig. 4). The banks of two successive meander paths with adjacent flood planes

located downstream from the village of Neubrück were armored and preserved in the same form as in the beginning of the last century. Field observations indicate the presence of remnant channels in the down stream parts of flood planes that are so clearly depicted in the historical map (Fig. 4a). The results of field measurements completed in April 2003 are shown in Figure 4b, and a corresponding piece of the contempo rary map is presented in Figure 4c. The centerlines of all three channels were digitized, scaled and aligned for comparison. The locations of remnant channels on the flood planes served as the benchmarks for alignment. Comparison of the obtained centerlines is shown in Figure 5. Close correspondence between the contem porary map and the topographic plan (Fig. 4b) outlines an ideal case of comparative analysis. The preindus trial channel deviates systematically all over its path from the present-day centerline.The trend in the devia tions of the historical centerline is quite real because it displays natural expansion of the meander.At the same 0 500 m 0 500 m 0 500m 1769 1985 a) b) c) Figure 3. Centerlines of the meandering path downstream of the village of Neubrück. time, in the downstream part both lines converge owing to the limitations of plane erosion by the valley side (Fig. 4c). Thus, the completed comparison indicates a correspondence between these channel forms. 2.2 Analysis of meander plane geometry Although comparative analysis completed in the preceding section revealed reliability for the particular characteristic form of river channel portrayed in the historical map, the overall pattern of the river channel requires closer examination. To accomplish this goal we provided quantitative characteristics for the plane form of all detectable menders presented in the historical map (Fig. 2), and compared those characteristics to the theoretical description provided by the sine-generated channel pattern and its modifications. The plane geometry of the individual meander path can be described with the use of some simple geometric quantities. Langbein & Leopold (1966) introduced a concept of minimum variance preceding the development of the principle of self-organization for fluvial systems (Grishanin 1974). Von Schelling (1951) applied the concept of minimum variance and has shown that the most probable path of a meandering stream satisfying the principle is sine-generated curve Apex

Point of

inflection R c u l s = S m Y m s = S m / 2 s = 0 a

Figure 6. Definition of the meander geometry.

where θ= the angle between the direction measured at

a given point along the curve and the mean downstream

direction, θ 0 =maximum angle of deviation such as

2θ 0 =α= arc angle (Fig. 6), s= current distance along

the path, S m = total path length.The quantities describ

ing the meander path are shown in Figure 6.

Sine-generated curve is a very useful tool for the

quantitative assessment of river meandering pattern

because the relationships between principal variables

of a meander path can be deduced theoretically. Yalin

(1992) presents an extended illustration of the theoret

ical solution for sine-generated curve that gives ratio

Sm/λa sinuosity of the meander path

where J 0 (θ 0)=Bessel function of the first kind

and zero-th order, and λ=meander wavelength.

Zamishlyaev (1982) presented some other quantitative

relationships for sine-generated curve α 1 α 2 Y m a x / 2 S 1 / 4 S 2 / 4 λ 1 / 4 λ 2 / 4 Figure 7. Meander approximation with two adjacent meander bends, the Spree River near the village of Neubrück (the same as in Figure 4). where Ym=meander amplitude, R c =mean radius of curvature, H 0 (θ 0)=Struve function of the first kind and zero-th order. Although sine-generated curve represents the symmetric meander bend, the natural meanders of river channels are asymmetric (Fig. 4). To account for asymmetry, it was proposed to describe the meander arc as the combination of two quarters of symmetrical meanders with different parameters (Kondratiev et al. 1982). Their approach is illustrated in Figure 7. Using the hybrid scheme of two sine-generated curves Zamishyaev (1982) developed the following relationships for asymmetric meanders. The approach was successfully tested on a large data set comprised of rivers from different regions in Russia (Kondratiev et al. 1982) as well as subsequently in Moldova (Nikora 1992) and is therefore recommended as an advanced tool for the analysis of meandering river channel patterns (Nikora 1992, Arnaut 1995). The historical map (Fig. 2) was manually processed with a compass and protractor to obtain the quantitative characteristics for 44 recognizable meanders in the frame of the approach by Kondratiev et al. 1 2 3 4 5 0 1 2

Figure 8. Characteristics of meanders of the Spree River channel and the comparison with theoretical relation ships 2-7.

(1982).The obtained results and their comparison with relationships 2-7 are shown in Figure 8.

It can be seen from Figure 8 that geometrical quantities of meanders obtained from the histori cal map agree with correspondent theoretical rela tionships. Moreover, scatter in the values and the character of deviation is practically the same as for geometrical quantities measured on contemporary car tographic materials (Arnaut 1995). This particular result confirms the reliability of channel patterns presented by the historical map. Besides characterization of the plane form of a channel, complete geomorphological description of the river channel should include quantitative description of the channel cross-section. Such characteristics as the bank-full width and depth of the channel are very important for the assessment of hydraulic characteristics and fluxes of water and dissolved substances. Unfortunately the historical maps could provide only little information regarding the channel cross-sections because relief was not measured at that time with sufficient details and the maps as a rule do not provide elevations.To complete the geomorphological description, the analysis of relict channel forms is required, and therefore the next sections describe the assessment of relict channel forms with methods of aerial photography in ordinary and infrared lights. 3 ANALYSIS OF RELICT CHANNEL FORMS 3.1 Processing aerial photographs Many studies show that meandering is quite a general phenomenon observed in different physical systems: studies of oceanic currents (Robinson et al. 1989) revealed a meandering Gulf Stream, meandering of supra-glacial channels was reported in glacial studies, and space-photographs of Mars indicated meandering patterns of relief. A notable feature of meandering flows is a certain relationship between channel width and the meander

wavelength. Leopold & Wolman (1957) have obtained an empirical relationship where B 0 =width of the channel at bank-full discharge. Relationship 8 and empirical data reported in different studies are shown in Figure 9. Although relationship 8 is purely empirical, it captures most of the fundamental properties of the phenomenon and displays universality over an extremely wide range of scales. Therefore this property can be used for reconstruction of channel cross-section of relict channels. In the industrial period the channels of many rivers were straightened and canalized – a common practice for land use of flood planes and prevention of disastrous flooding. It is usual in river training to fill the meanders of pre-canalized channels with excavated material of a new channel.Therefore relict meanders of the preindustrial period are scarce, but not completely impossible to find. Because the valley of the Spree River was not heavily used for agriculture or industrial purposes, many preindustrial-channel meanders were not buried during river-training works and can be directly assessed with the use of contemporary 1 10 100 1000 10000 channel width, m 1 10 100 1000 10000 100000

methods of aerial photography for direct evaluation of relationship 8 in our case study.

An example of an aerial photograph of an oxbow lake – relict form of the preindustrial channel of the Spree River located near village of Freienbrink is shown in Figure 10. Field observations to verify that bank-full width of relict channels can be accu rately measured from the aerial photographs. The bank lines of the channel were contoured by the vegetation on its margins and the channel was segmented over equal distance intervals and the channel width was de-determined at wedges of segments (Fig. 10). The average width of the channel was computed from the data sets. In all, four well-preserved oxbow lakes were identified from aerial observations and processed. The measured channel widths were plotted versus meander wavelength (Fig. 10). Comparison with relationship 8 (presented by line in Fig. 10) reveals applicability and

high performance for the relationship. λ/2 B i 0 100 m
Figure 10. Example of an aerial photograph of relict meander of the Spree River near Freienbrink. Besides modern methods of aerial photography providing assessment of apparently visible oxbow lakes, the infrared aerial photography also enable visualizing completely filled with sediments paleooxbow lakes. Differences in soil composition and consequently differences in vegetation produces pronounced patterns on infrared aerial photographs (Fig.

11). Paleo-oxbow lakes and other distinct elements of the relief such as paleo-meander scroll bars are clearly depicted and can be measured with the use of the same methodic as described above. Five paleo-oxbow lakes were identified for the investigated channel reach and the corresponding average values of their bank-full width and meander wavelength were plotted in Figure 9. Although the deviation of these data from the relationship 8 was not greater than scatter in the data presented in Figure 9, the data indicate systematic deviation into the region of larger values for channel width. A possible explanation for this observation is the diffusion of boundaries of paleo-oxbow lakes because of denudation, erosion, and agricultural land use. Confirmation or rejection of this hypothesis required direct field investigations. Spatial distributions of alluvium and soil from drilling in the oxbows obtained from those investigations are described in the next section.

Figure 11. Example of aerial photography of the Spree

River valley in infrared light.

3.2 Drilling in paleo-oxbow lakes

Four paleo-oxbow lakes unambiguously determined

with infrared aerial photography were subjected to

detailed field measurements. Drilling was performed

in representative cross-sections of the lakes (Fig. 12a).

An example of spatial distributions of soil in a cross

section of paleo-oxbow lake is presented in Figure 12b.

The distribution of peat in drills contours the paleo

channel of the oxbow. It also shows that peat was

covered with sand and that the width of the peat area

is sufficiently shorter than the width detected from

infrared aerial pictures. These measurements support

the hypothesis on diffusion of fine sand can explain

the deviations of points in Figure 9. The values for the

width of paleo-oxbow lakes were corrected according to measurements taken from drillings and were presented in Figure 9. The corrected values indicate a better correspondence with relationship 8.

4 CONCLUSIONS

The present study examined the reliability of a historical map of the preindustrial channel of the Spree River in Germany by direct comparison of the remnant meanders of the river and by applying modern methods of hydromorphological analysis. It is shown that despite their archaic style the historic maps represent a valuable source of reliable information. Major

elements of the landscape of the river valley meander
Figure 12. a) Contours of a paleo-oxbow lake and locations of drillings, valley of the Spree River near Mönchwinkel, b) spatial distributions of soil in the drillings, Ba and Bd are paleo-channel width detected by aerial and drilling respectively. bends of different sizes – are presented with sufficient details and their quantitative characteristics can be determined with an accuracy comparable with that of the modern cartographic material. The historical map and the quantitative characteristics it contains can be used in river channel restoration projects. The relationship between planform of meanders of the preindustrial period and width of the channel cross-section was revealed by the comparison of data collected from aerial photographs and field investigations. Diffusion of the banks of paleo-oxbow lakes because of erosion and agricultural use significantly affects the accuracy of determined parameters.

ACKNOWLEDGEMENTS The authors wish to express their acknowledgements to Randi Carls for the assistance with the analysis of infrared photographs and for providing the results of drilling. The study was supported by the Berlin Senat, Department of Urban Development.

Monte Carlo method applied to a two-dimensional morphodynamic model

J.J.P. Lambeek, H.R.A. Jagers & H. van der Klis

WL|Delft Hydraulics, Delft, Netherlands

ABSTRACT: Two main issues in river management in The Netherlands are safety against flooding and naviga

bility. During the recent year a lot of research has been carried out with the objective to increase the capacity of

the Dutch Rhine branches with respect to discharge capacity and navigability. The enlargement of the capacity

of the rivers by measures within the floodplain appears to be a promising intervention that combines nature

restoration and possibilities to guarantee safety against flooding. The investigations concerning the impact of

measures to increase the river capacity have been limited, so far, to the hydraulic impact. Little attention has

been given to the impact of these measures on the morphodynamic behavior of the river bed and its relation with

navigability and safety against flooding.

An improved approach has been developed to investigate the morphodynamic behavior of the river bed

under changing discharge conditions. This improved method comprises a Monte Carlo simulation with a two

dimensional morphological Delft3D model that includes the main channel and floodplains. The results of the

Monte Carlo simulation have been used to determine the specific locations that are sensitive to changing discharge

conditions and where the morphodynamic behavior has impact

on the navigability. The present investigation has been limited to the situation without structural interventions. The procedure presented in this paper is considered to be a promising method to obtain insight in the impact of structural floodplain measures on the morphodynamic behavior of the river bed and its relation with navigability and safety against flooding.

1 INTRODUCTION

1.1 Context

Recent river management studies in the Netherlands have focused on three topics: safety against flooding, navigability and environmental issues. During the recent year a lot of research has been carried out with the objective to increase the capacity of the Dutch Rhine branches (Silva et al., 2001; WL|Delft Hydraulics & RIZA, 2002, 2003). The enlargement of the discharge capacity by removing narrow sections in the floodplain appears to be a promising measure to combine nature restoration in the floodplains with possibilities to guarantee safety against flooding. Furthermore, the same studies intend to solve navigability problems that are faced at some locations.

For a reach of the river Rhine at the Dutch-German border a two-dimensional morphodynamic model has been applied in order to investigate the morphological impact of possible measures (such as dredging,

construction of non-erodible layers, and floodplain widening) on the navigability in this reach (WL|Delft Hydraulics, 2003).The investigation has been based on a single representative hydrograph that was repeated for several years in order to investigate the long-term morphological impact of structural interventions. That approach with a single representative hydrograph is already much better than using a single representative discharge. However, the approach is still deterministic, since it is based on only a single simulation with one repeated hydrograph.Therefore, the approach does not provide you with information on the uncertainty in the impact of the interventions since the natural variability of the hydrograph is not taken into account. Different hydrographs may cause a significantly larger or smaller effect than the hydrograph selected for the single simulation. The objective of the present research is to investigate the impact of uncertainties in the discharge values on the morphodynamic behavior of the river bed. 1.2 Uncertainty of discharge fluctuations Van der Klis (2003) analyzed the uncertainty of discharge fluctuations and the impact on the river bed development. She examined the applicability of Monte Carlo Simulations to quantify the uncertainty in the results of a one-dimensional morphological numerical model. Her conclusion was that the Monte Carlo method is the best method to quantify the impact of uncertainties in the river discharge on the develop ment of the river bed morphology. The Monte Carlo method makes it possible to analyze the morphological and hydraulic output of the simulations with normal statistical methods.

The objective of the present research is to inves tigate whether the application of this Monte Carlo method to a two-dimensional morphodynamic model would provide additional useful information that is consistent with prototype observations. For this rea

son, the number of simulations has been limited to only ten. Later on it is aimed to define a statistical parameter that can be used to determine how many simulations are required for actual statistical analyses of the morphodynamic behavior. It is also aimed to apply this method to study the morphodynamic impact of structural interventions like floodplain lowering.

1.3 Improved knowledge of morphological behavior

The knowledge about this morphodynamic behavior of the summer bed is only limitedly used in the man agement and planning of the Dutch rivers. The results of the present research show that the application of the Monte Carlo method to two-dimensional morphody namic models is a very promising non-deterministic approach that includes the uncertainty of the dis charge and by which the morphodynamic behavior of the riverbed can be studies with standard statistical procedures.

This paper will present the case study that has been used in the investigation in Chapter 2. This is followed in Chapter 3 with an explanation of the Monte Carlo method as it has been applied in the present investiga tion. Chapter 4 presents the results of the Monte Carlo simulations. Conclusions and recommendations will be presented in Chapter 5.

2 CASE STUDY

2.1 Two-dimensional morphological Delft3D model

In the investigation a detailed two-dimensional mor

phological Delft3D model (Fig. 1) has been used that

was earlier developed to study the impact of structural

interventions that were planned to solve local navi

gability problems (Baur et al., 2002). Baur et al. used

the model to define combinations of engineering mea

sures which guarantee the required dimensions of the

shipping lane, minimize the degradation of the river

bed and that do not increase the design water levels

for extreme flood conditions. These engineering mea

sures consisted of the use of non-erodible layers, the

adaptation of the groynes in length and height and the bed elevation (m) 5 10 15 20 flow direction Figure 1. Morphological Delft3D model. relocation of the embankment at a specific location as well as lowering of the floodplains. 2.2 Model schematization The model schematization includes the main channel (summer bed) and floodplains (winter bed) so that discharge exchange between the summer and winter bed during high discharges is represented by the model. The model area has a length of 42 km. The model topography is schematized in a curvilinear computational grid. The average cell length and width in the summer bed are 150 m and 35 m, respectively. The groyne fields are schematized by two cell rows at the right and left side of the summer bed. The model topography in the areas between the groynes is schematized with the appropriate elevation of the summer bed. The groynes are represented by 2D-weirs of the same heights as the groyne crests. The weirs are oriented perpendicular to the flow direction. The summer bed roughness and the grain size vary in longitudinal, not in transverse direction.The Chézyvalues in the summer bed vary between 52.5 m ⅛ /s and 56.5 m ⅛ /s for medium flow and flood conditions and are reduced by 2.5 m ⅛ /s for low flow conditions. The median

grain size is 10 mm. The hydraulic calibration was performed for the topography of 1995. Computed and measured water levels at four steady-state flow conditions were compared. Deviations of more than 15 cm occur only at two locations for the highest flood conditions; the differences were generally less than 5 cm at low/medium discharge and less than 10 cm at high discharge. The simulation of the 1995 discharge hydrograph provided a verification of the calibration with good results. For the morphological calibration of the model, a constant discharge simulation was applied. The location and extension of point bars and deep outer bend are well represented. The validated against the morphodynamic development during the period 1995-2000.

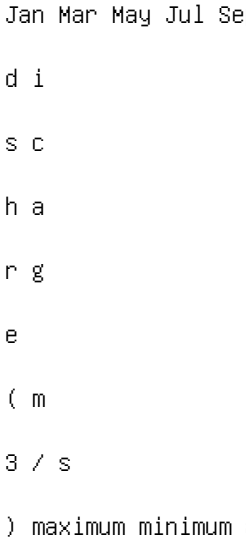

Figure 2. Maximum, average and minimum measured historical Rhine discharge at Lobith.

2.3 Boundary conditions

The boundary conditions for the model simulations consisted of the water level at the downstream model boundary and the discharge distribution over the grid cells of the upstream boundary.

In case of a Monte Carlo simulation this implies that for every discharge value to be used in the simulation a separate set of water level and discharge distribution

values is required. For only 10 discharge hydrographs of 3 years each approximately 1000 boundary con dition sets are required. Normally, the number of hydrographs simulated in a Monte Carlo simulation is even higher. In the present investigation it has there fore been decided to limit the boundary data-set to a limited amount.

The historical data have been converted to see which set of discrete discharge values would have similar characteristics as the historical dataset and still would be workable as input for the Delft3D simulations. As the present research is only first approach, later on the number of discrete discharge values for which bound ary conditions are made available can be extended. For now, it was concluded that discretization with steps of 500 m 3 /s would represent the actual discharge values well enough for a first approach.

The river bed in the model represented a river bed survey that was carried out in the year 2000. Other prototype data were historical discharge data at the Lobith gauging station (Fig. 2) at the downstream end of the model reach.

3 MONTE CARLO APPROACH

3.1 Large amount of deterministic simulation

The principle of Monte Carlo simulation is to run

a deterministic model many times. Each model run

is driven by a different realization of the input time series (synthesized on the basis of randomly generated parameters). The set of outputs resulting from all model runs is used to determine the statistical properties of the resulting bed levels, like the expected bed level position, its variance and the percentile values. In case of non-linear systems, the statistical mean of the possible morphological responses is not equal to the morphological prediction based on the ‘mean’ value of each model input (Gardner & O’Neil, 1983). The random discharge generator is based on a method derived by Duits (1997). The seasonal dependency and the correlation between successive river discharges are considered in this method. The basic data represents 55 years of daily measured Waal discharges at the location Lobith. A statistical description has been derived in five steps: - Each year is split into 36 periods of 10 days each. - The measured daily discharges are averaged over these 10-day periods. - For corresponding 10-day periods through the years, a shifted lognormal distribution function is estimated. - The correlation between discharges in successive periods is estimated. Duits shows that the discharge in 10-day period i depends on that in the two preceding 10-day periods, i- 1 and i- 2. - Construction of a multivariate lognormal distribution function per 10-day period. The correlation between the discharges within successive time intervals has been taken into account. This method has been previously applied to the same data by Van Vuren et al. (2002) and Van der Klis (2003). With this statistical model discharge hydrographs have been synthesized by random sampling from these multivariate lognormal distribution functions. The set of results from these simulations is used to determine the statistical properties of the predictions. The averaging process used in the Monte Carlo sampling includes a method that adjusts the discharge values in such a way that the sediment transport generated by the averaged discharge data for the period of 10 days is equal to the sediment transport generated by the daily average discharge data. 3.2 Comparison historical and sampled discharges Figure 3 presents the maximum, average and minimum historical discharge values of Figure 1 that have been averaged over 10-day periods. The maximum values in Figure 3 are somewhat lower than in Figure 1. This is caused by the fact that very high discharge values usually last shorter than the 10 days over which the values are averaged. The maximum, average and minimum discharge values of the synthesized discharge hydrographs used in the simulations are presented

in Figure 4. The overall characteristics of Figures 3 and

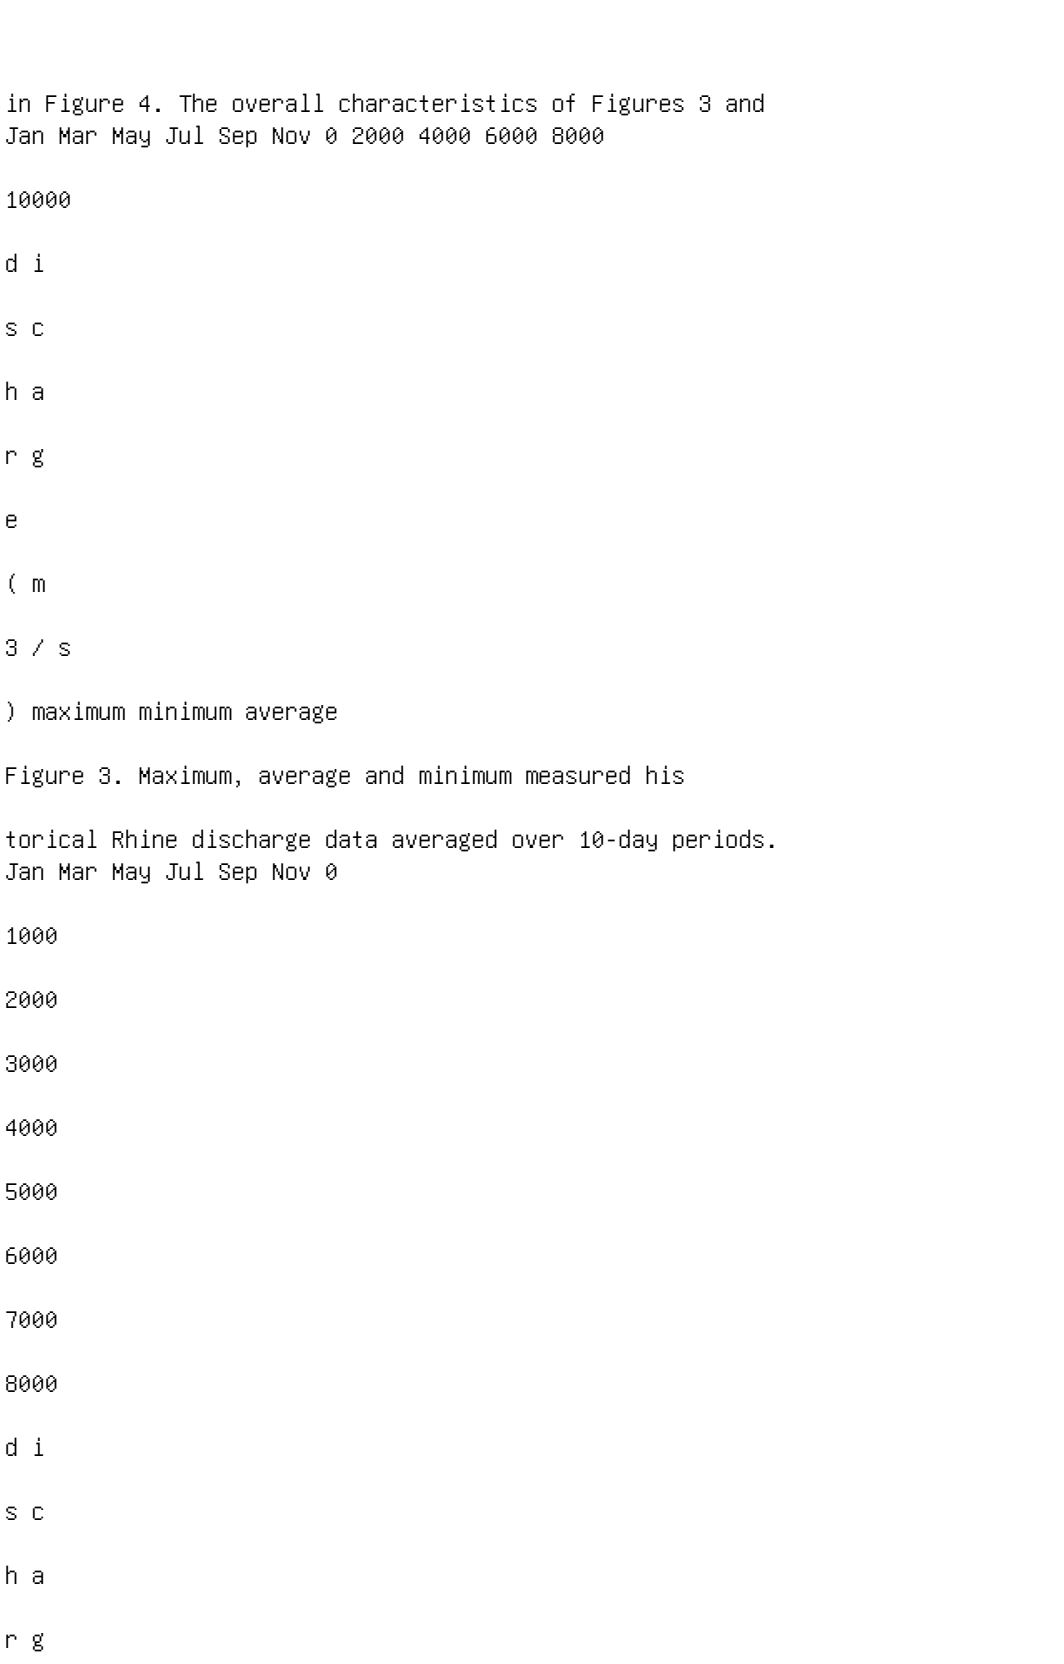

Figure 3. Maximum, average and minimum measured his

torical Rhine discharge data averaged over 10-day periods.

e

(m

3 / s

) maximum average minimum

Figure 4. Maximum, average and minimum values of 30 discharge hydrographs synthesized by random sampling from the multivariate lognormal distribution functions.

4 are the same. It can, therefore, be concluded that the sampling method described above has led to discharge hydrographs that give a good representation of the main statistical properties of the prototype discharge distribution.

A few hundred number of simulations may be required for a good statistical analysis of the morpho dynamic behavior of the river bed (Van der Klis, 2003). However, the objective of the present research is not to carry out a complete statistical analyses. The results presented here, are only intended as an initial test to see the applicability of a Monte Carlo simulation with a two-dimensional morphological model. Therefore the number of simulations is limited to 10 simulations with a duration of 3 years (i.e. 30 independent hydrographs).

3.3 Simulations

A procedure has been developed to run a Monte Carlo simulation with the two-dimensional morphological

Delft3D model. This procedure controls the execution

of the different model simulations and the exchange of input and output data with a database. During the morphological simulation the hydraulic and morphological output is stored with time steps of five days. Two types of analyses can be carried out with the output data of the simulations.The first analysis considers the impact of discharge fluctuations on the morphodynamic behavior of the river bed. This can be done by directly statistically analyzing the output of the bed elevation data that have been stored in the output database. The second analysis considers the impact of discharge fluctuations on the navigability. To guarantee navigability towards Germany, a shipping lane of 170 m wide and 2.8 m deep (under OLR-conditions) is maintained in the considered reach. The abbreviation OLR represents a standardized low water level (in Dutch: overeengekomen laagste rivierstand) which is associated with a characteristic discharge: during 5% of the year a lower discharge occurs. To check whether the dimensions of the shipping lane were satisfied during the simulations, steady state hydrodynamic simulation of OLR-conditions were carried out after each period of 5 days of the morphodynamic simulations. For each model grid the fulfillment of the OLR-criteria (water depth of 2.8 m channel width of 170 m) can be analyzed statistically to investigate the impact of the morphological development under varying discharge conditions on the navigability. So far, these analyses have focused on the morphodynamics of the navigation channel and on the fulfillment of the OLR-criteria for the present situation only. Structural interventions in the floodplain, like floodplain lowering and other changes to the cross-sectional area of the river, have not yet been considered. The procedure has been successfully tested with 10 discharge hydrographs for a period of three years each. The statistical analyses carried out on the output of the simulations are described in the following chapter. 4 RESULTS The morphological sensitivity to discharge fluctuations for the present situation has been analyzed with figures of the maximum bed level difference (maximum bed level minus the minimum bed level) and with the standard deviation of the bed elevation during the Monte Carlo simulation.As stated earlier, these data have been determined from the 10 simulations of 3 years with output every 5 days. For each grid cell, therefore, the statistical output for each of the presented parameters is based on 2190 values. The magnitude of the morphodynamic variations under varying discharge conditions is presented in the Figures 5 and 6. Figure 5 presents the absolute maximum bed level differences for a certain model

reach. abs. max. bed level difference (m) 0 0.1 0.2 0.3 0.4 0.5 0.6 0.7

Figure 5. Absolute maximum bed level difference during

the Monte Carlo simulation. 0 0.04 0.08 0.12 0.16 std.dev. bed elevation (m)

Figure 6. Standard deviation of the bed elevation.

Figure 6 presents the standard deviation of the bed ele

vation of another model reach. In case the parameters

presented in Figure 5 as well as in Figure 6 have high

values this implies that the local river bed (elevation)

is highly sensitive to discharge fluctuations.

The impact of the morphodynamic behavior on the

navigability has been analyzed in two ways. The first

method focused on the navigation channel depth, the

second on the navigation channel width. Figure 7

presents the frequency that the water depth during

OLR-conditions is smaller than the OLR-criteria of

2.8 m. High values of this parameter represent loca

tions where the OLR-criteria for the navigation depth

is frequently not fulfilled. This is especially true in the

floodplain, but also some locations can be identified 0 20 40 60 80 100 frequency of water depth smaller than 2.8 m Figure 7. Frequency that the water depth during OLRconditions is smaller than the OLR-criteria of 2.8 m. chainage (Rkm) → s t d . d e v . s h i p p i n g w i d t h (m) → 82583083584084585085586086 5 0 20 40 60 80 100 Figure 8. Standard deviation shipping width based on a minimum water depth of 2.8 m during OLR-conditions. within the navigation channel where the OLR-criteria for navigation depth are frequently not fulfilled. Figure 8 presents the standard deviation of the channel width in which the water depth is more than the OLR-criteria of 2.8

m. In this figure a high value of the standard deviation means that in this reach the navigation channel width is highly sensitive to discharge fluctuations. In case this is combined with a small absolute values of the navigation channel width this implies that the navigation in this reach could face difficulties during certain discharge conditions. Figure 9 presents the maximum and minimum value of the navigation channel. In case large differences occur in these two parameters, the navigation channel width is highly sensitive to discharge fluctuations. At some locations the values of the minimum shipping width and even of the maximum shipping width fall below the OLR-criteria of 170 m. The navigability in these reaches clearly faces difficulties. Based on the statistical data obtained from the Monte Carlo, it is possible to determine the likelihood that the OLR-criteria will not be fulfilled and that the navigability in a certain reach may not be chainage (Rkm) →

guaranteed without additional measures. This information could be used to make a decision whether, where and when dredging should be carried out to guarantee navigability.

The results of the Monte Carlo simulation are consistent with prototype observations. The reaches where navigability problems occur in prototype are clearly represented in the results of the Monte Carlo simulation.

5 CONCLUSIONS AND RECOMMENDATIONS

The application of a Monte Carlo simulation to a two-dimensional morphological model is considered to be a promising method to obtain insight in the morphodynamic behavior of the river bed.

The results of this non-deterministic modeling

approach clearly provides insight into the impact of

discharge fluctuations on the morphodynamic behav

ior of the river bed. This additional information is

considered valuable when insight is required about

the impact of the morphodynamic behavior on other

functions of the river.

The impact of discharge variations on the morpho

dynamic behavior is clearly visible in the results of

the Monte Carlo simulation. The results appear to be

ABSTRACT: The commonly adopted approach for modelling unsteady river morphological processes is to

couple the Saint Venant equations, for unsteady flow routing, with the Exner equation, for sediment mass

conservation. Despite this model is widely adopted, some of its properties do not match physical behavior.

Recently, a new class of morphodynamical models has been proposed, in which the sediment dynamics is

somewhat reproduced (four-equations models).

The object of present note is to better exploit the response of a four-equations model to a small bed perturbation

through a mixed analytical-numerical procedure in a quasi-linear approximation.

1 INTRODUCTION

Modelling unsteady river morphological processes is

a complex, fascinating and still open task. In present

work only bed load transport will be considered.

ManyAuthors (e.g. Correia et al., 1992, Graf, 1998)

have proposed morphodynamical models using differ

ent approaches. However, a common feature of most

of them, is to couple hydrodynamics and morphody

namics equations. While the former are well assessed

(for a river reach 1D or 2D depth-integrated equa

tions can be applied), many proposals exist about the

latter.

The most classical form of morphodynamical mod

els can be obtained coupling sediment continuity

equation (the so-called Exner equation) to hydro

dynamics equations. This approach (Three-equations

model) implies the choice of a bed load transport

formula. Because this formula is usually a uniform

flow formula (e.g. Meyer-Peter and Muller, 1948), the

implicit hypothesis of instantaneous adaptation of bed

load transport to variations in flow conditions is made

(de Vries, 1965).

Many examples exist of physical processes that can

not be modelled through this approach. For instance,

the earth-dam break test by Benoist (1983, 1989)

used as a reference by many Authors (e.g. Leopardi

et al., 2003). This can be explained because in a three

equations model an accelerating stream implies scour

ing while a decelerating one always causes deposition. In order to overcome above cited limitations, recently, a new class of morphodynamical models has been proposed: the so-called four-equations models (Nakagawa & Tsujimoto, 1980, Armanini & Di Silvio, 1988, Phillips & Sutherland, 1989, Di Cristo et al., 2002, Fraccarollo & Capart, 2002). Encouraging results have been obtained using four-equations models both from theoretical and modelling point of views. In particular, a behavior of notable relevance in natural streams, i.e. the development of bed forms, cannot be addressed by three-equations model (Cui & Parker, 1997), but only considering the flow in vertical direction (Kennedy, 1963, Engelund, 1970, Raudkiwi & Witte, 1990, Coleman & Melville, 1994, 1996). It has been interpreted better by referencing to four-equations model. In more detail, linear stability analysis of a four-equations model showed an unstable behavior in regions where bed forms appear (Vacca et al., 2003), so the stability region in mobile bed conditions is considerable smaller than the one of a fixed-bed model. From the modelling point of view, Leopardi et al. (2003) reproduced satisfactorily the Benoist test using a four-equations model. In order to better understand the behavior of this four-equations model, in the present work the flow over a mobile bed with an initial condition in which a small and smooth disturbance (bump) is superposed to an initially flat bed is solved. The scheme considered, thus, is similar to that used by Lyn & Altinakar

(2002) for the classical three-equations model. In their

approach the equations were integrated by means of

the Riemann Invariants computation, in the hypothe

sis of balance between friction and slope terms, and

linearizing the equations.

One of the main results highlighted in Lyn & Altinakar (2002) is that the evolution of the bump is strongly influenced by the flow regime (subcritical, supercritical, transcritical).

In facts, in the hypocritical case, two perturbations originate from the bump, one positive (deposition) travelling downstream, and one negative (scour) travel ling upstream, whose celerities are given by two of the characteristics slopes. In hypercritical flow, the same behaviour is observed, the only difference being the kind of perturbations: scouring downstream and depo sition upstream. Finally, in the transcritical flow the bump is first eroded, than a nearly symmetric scour appears giving rise to a hole whose length increases with time. Direct numerical simulation of the full prob lem by the Authors did confirm such general behavior.

It can be seen that the eigenstructure of the model analysed strongly influences the way the bumps travel. This despite the fact that for the three-equations model, no critical state can be defined based upon the criterion of a vanishing celerity (Liggett, 1993). Such a behavior is not shared by Di Cristo et al. (2002) model, as it is shown in Iervolino et al. (2003).

The object of the present note is to investigate more

in depth the response of the four-equations model by

Di Cristo et al. (2002) to an initially perturbed bed,

via a mixed analytical-numerical procedure. In this

approach the integration of the nonlinear system is

performed by the characteristic method, with the mere

linearisation the characteristic curves only.

2 MORPHODYNAMICAL MODEL

In what follows, the model proposed by Di Cristo et al.

(2002) will be considered. This four-equations model

can be written as:

in which:

t: time;

x: space coordinate;

h= h(t, x): depth; u= u(t, x): mean velocity; z= z(t, x): bottom elevation; u p = u p (t, x): average particle velocity in the bed-load transport layer; g: gravity; p: bed porosity; q s = q s (u p): bed load volumetric discharge per unit width, where, according to the Authors, q s may be considered a function of u p only; a= g□/(□+ 1), where □= (ρ s − ρ)/ρ; ρ: water density; ρ s : sediment density; S f : bottom friction term; S 4 : source term in sediment dynamical equation (see Di Cristo et al., 2002, for more details). The following change of variables is introduced: The variable ζ represents the bed elevation respect to the original level z 0 pertaining to each abscissa. For an initially flat bed profile of slope S b , it is obviously: 2.1 Mathematical background System eigenstructure has been derived by Iervolino et al. (2003). We recall that the four eigenvalues are: Resulting left eigenvectors, v i , i= 1, 4, are:

Finally, it is possible to compute Riemann Invariants.

Multiplying system (1) by left eigenvectors one can

obtain:

Riemann invariants are scalar functions Q i (U) char

acterized by ∂Q i /∂U= v i ; so they can be computed

integrating eigenvectors components respect to system

variables.

System (4) can be rewritten in terms of Riemann

Invariants so:

in which: 2.2 Integration technique Integration of system (5) can be performed in the following way. An uniform, equilibrium flow is assumed as initial condition. Let us note that, according to the given definitions, such a configuration is characterised by constant values of the four variables (u, h, u p , ζ). The initial disturbance is then expressed in the form: where δ is the perturbation amplitude and L= h 0 , the mean water depth,is the longitudinal scale of the bump. Initial condition is computed in steady state, neglecting the friction term, and evaluating particle velocity through an equilibrium relation, according to the procedure shown in Di Cristo et al. (2002). The most important assumption is that changes in the characteristics slopes are negligible for all the integration, so that the characteristic curves are approximated by the straight lines of equations, where λ 0 i is the i-th celerity valued at the initial state. Being the characteristic paths known a priori, for a given time t ∗ it is possible to individuate the extension of the domain in which the perturbation affects the solution (Figure 1). Let us divide this domain into N- 1 intervals, bounded by N points. For each point, we can trace back the four characteristic curve to the t= 0 axis, thus individuating four intersections.

Along each characteristic curve, the equation (5) is

written in the form:

To solve this equation, an estimation of the inte

gral term is required. Here, the following predictor

corrector technique is used:

the equation is first solved assuming:

being:

ζ 0 i is computed where the i-th characteristic line

intersects the t= 0 axis.

This permits to obtain an estimate of the solution at

time t ∗ , as:

Which is used to compute again the source term

in (14)

Both (14a) and (14b) represent, for i= 1, . . . , 4, a

system of non-linear algebraic equations respectively

in the four unknowns (u + , h + , u + p , ζ +) and (u ++ , h ++ ,

u ++ p , ζ ++). P P 2 P 1 P 3 P 4 t × t ∗

Unperturbed

zone Unperturbed zone 3 4 1 2

Figure 1. Conceptual sketch (hypercritical flow). The commercial software Maple™was used to solve numerically the two systems. Finally, the variables at time t= t ∗ are computed as: If the solution is known at a sufficiently high number of points, a numerical integration of the bed profile can be performed. Because the initial flow is in equilibrium, the sediment mass in the perturbed region should remain constant. This procedure has been used as a check of the accuracy of the solution technique here presented. With a sufficiently high spatial resolution, the error in sediment mass has been maintained below 1% respect to the initial mass for all the computations. This residual error seems to be imputable to the hypothesis of constant characteristics slopes for t > 0. 3 RESULTS In Iervolino et al. (2003) system characteristics were computed. It has been shown that for Froude number less than one, two positive and two negative slopes exist, while for hypercritical conditions three downstream-directed celerities and one upstreamdirected characteristic celerity (which is the situation depicted in Figure 1) are found. More in detail, the Table 1 reports data relative to the cases examinated. Results are plotted in non dimensional form; the length and time scale for normalization are assumed to be L and L/λ 4 , respectively, while the ζ

values are scaled respect to the initial bump height, δ. The first case (Figure 2) corresponds strictly to the example discussed in Lyn & Altinakar (2002). In that reference, a linearised model was considered, with the further assumption of balance between friction and slope terms (the so-called quasi-uniform hypothesis). Table 1. Case number δ/h 0 F r 1 10 −5 0.98 2 10 −4 0.98 3 10 −3 0.98 4 10 −5 1.02 5 10 −5 1.10

The computation reproduced here was made

through a finer approximation, because the friction and

slope terms are taken account separately and only the

linearization of characteristic slopes is used. Results

here obtained are similar from a quantitative and qual

itative point of view, to those by Lyn and Altinakar, so

their assumption seems to catch the main features of

the phenomenon. Of course a major conceptual differ

ence between the two computations exists, due to the

different transport models applied.

Two bed waves are found: a deposition wave, mov

ing downstream with the celerity λ 4 , and a scouring

wave moving upstream with celerity λ 3 .

In order to better understand the influence of the

quasi-linear approximation here adopted, we repeated

the computation increasing the ratio of the bump

height to the undisturbed water depth.

In Figures 3 and 4 results are shown, for a ratio

δ/h 0 of 10 −4 and 10 −3 , respectively. In both cases, the

qualitative feature of the evolution does not change,

and a growing bump propagating downstream is

observed.

The bump growth rate, defined as the ratio of the

bump non dimensional height at two different non

dimensional times (2 and 3) to the time gap between

them, seems to depend on the initial bump height itself.

In fact, in Figure 5 it is shown that, for a Froude number

of 0.84, it exists a bump height to which corresponds

a maximum in the non dimensional growth rate. It can

be conjectured that a particular bump height exists, □/h 0

The first (Figure 6) corresponds again to an example discussed in Lyn & Altinakar (2002). In our computations, from the original bump, two perturbations arise: one of scour and one of deposition, just like the results by Lyn and Altinakar. However, both waves travel downstream, while the two previous Authors found the deposition wave to travel upstream. It is interesting to note that this latter wave moves with □/h 0 =10 -3 -0.5 0 0.5 1 1.5 □/□ -5 0 5 10 x/L t/T=0 t/T=2 t/T=3 Figure 4. Figure 7. Hypercritical test (case 5).

a celerity corresponding to λ 1 = u- √ gh, and, while directed downstream, lays behind the erosion wave as in Lyn and Altinakar work.

The same behavior (Figure 7) is observed for a greater Froude number. The difference in propaga tion direction could be explained through the different eigenstructure between the two models.

For this latter example, the solution has not been plotter where the corresponding celerities differed of more than 1% respect to the values at t= 0.

Indeed, useful information can be inferred from the results here presented. It has been shown that none of the four celerities can be definitely associated with only bed or water surface propagation, at least as soon as finite amplitude perturbations are considered. As a way of principle, all the the four celerities could carry information, triggered by a bed perturbation, relative to the bed evolution, even the ones which have the same expression of the fixed-bed model celerities.

It seems that in the range of Froude number and bump height here considered, initial bed disturbance affects the bed evolution only downstream in hyper critical streams, both downstream and upstream in hypocritical flows.

4 CONCLUSIONS

In the present note the behavior of a small, but finite,

bed perturbation was analyzed.

Starting from an initial flat bed with a small and

smooth perturbation (bump), integration of a mor

phodynamical four-equations model was performed

through a linearized method of characteristics.

When dealing with hypocritical flows, two bed

waves are found, one which is a deposition wave, mov

ing downstream with the celerity λ 4 , and a scouring

wave moving upstream with celerity λ 3 .

Both perturbations grows in magnitude with time,

and the bump growth rate seems to depend on the initial

Bar height formulas to predict the maximum scour depth at riverbanks

G. Del Giudice, G. Rasulo & E. Viparelli

Department of Hydraulic and Environmental Engineering G. Ippolito,

University of Naples Federico II Naples, Italy

ABSTRACT: Floods in alluvial rivers are characterized by channels incision in the alluvial bed during the

rising stage and their filling up in the falling stage; this phenomenon is well known and called scour and fill.

In this work scour and fill during floods will be described as bar migration in the alluvial bed; when bar trough

reaches the riverbank protection, the undermining of longitudinal protection structures may occur if the river bed

level is lower than the bank foundation structure. Scour or trough depths below the average riverbed level can be

predicted with formulas calibrated using flume data or derived theoretically. In this paper four different formulas

for alternate bars will be discussed and their applicability to field data is tested. A simple criterion for riverbank

foundation depth estimate is proposed and its applicability to braided rivers is derived by using a correction factor.

1 INTRODUCTION

During flood rising stages velocity and shear stress on

the bed increase and the channel bed tends to scour;

during falling stages the shear stress decreases and the

bed fills. Channel scour and fill are words used to

define bed cutting and sedimentation during relatively

short periods of time, whereas the terms degradation

and aggradation apply to similar processes that occur

over a longer period of time. Scour and fill involve

times measured in minutes, hours, days, perhaps even a season, whereas aggradation and degradation apply to persistent mean changes over periods of time measured in years (Leopold et al., 1964).

Major scour can be locally caused by transverse structures built in the middle of the alluvial bed or jutting out into it and by the presence of huge boul ders in the bed or near the banks. Therefore in alluvial riverbeds each obstacle, which causes whirling motion and alters the sediment exchange between stream and bed, causes rapid local scours or fills, owing to the con tinuous variations of discharges and stream direction (Viparelli, 1972).

In technical literature many indications are given to predict local scour depths (Raudkivi, 1998) but it is difficult to estimate the scour that a flood causes in alluvial channels without transverse obstacles. In this work scour and fill during a flood will be described as bar movement in the alluvial bed: scour occurs on bar troughs and fill on the crests.

Bars can be classified relative to their position in the bed and their orientation towards the stream direction.

Alternate bars are typical of streams flowing in a single
Figure 1. Riverbank protections undermined along Basento river in southern Italy. channel: these bedforms grow near the banks so the stream flows assuming a pseudomeandering thalweg. In braided rivers the stream flows in two or more channels in the valley and the bars can grow both near the

banks and in the middle of the bed, causing the flow to split. They are differently named depending on their orientation towards the stream direction (central, diagonal, transverse, midchannel…) (Leopold & Wolman, 1957; Raudkivi, 1998). During floods bars are in movement in the alluvial bed and their troughs can reach riverbank protection toes causing undermining, if the trough depth below the average bed level is lower than the foundation depth (Fig. 1).

In this paper four formulas to predict trough depths will be briefly described and then estimated and measured scour depths will be compared by means of field data.

2 DESCRIPTION OF FORMULAS

All the considered formulas described in this paper predict the trough depth below the average bed level for rivers with alternate bars.

Three of them use laboratory experiments (Kishi, 1980; Jaeggi, 1984; Ikeda, 1984); the other, on the contrary, results of a mathematical model describing the development of a finite-amplitude alternate bar in a straight channel with erodible bottom (Colombini et al., 1987; Seminara & Tubino, 2003).

In all the flume experiments both the banks and the bottom of the channels were modelled; therefore, these formulas describe alluvial rivers with alternate bars. On the contrary, Seminara's formula, based on the hypothesis of fixed banks, describes alternate bars in reaches where the bottom is much more erodible

than the banks.

Maximum trough depths below the average bed

level (S) are considered as a fraction of the bar height

defined as the elevation difference between the highest

and the lowest point in a bar unit (H BM) or in a cross

section (H B). The difference between H BM and H B is

defined in Figure 2.

Kishi and Kuroki

Bar heights and scour depth are maximum along the

side walls of a channel and minimum along the centre

line (Kishi, 1980). The bar height along the channel

wall can be estimated with

where B is the channel width (Fig. 2). h S H BM A A B

Reach averaged

bed surface Bar Unit B B Bar Front Lowest depression in bar unit Thalweg h S H B B A A Lowest depression in cross section Water level

Figure 2. Definition sketch of alternate bars; hatching and

broken line indicate pools and thalweg, respectively.
Following Jaeggi to be discussed below, the scour depth can be estimated with Jaeggi From laboratory experiments in a 30 cm wide flume Jaeggi found that the total bar height (H BM) is much higher for alternate bars than for others bedforms, including central bars (Jaeggi, 1984). He also underlined that H BM is almost independent of discharge and slope and that the ratio of maximum scour depth (S) to the total height seems to be fairly constant and equal to 0.76 for all experiments. His results are described as where Z B =B/d 50 , B is the channel width and d 50 is the median diameter of the particle size distribution of the material used. Ikeda In examining his laboratory tests Ikeda found a linear relationship between S and H B as Here h is the mean depth of flow and the function ψ(B/h) (Fig. 3) is defined for B/h≤ 70, considering B/h= 70 as the upper limit of the

alternate bar formation region. For B/h> 70–100 alternate bars disappear and multiple bars develop, which characterise the braided river pattern (Ikeda, 1984). 1 10 100 1 10 100 B/h Ψ Figure 3. Function (B/h) (Ikeda, 1984).

Seminara

The maximum scour depth below the average bed level

is considered as a fraction of the total bar height

Here β =B/(2h) and b 1 , b 2 , and β c are functions of the

ratio d/h and the Shield's parameter (θ); these functions

are defined for 0.001≤ d/h≤ 0.05 and 0.05≤ θ ≤ 0.5.

Therefore, H BM can be considered as a function of

channel width B, average stream depth for the uniform

unperturbed flow h, average slope i and diameter of

sediment modelled as unigrains d. This formula can

be applied for β ≤ 2β c .

3 FIELD DATA

The described formulas have been tested with flume

data; predicted scour depths have to be compared with

measured scours along natural rivers to investigate

these formulas applicability for designing.

Field data available in technical literature are unfor

tunately scarce and can be classified in three groups:

Scour depth measured with scour-chains, Scour depth

measured with load-cell sensors and Scour depth mea

sured at the United State Geological Survey (USGS)

gaging stations.

Measuring stations equipped with scour-chains

were installed along Quatal Creek (Foley, 1975) and Redwood Creek (Madej, 1995) in California. These are two small rivers with coarse riverbed material. Measurements with load-cell sensors were per formed on Torrente Serrapotamo in Southern Italy (Penta et al., 1977a and 1977b; Penta et al., 1980). Load-cell sensors give more information than scour chains because of their ability in showing the cross section evolution during a flood while the chains only measure the maximum scour depth. Scour measurements at the USGS gaging stations were performed on the Redwood Creek and they describe the cross section evolution during floods. Gaging stations are usually characterized by restricted laterally flows, causing deeper vertical scour than in unconfined sections. Other field measurements available in technical lit erature are bar heights (H BM); these can be considered as a fourth class of measures to test the previously described formulas. Bar heights were measured in Washington State along Jenkins, May and Swamp Creek (Konrad et al., 2002). Field data are reported in Appendix. 4 SCOUR INTERPRETATION As previously mentioned, this paper aims to compare predicted with measured scour depths along alluvial rivers. All the described formulas predict the maximum trough depth below the average bed level as a bar height fraction. Field data,

on the contrary, give the maximum measured scour depth in a cross section. It may happen that in a cross section the maximum scour depth occurs far from the sensor (scour-chain, load cell…); therefore, in cross sections with a significant number of sensors (nine on Torrente Serrapotamo) measured scour depths can be considered as maximum, while in other sections with less sensors only a rough approximation of the maximum value may be made. It is well known that the bar migration celerity in alluvial beds is much smaller than the flood wave celerity. Considering that all the measuring stations refer to small basins, floods should persist for only few hours and bar troughs can not cross the measuring section.Therefore, the recorded scour depths could be smaller than the maximum trough depths below the average bed level. It is logical to expect that scour depth prediction should be larger than recorded field data. 5 INTERPRETATION OF FORMULAS All the experimental formulas mentioned have been tested with flume yet indications for their applicability to natural rivers are hardly mentioned. Jaeggi pointed to the good agreement between scour depth predictions and measurements by replacing the channel width B with B ′′ =B-2nS, where 1/n is the bank slope and S is the scour depth. His formula can be rewritten as where Z ′ B =B ′′ /d 50 and the scour depth (S) has to be found by iteration. Ikeda illustrated the applicability of his formula to natural rivers comparing predicted and measured bar heights along the Naka River, Japan.The calculated bar height is 7.20 m while the measured value is 5.68 m. Applying the described formulas to natural rivers is not as easy as it seems. Each river is different, therefore it is fairly impossible to classify them in a rigorous way. Moreover several parameters, as defined in the laboratory and by theoretical models cannot be easily estimated. For this reason, it seems necessary to underline how the experimental parameters will be considered in this work, how rivers can be distinguished between alternate bars and braided forms and how formulas for alternate bars will be applied to predict scour depths along braided rivers.

Riverbed material

In natural alluvial rivers the particle size distribution

is characterized by a coarser and a finer fraction. It

is necessary to describe the riverbed material move

ment referring to a coarser fraction diameter in order

to consider the armouring effect.

In this work the riverbed material will be described by d 90 of the particle size distribution; only along Redwood Creek the median diameter d 50 of the parti cle size distribution will be considered because of lack of d 90 value.

Active riverbed width

All the experimental formulas consider the scour depth as a function of channel width B. In this work B is considered as the active riverbed width.

In narrow reaches the active riverbed coincides with the valley; on the contrary, in reaches where even dur ing rare floods the stream only flows in a part of the valley (large reaches), the active riverbed width has to be determined.

All the reaches, considered in this work, are not very large: during high flow the active floodplain coincides with the whole valley. Therefore, the active bed will be considered as wide as the whole valley.

Gaging stations are characterised by restricted lat eral flows, therefore the active floodplain is narrower than the valley; in this work the restricted width will be considered as B in the experimental formulas.

Water depth

It is important to underline that the field data do

not always give the average water depth, a parame

ter necessary to apply Ikeda and Seminara formulas.

In this work the average water depth will be estimated

with the Gauckler and Strickler formula, hypothesis

ing a rectangular cross section and a friction factor

equal to 35 m 1/3 /s.

Braided rivers

In this work rivers are distinguished between “rivers

with alternate bars” and “braided rivers” (Kishi, 1980)

using Kishi and Kuroki’s bed form chart (Fig. 4). In this

5

chart the transition region and the existence regions of
alternate bars and braided rivers are plotted as functions
of the ratio of shear velocity and its critical value (u *

/u ∗ c) and the parameter Bi/h, where B is considered as the active bed width, i is the average riverbed slope and h is the average water depth. This classification is quite simple and shows whether the described formulas can be applied or not. It is not possible to state how many channels characterise braided rivers. The number of channels that the stream incises in the alluvial bed of braided rivers is an important parameter to extend formulas for alternate bars to braided rivers. Alternate bar heights depend mainly on the channel width (B) (Kishi, 1980), a parameter that is here interpreted as the active bed width along natural rivers. Braided rivers are characterised by two or more channels and the active bed width is, in general, larger than that of alternate bar streams while the scour depth is smaller (Jaeggi, 1984). In this paper experimental formulas to predict scour depths will be applied along braided rivers considering the active bed width of each channel B ′ =B/m, where m is the number of channels (Rossi & Silvagni, 1983). 6 COMPARISON BETWEEN PREDICTED AND MEASURED SCOUR DEPTHS In this paragraph river patterns will be predicted using Kishi and Kuroki's diagram (Fig. 5), then estimated and measured scour depths will be compared. Finally all the formulas will be applied along Torrente Serrapotamo to discuss the extension of formulas for alternate bars to braided rivers. Kishi and Kuroki's bed form chart shows that all field data along American rivers are in the alternate bars and in the transition regions. Considering that in the transition region alternate bars can develop and that the authors describe bars in their works, all the American rivers will be considered with alternate bars. 5 10 -2 10 8 6 3 2 1 4 u ∗ / u ∗ c 10 -1 10 1 Bi/h o 10 0 Torrente Serrapotamo Redwood Creek E Quatal Creek Redwood Creek 86km Redwood Creek 36km transition alternate bars braided Figure 5. Field data in Kishi and Kuroki's bed form chart.

Kishi and Kuroki

The maximum scour depth was predicted along all the

rivers where measurements were performed, because

of all the field data report the active bed width (Fig. 6

and Table 1).

Bar heights, measured along Jenkins, May and

Swamp Creek, have been multiplied by 0.76 to trans

form them in scour depths.

Swamp Creek A 0.08 0.19 150

Swamp Creek B 0.15 0.34 125 Kishi and Kuroki’s formula tends to underestimate the scour depth only along May Creek, a very narrow stream with a steep slope. In the other three sections of rivers with very narrow banks and

high slopes the formula tend to overestimate the scour depth (May and Swamp Creek). Because the bar height depends only on the active bed width, this formula cannot predict the bar height with sufficient accuracy in very narrow reaches. In section E of the Redwood Creek this formula overestimates again the scour depth; this section was equipped with 3 or 5 scour chains and is about 76 m wide from one bank to the other. The measured scour depth cannot be considered as the maximum in the section because of very few sensors used to monitor the riverbed evolution. Moreover, it is possible that the stream does not flow in a single channel in this reach because the average slope is higher than in the up and downstream reaches. If this hypothesis is true, the scour depth should have been estimated for a braided river. In all the other sections the difference between the measured and predicted scour depths do not seem very appreciable considering that the authors give this formula to roughly estimate the bar height: the percent error is smaller than 50%. Jaeggi This formula predicts the maximum scour depth as a function of the active bed width and the characteristic diameter of the riverbed material. As said before, defining the characteristic diameter of the riverbed material is not easy, therefore the formula has been applied twice, once using the median diameter of the particle size distribution (Fig. 7 and Table 2) and then referring to d 90 of the same distribution (Fig. 8 and Table 3). As done for the Kishi and Kuroki’s formula, bar heights were multiplied by 0.76 to transform them in scour depths. Jaeggi’s formula tends to overestimate the scour depth if d 90 is used to describe the riverbed material instead of d 50 : the percent errors are all larger than 50% and they show that this formula tends to overestimate scour depth. Significant differences between predicted and recorded scour depths occur in the same sections as observed using Kishi and Kuroki’s formula; while in the other sections this formula tends to overestimate the scour depth more than the Kishi and Kuroki’s relation. Ikeda The maximum scour depth is considered as a function of the active bed width, the diameter of riverbed

material coarser fraction and the average water depth

(h). Therefore in the measuring stations, where several

flood discharges were reported, it has been possible to

predict different scour depths. In this work only the

maximum and the minimum estimates are considered

to define a range variation for scour depth prediction

(Fig. 9 and Table 4).

This formula cannot predict scour depth along

Jenkins, May and Swamp Creek, because of lack of

flood discharge and average water depth measure

ments in the reference article.

The formula was applied even for B/h> 70 extrapo

lating the function ψ (Quatal Creek, where B/H= 95,

and Torrente Serrapotamo, where B/h= 106–118). 0 1 2 3 0 2 S m [m] S p [m] 1 3 Figure 8. Comparison between measured and predicted scour depths according to Jaeggi's formula for d= d 90 . lack of field data. Furthermore along the Torrente

Serrapotamo and at the USGS gaging station at the

36th kilometre from the Redwood Creek head either,

the inapplicability of formula was stated because of

functions b 1 , b 2 , and β c being not defined for those

reaches characteristics (Fig. 10 and Table 5).

The percent difference between the predicted and

the measured scour depths are comparable with the

other formulas but this relation was not applied along

several rivers considered here because of lack of field

data and a restricted range variability of its parameters.

6.1 Scour depth prediction along braided rivers: Torrente Serrapotamo

In this paper four formulas to predict the maximum

scour depth below the average bed level are tested by

comparing measured and estimated scour depths along

natural rivers. All the experimental formulas predict 0 1 2 3 0 2 S m [m] S p [m] 1 3 Figure 10. Comparison between measured and predicted scour depths according to Seminara's formula; points connected by lines are the minimum and the maximum scour depth predicted along a river, where several discharges were recorded. (S p −S m)/ River S m [m] S p [m] S m [%] Quatal Creek 0.90 1.06 1.15 18 28 Redwood Creek 86 1.60 1.08 2.33 −33 46 Redwood Creek E 1.20 2.37 98 the maximum scour depth in rivers with alternate bars; field measurements, on the contrary, were also performed along braided rivers. Considering that few field data are available in technical literature and that riverbank protections are also built along alluvial rivers, it seems important to test the described formulas along braided reaches. Scour depths in braided rivers are, in general, smaller than in alternate bar streams depending on a smaller bed-load transport capacity being the discharge split in two or more channels. Scour depth predictions alongTorrente Serrapotamo were performed with the stream flows in two channels divided by a central bar (Fig. 11); therefore the active bed width (B) was substituted by B ′ =B/2. These predictions show that there is not a significant difference between measured and estimated scour depths along that river. It is important to underline that Ikeda's formula, defined for B/h smaller than 70, predicts the scour depth with a small error of 6%, even if it has been used for B/h> 70. fill scour

Ikeda	Not applicable	1.22 1.31
Seminara	Not applicable	Not applicable

The suggested correction on the active riverbed

width, used to extend the formulas to braided rivers,

should be tested comparing the measured scour depths

with predictions made with the whole active bed width

(Table 6).

Scour depths predictions reported in Table 6 indi

cate that the extension of formulas for alternate bars

to braided rivers seems to be possible if the active

riverbed B is replaced by B ′ =B/m, where m is the

number of channels. This extension, like the practi

cal use of described formulas, ought to be tested with

other field data to deeply investigate their applicability

to natural rivers.

7 CONCLUSIONS

A design criterion to estimate the riverbank foundation depth in alluvial rivers is derived assuming that the scour at the toe of riverbank corresponds to the trough depth of migrating bars.

The four considered formulas were tested with flume data but few indications are available for their applicability to natural river. Moreover, these formulas predict the scour depth along rivers with alternate bars but the authors do not give suggestions about scour depth estimation along braided rivers, where scour depths are smaller. The comparison between predicted and measured scour depths underline that all the described formulas overestimate the scour depths with comparable errors. Because of difficulty in defining natural river patterns and parameters, it seems logical to refer to a simple design criterion to estimate the maximum scour depth. Such a requirement is well satisfied by adopting, in rivers with alternate bars, the simple formula 0.76B/20, where B is the active riverbed width. Moreover, for braided rivers, formulas for alternate bars can be used considering the active riverbed width B ′ =B/m, where m is the number of channels. The estimated maximum scour depth should be finally multiplied with a safety factor to state the riverbank foundation depth. ACKNOWLEDGEMENT The authors would like to thank the reviewers for their useful comments and suggestions. APPENDIX: FIELD DATA A Quatal Creek Quatal Creek is an ephemeral stream in the northwestern Ventura County, California. Its upper reach is on the western side of Cerro Noroeste (2526 m) and it is an eastern tributary of Cuyama River. Field data are summarized in Tables A1, A2. Scour measurements were performed during the 1973–75 winters (Foley, 1975). In this period two important floods occurred (January and December 1974): the scour-chains measured scours of depths 0.4 and 0.9 m. Riverbed material has defined as coarse sand, of median diameter 1.99 mm and of standard deviation 6.15 mm; hypothesizing a Gaussian distribution for the bed material d 90 = 1 cm. B Redwood

Creek Redwood Creek is an alluvial river in northern California. It drains a 725 km 2 basin and is approximately 108 km long (Madej, 1995). Field data are summarized in Tables B1–B6. In Madej's work two approaches were used to estimate the depth of scour during winter floods: scour-chains were installed at seven cross sections (3 to 5 chains per section) and the USGS discharge measurement notes were used to state gaging stations evolution during floods. Sections equipped with scour chains will be identified with letters A through G, gaging stations with their distance from the riverhead.

7	111	48	0.6	0.3

The measuring station was 1.3 km upstream the stream mouth, the basin average height is 697 m. Tor rente Serrapotamo in the monitored reach is braided

with two channels.

D Jenkins Creek

Jenkins Creek drains a 37 km 2 basin on a glacial out

wash plain in the Puget Lowland, Washington State.

The mean discharge during the years 1989–1998 was

1.1 m 3 /s at the King County station near the mouth.

Flood recession is gradual and base flows are high rela

tive to the other streams in the region (Konrad et al.,

2002). Bar material is in general well sorted and the

median diameter varies between 30 and 48 mm. Field

data are summarized inTables D1, D2.Two gravel bars

were observed in the monitored reach: bar A is a mid

channel bar in a straight reach and bar B is transverse

and coarser than A.

E May Creek

May Creek drains a 32 km 2 basin with steep head

waters and extensive glacial till deposits in the Pudget Table E1. May Creek data at bar A. B [m] d 90 [mm] d 50 [mm] i [%] H BM [m] 10 95 40 1.1 0.6 Table E2. May Creek data at bar B. B [m] d 90 [mm] d 50 [mm] i [%] H BM [m] 9 88 31 1.6 0.5 Table E3. May Creek data at bar Z. B [m] d 90 [mm] d 50 [mm] i [%] H BM [m] 9 135 50 1.1 0.2 Lowland, Washington State. The mean discharge during the years 1989–1998 was 0.7 m 3 /s at King County station near the mouth. Floods are characterised by relatively high peaks and rapid recession rates (Konrad et al., 2002) and base flows are low. Field data are summarized in Tables E1–E3. Bar material is poorly sorted gravel with a large fraction of sand and finer material and the median diameter varies between 31 and 50 mm. Three bars were monitored: Bar A is a transverse gravel bar with the upstream end in a plane bed reach and the downstream part very steep; Bar B is a transverse bar 200 m downstream from bar A and Bar Z is a transverse bar too, in a relatively straight pool-riffle

reach. F Swamp Creek Swamp Creek drains a 59 km 2 basin comprising a glacial till plateau in the Pudget Lowland, Washington State. The mean discharge in the water years 1980- 1989 was 1.0 m 3 /s at the USGS station near the mouth. The hydrologic regime falls between those of Jenkins and May Creek: floods have intermediate peaks and mediate recession rates (Konrad et al., 2002). Field data are summarized in Tables F1, F2. In the upper reach bar material is poorly sorted with very large cobbles lying beneath the gravel surface layer; the lower reach has low gradients and lower capacity to transport sediment, therefore the material is finer. Median diameters vary between 19 and 48 mm. Two gravel bars were monitored: barA is a midchannel bar in a straight reach with uniform width and a nearly plane bed; bar B is a midchannel bar located in a lower gradient pool-riffle reach.

Use of sheet-piling submerged vanes

R. Guercio, R. Magini & M. Rotondi

Department of Hydraulics, Transportation & Roads, University of Rome “La Sapienza”, Rome, Italy

ABSTRACT: Submerged vanes have found a large number of applications in river hydraulic to control river

bed morphology in different conditions and with different aims. Here an experimental and numerical study,

describing the efficiency of vanes built using steel sheet-piling, is described. The employment of steel sheet

piling vanes should simplify the construction of these structures, reducing their costs as well. In particular both

in the experimental and numerical experiences the performances of steel sheet-piling vanes have been compared

with those of the more usual thin vanes. Both for steel sheet-piling vanes and thin vanes the peculiar features of

the hydrodynamic field have been also enhanced through numerical simulations.

1 INTRODUCTION

1.1 Vanes description

Submerged vanes are structures installed on river bed

at angles of attack between 15 ◦ and 20 ◦ . They are

characterized by a thin thickness or a hydrodynamic

profile.Their height is generally equal to 0.2–0.5 times

the river mean flow depth, their length is equal to

2–3 times their heights. The presence of these struc

tures generates the formation of secondary flow which modify the intensity and the direction of the shear stresses on the river bed, altering the natural processes of sediment erosion and deposition.

Although the literature indicates that obstacles with characteristics similar to the submerged vanes already had been used in the past for rivers and channels con trol (Potapov & Pyshkin 1947, Chabert et al. 1961, Jansen et al. 1979), only with the studies lead at the Iowa Institute of Hydraulic Research (IIHR), starting from the ’80s, a systematic experimentation on these structures was begun. For this reason in literature it is often spoken of Iowa vanes.

Submerged vanes have been used to control spiral flow and bank-erosion in bends and to deflect sediment in straight channels. A variety of experimental stud ies (Odgaard & Kennedy 1983, Odgaard & Lee 1984, Odgaard & Mosconi 1987) have yielded a detailed guidance in the design of these types of vanes. More over submerged vanes can find also application in many other fields of river hydraulics, namely: mainte nance of the optimal depth of a river bed; deepening of the river bed in order to improve or to allow navigabil ity; bridge piers protection; avoiding the obstruction of bridges, water derivations for hydroelectric plants, irrigation channels, braided or wandering rivers control

with consequent removal of sand bars; creation of suitable habitats for aquatic fauna; etc. The main advantages of these obstacles are mainly low costs and low environmental impact. Actually it must be emphasized the difficulties of production and installation of structures having, according to the theory, very low thickness or hydrodynamic shape. 1.2 Straight channel theory The most significant feature of the flow formed when a two dimensional boundary layer developing over a flat surface encounters a surface mounted protrusion is the appearance of three complex vortical systems: the horseshoe vortex, the wake vortex and the tip vortex. The first one is generated by adverse pressure gradient upstream of the obstacle and it is characterized by horizontal axis and two counter-rotating legs that wrap the obstacle toe. The wake vortices, characterized by vertical axis, is due to boundary layer separation on the obstacle surface. Finally the tip vortex, typical of submerged obstacles, is generated by pressure gradients between the different sides of the protrusion. In particular a submerged vane induces a horizontal circulation in the flow downstream. The pressure difference between the pressure side and the suction side of the vane causes the flow on the pressure side to get an upward component and the flow on the suction side a downward component. As a result a tip vortex, springing from a position near the top of the vane, is formed. This vortex travels downstream with the flow where generates an helical motion of the flow and related changes in bed shear stress and bed

topography (Odgaard & Wang 1993). In particular the

river bed aggrades in one portion of the channel cross

section and degrades in another. The induced transver

sal velocity can be described by the following equation

(Odgaard & Spoljaric 1986):

where v= time-averaged velocity component in the y

direction; v s = transverse velocity component at water

surface; z= coordinate in vertical direction; h= dept

of the flow.

The variation of v s along the y direction is given by:

where v sc is v s at the channel-center line and:

whereV sc = v sc /v so ; v so = v s at (x, y)= (0, 0); k=Von Karman’s constant; f=Darcy-Weisbach friction factor.

The induced transverse velocity component v gives rise to a transverse bed-shear stress which generates changes in the channel bed. The depth distribution is given by:

where Δh= h – h ∗ ; h ∗ = average flow depth; is function of v sc .

Other analytical theories have been developed (Odgaard & Wang 1991) validating the effects of vane in sediment management.

1.3 Vane material and shape

Since the first experiments different materials and shapes have been used in vanes installations. They have been constructed from planks supported by h-piles, round wood poles, rows of dumped rock and reinforced concrete. In recent installations were used patented Iowa vanes having a hydrodynamic design, the vanes were shaped as a double-curved foil with a twisted rear edge and a rounded nose. It has to be underlined that vanes designs are functional as long as their thickness is small compared to their length and height. This is due to flow separation at the leading

edges of the vane that generates local scour under

mining the stability of the obstacle. To reduce all

the problems that occur when constructing, installing and piling thin thickness vanes in this work experimental and numerical tests have been conduced to validate the use of steel sheet-piling vanes. This type of vane simplifies many of the problems related to the installations, reducing the costs as well. 2 EXPERIMENTAL TESTS 2.1 Details of the experiments Laboratory experiments were conducted to evaluate the effectiveness of submerged vanes in controlling sediment redistribution, to validate the foregoing theory and to compare the induced effects on bed channel of sheet-piling vane and thin thickness vane. Tests were focused on finding the possible loss in efficiency of the sheet-piling vane due to the nonhydrodynamic shape, that could cause greater flow separation at the leading edge of the obstacle. The evaluation of the efficiency was based on verifying the changes on bed morphology due to the two different kind of vane and observing local scour around the obstacle. Many tests were carried on changing angles of attack (from 10 ∘ to 20 ∘), geometry and flow conditions. In this paper only the most significant is presented. A 12 m long and 0.4 m wide channel was used for all experiences. Flow rate was 0.018 m 3 /s with a corresponding mean velocity, u= 0.3 m/s and an average flow depth, h= 0.15 m. The bed consisted of a 0.1 m thick of sand having a median diameter of 0.5 mm and a density of 2650 kg/m 3 . The thin vane was made of aluminum sheet having length L= 17 cm, thickness S= 0.5 cm and height H= 5 cm. The sheetpiling vane presented the same dimensions of the thin one and was a scaled steel sheet-piling Larssen L603K (Fig. 4). The angle of attack was set equal to 20 ∘ . Both vanes were installed 6 m downstream of channel inflow; the origin of the axes was placed in the middle of the vane as shown in Figure 4. The choice of the flow conditions and of the dimensions of the vanes resulted from Odgaard’s theory and from the available experimental apparatus. 2.2 Results and analysis According to Odgaard & Spoljaric studies, the effects of vanes on downstream bed morphology are significant only until 15/30 times their height, for this reason changes of the bed were measured only for a distance of 24 H downstream of the vane. As soon as the experiments had run it was observed the rise of a sand ridge just downstream the vane. During the test the ridge grew up and the channel was ideally divided in two regions: in the first one sedimentation occurred, in the second one scour took place. Each test lasted 3 h 30 ′ , time at which quasi-steady condition were reached.

Excluding cross-wise sections at the leading edge

of the obstacle, where local scour due to the horseshoe

vortex occurs, maximum changes in bed morphology

were localized between 40 and 70 cm downstream of

the vane. In Figures 1-3 bed profile measures from

experimental tests performed with thin and L603K

vane at different downstream distances are presented.

In the same figures are also reported bed profiles

predicted by equation 4.

These results show that the theoretical curve fairly

well describes experimental data. But, it can be noticed

that it underestimates bed changes for the thin vane, on

the contrary it overestimates the effects of L603K vane.

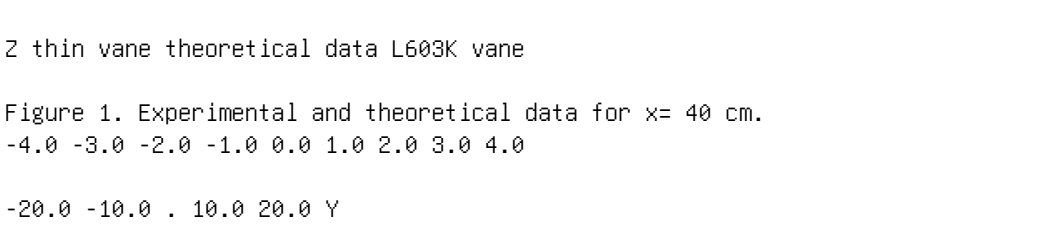

Figure 1. Experimental and theoretical data for x= 40 cm.

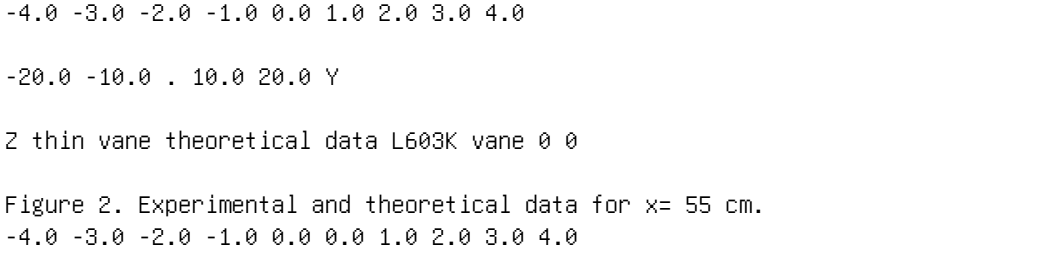

Figure 2. Experimental and theoretical data for x= 55 cm.

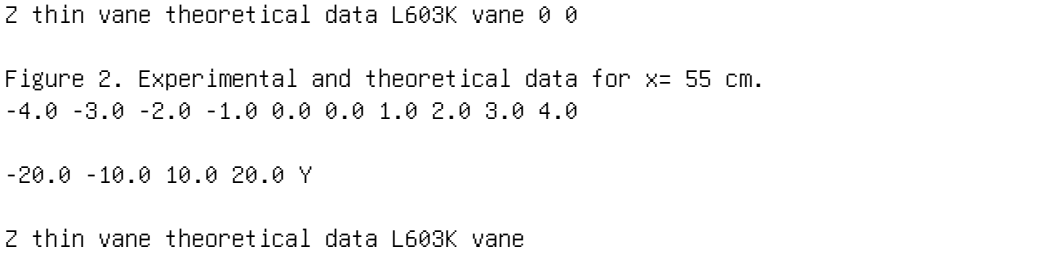

Figure 3. Experimental and theoretical data for x= 70 cm.
It was observed, in fact, that this kind of vane induced
less significant modifications in bed morphology. On the
other hand experiments enhanced lower values of local scour

for L603K vane, namely for this kind of structure local scour was reduced of about 30% with respect to the thin vane. 3 NUMERICAL EXPERIMENTS 3.1 Numerical models The CFD code used for the numerical simulations was FLOW-3D, which solves the Navier-Stokes equation by the finite difference method. The Volume of Fluid (VOF) method is used for computing free surface motion and the FAVOR method to model complex geometric regions. Three models were considered to investigate vortical structures, induced velocity fields and bed shear stress fields. The first two simulations were carried on to study the rising and the evolution of tip vortex for both kind of vanes, while the third simulation to obtain a better visualization of the complex vortical fields near the sheet-piling vane. The first two models had a mesh characterized by the following dimensions: length of 180 cm, wideness of 40 cm and height of 21 cm. The total numbers of cells were 250,000 and 480,000. The vane and the origin of the axes were placed 60 cm away from the fluid entrance. For the third simulation (Fig. 4) it needed a greater number of cells to visualize correctly the hydrodynamic field. The model was characterized by a length and a wideness of 30 cm and an height of 17 cm for a total number of cells equal to 780,000. The turbulence model used for all the simulations was the RNG (renormalized group). A “specified velocity” Figure 4. Numerical model of L603K vane.

Figure 5. Thin vane. Evolution of tip vortex: cross-wise

section y-z; t= 100 s; x=-0.75; 3.75; 6.75; 100 cm.

boundary condition was given for the fluid entering

the computational domain, while a “continuative” type

for the fluid flowing out.

Vanes dimensions and hydraulic conditions were the

same of the ones used in the laboratory experiments.

Thin thickness vane was generated by the means of

Flow-3D geometry panel, while L603K vane import

ing a STL file created with Autocad2000. The channel

bed had an equivalent surface roughness equal to

0.05 cm.

3.2 Results

The running time of the three simulations was

t= 100 s, after about 70 s the flow became quasi

steady. The evolution of tip vortex was obtained for

both vanes (Figs 5-6). It can be noticed that, exclud

ing the very first cross-wise sections close to the

leading edge of the obstacle, no substantial differences
Figure 6. L603K vane. Evolution of tip vortex: cross-wise section y-z; t= 100 s; x=-0.75; 3.75; 6.75; 100 cm. between vortices and induced transverse velocity generated by thin and L603K vane are present. The fluid approaching the vanes gave rise to a secondary flow, that 70 cm away from the obstacles occupies almost the whole cross-wise section. It is possible to note that for the L603K vane the vortical structure at this distance shows an elliptical shape, while the thin vane generated a circular-shaped vortical structure.The bed transverse velocity intensity and direction in both simulations are similar, namely for the L603K the maximum velocity is about 0.77 of thin vane one. The third model was created for a better description of velocity field around the sheet-piling vane. In Figure 7 it can be noticed the mechanism generating the tip vortex at the leading edge of the vane as described previously in paragraph 1.2. Figure 8 shows the presence of the tip vortex near the top of the structure, but also of another

Figure 7. L603K vane. Downward and upward compo

nent of velocity at low and high pressure side (plane y-z

at x=-5 cm).

counter-rotating horizontal vortical structure near the

bed. Plausibly it is one of the legs of the horseshoe

vortex system.

Moreover, according to observations performed

during the laboratory tests the presence of vortices

with vertical axes had also been enhanced by this

numerical simulation.

These vortices are generated by boundary layer sep

aration on L603K vane surface. They looks like to be

entrapped in between the indentations on the vane. Figure 10. Thin vane. Normalized bed shear stresses at z= 0. Figure 11. L603K vane. Normalized bed shear stresses at z= 0. Their presence is plausibly responsible for the local scour reduction around the structure. They dissipate, in fact, part of flow energy limiting its scouring capability. Figures 10, 11 show normalized bed shear stresses for both kind of tested vane. In both simulations it can be noticed the presence of two regions, where respectively sedimentation and erosion occur. The maximum values of bed shear stresses for the thin vane are about 30% higher than those of L603K vane. This result justify the lower efficiency of L603K vane as described by experimental tests. 3.3 Validation of theory for thin vane Results from the numerical simulation of the thin vane were compared with theoretical data resulting from equations 1-3, already illustrated in paragraph 1.2. 0.0 0.1 0.2 0.3 0.4 0.5 0.6 0.7 0.8 0.9 1.0

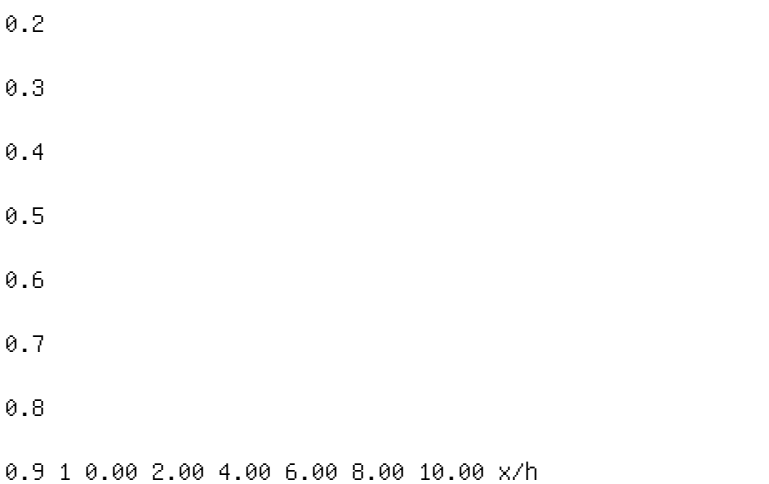

Figure 13. Measured and predicted downstream variation of maximum transverse velocity.

In Figure 12 data of induced transverse velocity are reported, it can be seen that equation 2, for values ranging between -0.5 and 0.5, is a realistic predictor for the transverse velocity.

Figure 13 shows a faster decay of the numerical values of the downstream transverse near-bed velocity than the predicted ones. This behavior had already been verified by the same Odgaard by the comparison between laboratory and theoretical data.

4 CONCLUSIONS

This study was conducted to understand the behavior

of sheet-piling vanes and to verify their efficiency in straight channels. Experimental and numerical tests have shown the similarity of the performances of thin and L603K vane. The visualizations of the tip vor tex have confirmed the same features for both kind of obstacle. On the other hand the laboratory experi ments have shown a minor efficiency of L603K vane in sediment control.

Though sheet-piling vanes induce less changes in

Double-averaged flow field over static armor layers

J. Aberle & K. Koll

Leichtweiss-Institute for Hydraulic Engineering,
Braunschweig Technical University, Germany

ABSTRACT: In a novel approach to investigating the interaction between grain-size distribution, surface geometry, and flow field of open-channel flows, the double-averaged (in temporal and spatial domains) momen tum equations are applied to rough-bed open-channel flow. Preliminary results of a laboratory study carried out in the hydraulic laboratory of the Leichtweiss-Institute for Hydraulic Engineering, University of Braunschweig, Germany are presented. The bed layer consisting of a gravel-mixture with d 50 = 5 mm had an initial height of 20 cm. By a step-wise increase of the discharge, armor layers with different stages of stability were developed successively until the maximum bed stability was obtained. After an intermediate armor layer was fully devel oped, i.e. when sediment transport rate was negligible for an intermediate discharge step, velocity profiles were

measured using a 3D-Acoustic-Doppler Velocimeter (ADV). A high resolution Digital Elevation Model (DEM)

of the armor layer topography was obtained from a laser scan of the bed. This detailed knowledge of topography

is a prerequisite for the applicability of the double-averaged momentum equations in the roughness layer, i.e.

the flow region between just above the roughness crests and troughs of the gravel bed. The relationships for the

double-averaged velocity distribution and hydraulic resistance are derived and compared with these data.

1 INTRODUCTION

The structure of flows over hydraulically rough beds

is important for the understanding of natural rivers.

An abundance of studies have been carried out to

explore theoretical aspects of turbulent structures of

these flows (e.g. Nezu & Nakagawa 1993, Kironoto &

Graf 1994, Song & Graf 1994, Nikora et al. 2001). In

these studies, progress was achieved in understanding

the turbulence structure for high relative submergence

and the flow field at distances from the bed sufficiently

greater than the roughness height. Recent investiga

tions concerning the nearbed flow structure in flows

over irregular rough beds (for both, large and shal

low water depths) resulted in improved approaches

for the description of the flow field (Dittrich & Koll

1997, Koll 2002, Nikora et al. 2001, 2003). How

ever, these approaches still require parameterization

and validation.

In general the turbulent flow field (Re> 2500) over

rough surfaces can be subdivided into three main

layers and a subsurface layer (figure 1). The outer

layer is composed of the free surface region and an

intermediate region. In the free surface region the tur

bulent structure is controlled by outer variables, with

length and velocity scales specified as the flow depth

h and the maximum mainstream velocity u max . The

intermediate region ((z- z t)/h≤ 0.6) is not strongly

influenced by wall properties or the free surface. In z z WS z F z L z R z C z t Outer layer Free surface region Intermediate region (z-z t)/h ≤ 0,6 Logarithmic layer (z-z t)/h ≤ 0,2 Roughness layer Subsurface layer Inner layer = wall region Figure 1. Turbulent flow field over rough beds after Koll (2002), modified; z t = elevation of roughness troughs, z c = elevation of roughness crests, z R = elevation of upper boundary of the roughness layer, z L = elevation of upper boundary of the logarithmic layer, z F = elevation of boundary of free surface region, and z WS = elevation of water surface. both regions viscous effects are negligible (Nezu & Nakagawa 1993). In the ‘inner layer’ or the wall region, which can be subdivided into a logarithmic (z R < z< z L , figure 1) and a roughness layer (z t < z< z R), viscous effects are

negligible, too. However, the characteristic scales of

the inner layer are different from those of the outer

layer. These scales are the shear velocity u * , the dis

tance from the bed and characteristic scales of the

bed topography. The logarithmic layer ranges up to

(z L - z t)≤ 0.2 h (Nezu & Nakagawa, 1993).

The roughness layer is influenced by individual

roughness elements and occupies the region between ‘just above’ the roughness crests and roughness troughs. Flow in this region is highly 3D and spatially heterogeneous for the case of natural, irregular beds. The main characteristic scales of the roughness layer are the shear velocity u ∗ and characteristic lengths of bed topography.

The subsurface layer occupies pores between granu lar particles.The characteristic scales of the subsurface layer are the shear velocity u ∗ and pore characteristic lengths.

An abundance of investigations of the flow struc ture in the near bed region has been based on the Reynolds equations which were used for both mod elling and interpretation of experimental data. How ever, due to the spatial heterogeneity of the flow in this region, time averaged-momentum equations are inconvenient and impractible. Giménez-Curto & Corniero Lera (1996) and Nikora et al. (2001) con cluded that 2D approximations based on the Reynolds equations as well as similarity considerations for time averaged variables are not possible for the near-bed region. To overcome this shortcoming, the Reynolds equations should be supplemented by spatial area (or volume) averaging in planes parallel to the bed

for theoretical considerations. The spatially and tem
porally averaged Navier-Stokes equations were first
introduced by Wilson & Shaw (1977) and further
developed by Raupach & Shaw (1982), Finnigan
(1985), Raupach et al. (1991), and Giménez-Curto &
Corniera Lera (1996). In hydraulics, the idea of spa
tial flow averaging was first introduced by Smith &
McLean (1977) and was recently adopted by various
researchers (e.g. Nikora et al. 2001, 2002a, 2002b,
2003, Lopez & Garcia 2001, Righetti & Armanini
2002).

In this paper we present preliminary results from a
research project carried out for the parameterization of
the spatially averaged momentum equations in the near
bed flow region. The experimental setup is described
and the relationships for the double-averaged velocity
distribution are derived and compared with hydraulic
and topographic data.

2 DOUBLE-AVERAGING METHODOLOGY

2.1 Governing equations and spatially averaging

The turbulent flow of an incompressible fluid can be
expressed by the general conservation of mass and the
Reynolds equations as: where we adopt the summation
convention for repeated index. Here u i and x i represent
the ith cartesian component of the instantanteneous
velocity and position vector with the usual convention u i
≡ (u, v, w), t is time, p is pressure, g i is the ith
component of the gravity acceleration, ρ is the fluid
density, and ν is kinematic viscosity. The overbar denotes

ensemble averaging and u i ′ denotes the fluctuating part of the velocity component u i according to the decomposition u i = u¯ i + u i ′ . A similar decomposition is used for the spatially averaging procedure.Velocity and pressure are decomposed into an overall mean ⟨u¯ i ⟩ and ⟨ p¯⟩ and a boundary disturbance according to u¯ i = ⟨u¯ i ⟩ + u˜ i and p¯= ⟨ p¯⟩ + p˜.The wavy overbar denotes the disturbance in the flow variables similar to the Reynolds decomposition with ⟨u˜ i ⟩ = ⟨ p˜⟩ = 0. Hence instantaneous velocities and pressure are defined as u i = ⟨u¯ i ⟩ + u˜ i + u i ′ and p= ⟨ p¯⟩ + p˜+ p ′ . The spatially averaging procedure for the flow region above the roughness crests follows the Reynolds procedure and does not present any difficulties. However, the averaging procedure for the flow region below the roughness crests is not trivial. The averaging region is intersected by roughness elements and, for this case, the spatially averaging operation does not commute with spatial differentiation. Detailed mathematical derivations of the spatial averaged equations are presented in Raupach & Shaw (1982), Finnigan (1985) and Giménez-Curto & Corniera Lera (1996). Here we present the equations from Nikora et al. (2001) which are based on the derivation of the spatially averaged momentum equations by Giménez-Curto & Corniera Lera (1996). The spatially averaged equations for flow above the roughness crests can be expressed as:

and for flow below the roughness crests as:

with A=A f /A 0 , where A f denotes the area occupied

by fluid within a fixed region in the x,y-plane at level

z within the total area A 0 .

The comparison of (3) and (5) with (2) shows

that additional terms appear in both equations which

are due to form-induced stresses, form drag and vis

cous drag on the bed. The form induced stresses

⟨u˜ i u˜ j ⟩ appear in both (3) and (5) as a consequence

of the spatial averaging like turbulent stresses appear

in the Reynolds equations, i.e. form induced stresses

⟨u˜ i u˜ j ⟩ are due to spatial disturbances in time averaged

flow. The form drag 1/ρ ⟨∂p˜/∂x i ⟩ and the viscous drag

ν ⟨∂ 2 u˜ i /∂x 2 j ⟩ appear only in the flow region below the

roughness crests. This flow region is highly depen

dent on roughness geometry as demonstrated by the

parameter A=A f /A 0 in (5) and (6). A is important if

the roughness elements change their density and cross

sections with coordinates, it disappears if they do not

(Nikora et al. 2001).

The spatially averaged Reynolds-equations (3)–(6)

may be simplified for the case of turbulent two dimen

sional, steady, uniform flow over a rough bed with a

flat water surface. For a stable, static bed for which the

roughness geometry function depends only the vertical

coordinate z (3) reduces to:

and (5) reduces to: In the above equations S b ≈ sin α (α= slope angle) is the slope of the averaged bed which is equal to the water surface slope (uniform flow). Equations (7a) and (8a) are for the longitudinal velocity component while (8b) and (9b) are for the vertical one. Due to 2D-flow conditions, equations for the transverse velocity component disappear. The derivation of the vertical distribution of the spatially averaged pressure and the spatially averaged stress distribution are found in Nikora et al. (2001). 2.2 Roughness geometry function A The foregoing derivation of the spatially averaged momentum equations shows the importance of the roughness geometry function A. From the definition A=A f /A 0 it follows that A= 1 for the region above the roughness crests (A f =A 0). On the other hand, for an impermeable bed A→ 0 (A f → 0) for z→ z t . These two values bound the roughness geometry function, i.e. 0<A(z)≤ 1. For a rough permeable bed the function A corresponds to the porosity coefficient of the granular material in the subsurface layer with ∂A/∂z= 0 (z< z t). For z t < z≤ z c , A is strongly dependent on bed

topography, i.e. grain-size distribution of the surface material and surface geometry are important factors. Further properties of the roughness geometry function are discussed in detail by Nikora et al. (2001). 2.3 Velocity distribution Based on (7a)-(8b), Nikora et al. (2001, 2003) derived velocity distributions for spatially averaged flows. Here we focus on equations for the velocity distribution over rough permeable beds. For such beds the position of the reference bed (or zero-plane) is of fundamental importance and the displaced vertical coordinate Z = z- d p instead of z should be considered (for a review of d p see Koll 2002 and Nikora et al. 2002). For rough impermeable beds, the reference level may be defined at z t where $\langle \bar{u} \rangle = 0$ and $\tau = \tau_0$. However, in general A(z t) is nonzero for permeable beds and the position of the reference bed may be higher (Nikora et al. 2001). Formulations for velocity distributions based on (7a)-(8b) dependent on the relative submergence and the flow regime are described in detail in Nikora et al. (2001, 2003). For flows with large relative submergence Nikora et al.

(2001) described a simple layer model similar to

the layer model described in the introduction. The

model includes an outer layer, a logarithmic layer and

a roughness layer with linear velocity distribution.

Linear flow velocity distributions for small relative

submergence have been observed by O'Loughlin &

Annambhotla (1969), Nakagawa et al. (1988), Dittrich

et al. (1996), Nikora et al. (2001) and Koll (2002).

Further possible velocity distributions in the rough

ness layer are discussed by Nikora et al. (2003). We

note that analytical or numerical solutions of (7a)-(8b)

require parameterization of the spatially averaged tur

bulent stresses- $\langle u' w' \rangle$, form-induced stresses- $\langle \tilde{u}\tilde{w} \rangle$

and the form drag $1/\rho \langle \partial \tilde{p}/\partial x \rangle$. Such data is not yet

available and our experiments described in section 3 are specially designed to develop physically based parameters.

3 EXPERIMENTAL METHOD

In this paper we present preliminary data from experiments carried out in a 20 m long, 0.90 wide and 0.60 m high tilting flume in the laboratory of the Leichtweiss Institute for hydraulic engineering, Braunschweig Technical University. The experiments were carried out with a constant flume slope of S = 0.0027.The discharge Q was adjusted by a valve and measured by an inductive flow meter. Eight piezometers were installed in the flume (Δx= 1.00 m) and the water surface slope was calculated from linear regression.

A coarse sediment mixture (0.63 mm< d < 64 mm, d 50 = 5 mm, see figure 12 for grain-size distribution) was used as movable bed material for the development of water worked roughness structures. At the first step of an experiment, the well mixed sediment was placed in the flume over a length of 13.40 m and flattened to a thickness of 0.20 m to ensure that the bed slope is parallel to the flume slope. The distance from the flow straightener to the sediment bed was 1.00 m and the gap between was bridged with bricks to avoid extensive scouring at the inlet. At the downstream end the

sediment body was stabilized by a 20 cm high sill. The sill was constructed of perforated metal to enable flow in the subsurface layer.

The surface was allowed to armor and a degree of bed stability was established for a given discharge Q 1 . When the transport rate was negligible the discharge was reduced to zero and photographs of the armor layer were taken and analyzed by applying a line by num ber method. The correction method of Fehr (1987) was used to enable a comparison of the results with volumetric samples.

The bed topography was measured along the 1.00 m long and 0.72 m wide test section with a laser dis placement meter. The test section was located 8 m from the transition bricks-sediment. The width of the y z x Figure 2. Flume and bed structure after an applied discharge of Q= 180 l/s. 0 5 10 15 20 25 0 200 400 600 800 1000 1200 1400 1600 Station [cm] H e i g h t a b o v e r e f e r e n c e l e v e l [c m] Flume bottom Initial bed surface Surface after Q = 210 l/s Surface after Q = 260 l/s Location of measuring section Figure 3a. Development of bed level for discharges of 210 l/s and 260 l/s. test section was smaller than the total flume width to reduce side wall effects on the measurements. Longitudinal bed profiles were recorded with a sampling interval of Δx= 1.0 mm and a lateral spacing of Δy= 4 mm. In total 180 longitudinal profiles were recorded.The precision of the laser probe was 0.06 mm in the z-direction and 0.05 mm in the x-direction. An additional survey was carried out by levelling the bed along its total length in the centerline with increments ofΔx= 10 cm.These measurements were used to estimate bed-slope. Figure 2 shows the flume and the bed structure after a discharge of Q= 180 l/s. After surveying the bed topography the bed forming discharge Q 1 was increased for the next step to a value Q 2 (>Q 1), so that the existing armor layer was destroyed and a new one developed. The

above measurements were repeated and the procedure continued as long as the stream could stabilize itself without a considerable loss of slope or the sediment was eroded to the flume-bottom. The development of bed level during an experiment is shown in figure 3a for two discharges of Q= 210 l/s and Q= 260 l/s. Note that Q= 260 l/s corresponds to the discharge, for which the maximum bed stability was obtained. Figure 3a shows

Figure 3b. Location of the positions of the randomly dis

tributed ADV-velocity profiles (indicated by black dots)

over the surface in the test section. Surface topography was

recorded with a Laser-displacement meter.

that the scour at the upstream end of the sediment

body and the sill at the downstream end of the sed

iment body have no influence on the morphology

in the test section. The bed slope remains approxi

mately constant and parallel to the flume slope during

the course of the experiment. In the test section,

a large number of velocity profiles are recorded

to ensure the applicability of the double averaged

equations.

Acoustic Doppler Velocimeter (ADV) measure

ments were carried out at a discharge of 180 l/s. ADV

measurements provide instantaneous 3D velocities

that makes it possible to obtain various turbulence

parameters (Nikora & Goring 1998a, Voulgaris and

Trowbridge 1998). Twenty-six randomly distributed

velocity profiles were recorded in the test section

with a sampling frequency of 25 Hz and with a verti

cal resolution of Δz= 1 cm. The ADV measurements were analyzed using WinADV (Wahl 2000). All pro files are referenced to the coordinate system of the 3D-traverse system, i.e. positions of the vertical pro files in the (x, y)-plane are referenced to topography data (figure 3b). Please note that ADV measurements were performed in planes parallel to the flume slope to simplify the spatial averaging procedure. Spatial data from the laser scan have been used for deter mination of the height of the roughness crests z c (highest measured elevation) and the elevation of the roughness troughs z t (lowest measured elevation) with

z c − z t = 5.3 cm. 4 DATA ANALYSIS ADV measurements are used to discuss differences between time-averaged velocity profiles and turbulence properties with their spatially averaged counterpart. For our analysis we use the transformed vertical coordinate Z = z− z t which allows the definition of an arbitrary reference level for z (e.g. vertical traverse coordinate). 4.1 Velocity distribution Figure 4 shows the time averaged velocity distributions $\bar{u}(z)$ (solid lines) and the double averaged profile (open circles). In the region far from the bed surface, the difference between the time averaged velocities $\bar{u}$ and the spatially averaged velocity is small (±10%). This difference increases in the region close to the bed surface due to irregularities of the rough surface (figure 4) and is responsible for the form induced stresses. Figure 5, in which the ratio of the standard deviation of $\langle\bar{u}\rangle$ and the double averaged velocity $\langle\bar{u}\rangle$ is plotted over depth Z demonstrates the spatial variability of $\bar{u}$ in the region close to the surface (note that the standard deviation of $\langle\bar{u}\rangle$ is calculated from the velocity measurements in the corresponding averaging plane). Thus figure 5 may be used to identify the transition between the roughness layer and the logarithmic layer. In figure 5 the identification of this separation point is straightforward at Z = 6.1 cm. However, this methodology cannot be applied to identify the

separation point for single, solely time-averaged velocity profiles. For such profiles, the separation point must be identified from data-fitting (logarithmic function), turbulence intensities u ′2 , or from Reynolds-stress distribution – u ′ w ′ (see section 4.2). However, as discussed above, each time-averaged profile depends on local boundary conditions and the heterogeneity of the near bed flow field, hence the obtained result may not be representative. Based on figure 5, the spatially averaged flow field can be subdivided in different layers (figure 6). In the roughness layer the velocity distribution can be approximated by a linear distribution followed by a logarithmic layer with increase in Z . For the logarithmic region a squared regression coefficient R 2 ≈ 1 is obtained when fitting the data to a log-function. The same applies to the linear region, although the maximum R 2 value is found for the three points below the roughness crests. Thus it can be concluded that the real value of z R – d is located between 5.1 and 6.1 cm. However, this issue cannot be resolved due to the spatial resolution of the ADV measurements (9 mm high sampling volume). The logarithmic distribution can be used to describe the flow field up to 0.2 h (figure 1). The velocity distribution in the outer layer is similar

With this displacement height the shear velocity can be calculated with $u_* = \sqrt{ghS}$ (with h= z WS - d) to $u_* = 7.8$ cm/s. 4.2 Turbulence characteristics The methodology based on spatially averaged flow variables should also be used in characterizing turbulence properties near rough beds. Figure 7 shows the vertical distribution of timeand spatially averaged turbulence intensities $\langle u'^2 \rangle$, $\langle v'^2 \rangle$, $\langle w'^2 \rangle$, and $-\langle u' w' \rangle$. The mean values of $\langle u'^2 \rangle$, $\langle v'^2 \rangle$, $\langle w'^2 \rangle$ and $-\langle u' w' \rangle$, are largest close to the roughness crests, i.e. approximately at the transition between roughness layer and logarithmic layer (6.1 cm≤Z ≤ 7.1 cm) and reduce below the roughness crests. However, investigating the deviations of the time averaged values from their spatially averaged counterpart reveals that the deviations increase with decrease in Z and that the maximum deviation is obtained below the roughness crests. This is demonstrated in figure 8, in which the vertical distribution of the standard deviation of $\langle u'^2 \rangle$, $\langle v'^2 \rangle$, $\langle w'^2 \rangle$ and $-\langle u' w' \rangle$ in each averaging layer are shown. The increase of the deviations can be interpreted as form induced influences due to effects of local conditions. As an example, the spatial variability of- $u' w'$ is shown in figure 9 at Z = 6.1 cm. The horizontal line in figure 9 indicates the spatially averaged value $-\langle u' w' \rangle$, the squares indicate the obtained Reynolds-stress for each profile. Similar results are obtained for u'^2, v'^2, and w'^2. The form-induced intensities and form-induced Reynolds-stresses can be evaluated using the same procedure as in figure 7 by plotting the vertical distribution of $\langle \tilde{u}^2 \rangle$, $\langle \tilde{v}^2 \rangle$, $\langle \tilde{w}^2 \rangle$ and $-\langle \tilde{u}\tilde{w} \rangle$ (figure 10). As expected, the form induced intensities attain maximum values below the roughness crests and then reduce with 0 5

increase in Z . For large values of Z the form-induced

intensities become negligible compared to their turbu

lent counterparts. However, below the roughness crests

their influence is significant as demonstrated by ⟨u˜ 2 ⟩

(figure 10). Large values of ⟨u˜ 2 ⟩ may be explained as

follows. If some points are measured directly above the

solid boundary, i.e. when the no slip condition is valid

(u¯≈ 0) and all other measuring points are above the solid boundary so that u¯> 0, the difference ⟨u¯⟩ − u¯ is large for points at the boundary.The squared difference amplifies this discrepancy (figure 10).

The form induced stress−⟨u˜w˜⟩ becomes negligible above the roughness crests and becomes comparable (though less) with−⟨u′w′⟩ in the roughness layer (figures 7 and 10). Similar results have been reported by Nikora et al. (2001) for near-bed flow structure for regular spherical segment type of roughness. Further turbulence properties for the flow over artificial beds using the spatial averaging methodology are found in Pokrajac et al. (2003). 0 5 10 15 20 25 30 -4 -2 0 2 4 6 8 10 12 14 Z [c m] 0 5 10 15 20 25 30 0 50 100 150 200 Roughness crests Roughness crests Water surface Water surface Z [c m] u 2 ˜ u 2 ˜ [(cm/s) 2] v 2 ˜ w 2 uw ˜ ˜˜ − [(cm/s) 2] v 2 ˜ w 2 uw ˜ ˜˜ , ,− Figure 10. Average functions A(z) are presented, Z b is bed elevation, Z¯ b is average bed elevation, and σ z is standard deviation of bed elevations. 4.3 Roughness geometry function A(z) The topography data can be used for the determination of the roughness geometry function A which is an essential parameter for the parameterization of (8a) and (8b). Figure 11 shows examples for A for waterworked beds at discharges of 180, 210, 240 and 260 l/s. The estimated averaged functions are comparable to roughness geometry functions shown in Nikora et al. (2001). Figure 11 shows that estimated values of A range from 0<A(z)≤ 1. We note that A= 0 corresponds to impermeable beds and the laser scan of the surface does not include measurements of the pore volume

nor potential free space below large stones lying on the bed. Hence A= 0 is the result for laser data although we estimated A min = 0.28 for the bed material (porosity). This discrepancy shows that a correction 1 10 100 0

method for the calculation of the roughness geometry

function has to be developed.

The roughness geometry function itself depends on

surface geometry and grain size distribution of the

armor layer and subsurface layer. Figure 12 shows the

development of the grain-size distribution of the armor layer for discharges of 180, 210, 240, and 260 l/s and the grain-size distribution of the armor layer showing maximum bed stability according to the method of Günter (1971). The grain-size distribution for the layer with maximum bed stability according to Günter (1971) is similar to the estimated grain-size distribution after Q= 260 l/s. We note that after a further increase of discharge to Q= 290 l/s the bed could not stabilize itself, indicating the applicability of Günter's (1971) approach. Investigating armor layer development according to our experimental setup (step-wise increase of discharge) will provide further insight into relevant processes. Furthermore, linking statistical parameters obtained from topography data (e.g. Nikora et al. 1998b, Aberle 2000 and Aberle & Smart 2003) with grainsize distribution will enhance our understanding of water worked roughness structures and their effect on the flow field based on the spatially averaged equations.

5 CONCLUSION

In this paper we suggested that the double-averaged momentum equations should be used for the description of the flow field over rough surfaces. The difference between the Reynolds-equations and the doubled

averaged equations were shown using ADV data. The main advantages of the double averaging methodology (temporaland spatially averaging of the Navier

The numerical simulation of time dependent flow structures over water worked gravel

R.J. Hardy & S.N. Lane

School of Geography, University of Leeds, Leeds, UK

ABSTRACT: Our ability to numerically predict the interaction between time dependent fluid flow structures and complex topography has yet to be fully developed. This is largely the result of the problems of designing numerically stable meshes for use with complex topographies and that Reynolds averaged turbulence schemes are typically applied. This paper deals with the numerical simulation of time dependent flows over a water worked gravel. This is achieved by the development of a porosity algorithm for representing complex surface topography in a Cartesian framework and the application of Large Eddy Simulation. The numerical simulations reported in this paper show that there are two distinct scales of boundary influence upon the shallow flow and emphasizes that the measured flow variability at any one point in a natural river will contain both locally derived and upstream inherited flow structures, according to the range of scales of topography present.

1 INTRODUCTION

Research undertaken over the last few years has demonstrated the importance of the structure of gravel river beds for understanding the interaction between fluid flow and sediment transport processes. This includes the observation of periodic high-speed fluid wedges interconnected by low-speed flow regions. These, potentially, have a considerable effect on the shear stress acting on the bed which may initiate sed iment transport. Our understanding of these flows has been enhanced significantly through a series of laboratory experiments and supported by field observations. However, the potential of high resolu tion three-dimensional Computational Fluid Dynam ics (CFD) modelling has yet to be fully developed. Although, there has been an increased applications of three-dimensional computational fluid dynamic (CFD) codes to study natural gravel bed river channels, they have normally been applied at the spatial resolu tion of a single geomorphological unit, such as river confluences (Bradbrook et al., 1998, 2000a,b, 2001; Lane et al., 1999, 2000) or a meander bend (Hodskin son & Ferguson, 1998; Ferguson et al., 2003). To date, no study has considered flow over a gravel bed surface where flow around each individual gravel particle is

modelled. This is largely the result of the problem of designing a numerically stable mesh for use with such complex topographies.

Furthermore, for the majority of CFD applications, turbulence closure is generally achieved by applying a Reynolds averaged turbulence scheme. This by definition provides a time averaged solution and thus prevents the numerical simulation of the dynamic fluid wedges discussed above. In order to gain further insight into the dynamics of the fluid wedges, one potential research avenue is the application of Large Eddy Simulation (LES). LES provides an intermediate case between Direct Numerical Simulation (DNS) and Reynolds averaging (RANS) approaches. While DNS deals with all eddies larger than the smallest (dissipation) scale and RANS methods deal with the mean flow characteristics, LES provides an intermediate solution where the properties of all eddies larger than the grid size are calculated and those smaller than this scale modelled by a sub-grid scale (SGS) turbulence transport model. Thus, LES attempts to compute the large scale motion, which is thought to contain most of the variation and momentum (Rogallo & Moin, 1984). In this paper we present a methodology that is; (i) able to represent complex heterogeneous gravel surfaces in a Cartesian mesh and (ii) provides a numerical framework for the application of LES simulation over complex surfaces. First, we discuss the numerical framework that allows the topography to be included in Cartesian space. This is followed by the validation of the porosity algorithm over a water worked gravel surface for a Reynolds averaged scheme. Finally we demonstrate the potential of this scheme for LES and the numerical prediction of coherent flow structures over gravel surfaces.

2 REPRESENTATION OF TOPOGRAPHY IN 3D CFD SCHEMES

The incorporation of complex topographies within a CFD scheme has been problematic to date as the representation of the large scale topographic features has required the application of boundary fitted

co-ordinates (BFC's), which involve mesh deforma
tion in the Cartesian space (if not in the computational
space) (Figure 1).

Mesh deformation may change the magnitude of
numerical diffusion in the model and lead to uncer
tainties as to whether observed changes in process
representation are due to topographic effects or grid
adjustment effects. Secondly, the sub-grid scale topog
raphy (e.g. grain surface morphology, grain interac
tions) within the CFD scheme has to be represented
using a roughness parameter (e.g. Hodskinson &
Ferguson, 1998; Nicholas & Smith, 1999; Lane et al.,
1999) which represents the frictional retardation of the
flow at the bed. Thus, the effects of sub-grid scale
topography are represented as frictional retardation of
the flow at the bed. This is normally based upon a
standard 'law of the wall':

where u ∗ is the shear velocity= √ τ b /ρ, κ is the Von
Karman constant (= 0.4), τ b is the bed shear stress, ρ
is the fluid density and z o is the height of zero velocity,
which depends on the bed roughness. Bed roughness
may be defined from the following:

where ν is the kinematic viscosity and k s is
the equivalent sand roughness following Nikuradse
(1933).

Whilst there are significant concerns over turbu

lence parameterization in these near wall treatments,

research has demonstrated that, in natural river chan

nels with gravelly beds, much greater uncertainty is

introduced into predictions of the three-dimensional

velocity field due to poor knowledge and treatment of

topographic variability than is introduced by uncer

tainty over turbulence treatments at the wall (Lane

et al., 1999).The basic principle adopted for represent

ing topographic variability involves the multiplication

upwards of the equivalent sand grain roughness (k s).

In a 3D modelling framework, this assumes that the

topographic variability that is not included in the

model geometry is represented as a sub-grid scale Figure 1. The application of boundary fitted co-ordinates to complex topography. effect through upscaling. Much of this uncertainty relates to debate over which grain parameter to upscale and by how much. For instance, field investigations suggest that z o should, including upscaling, take a value of approximately 0.1D 84 (Whiting & Dietrich, 1990; Wiberg & Smith, 1991). Others, specifying it as k s (noting k s = 30z o), have suggested approximately 3.5D 84 or 6.8D 50 (Hey, 1979; Bray, 1982). Clifford et al., (1992) show that multiplication of roughness length represents a measure of total flow resistance that incorporates contributions from both individual grains and larger bed forms. These uncertainties aside, the z o approach is associated with a number of problems. These include; (i) a wide range of grain percentiles have been adopted. Whilst there is a general preference for the D 84 (e.g. Whiting & Dietrich, 1990; Wiberg & Smith, 1991) the most appropriate percentile may depend upon the size and sorting of the gravel mix; (ii) the multiplier of roughness length will need to be spatially variable and scale dependent, in relation to both mesh resolution and the topographic content of the data set used to describe the surface; (iii) some studies have noted problems in terms of numerical stability and solution

accuracy for flows characterized by high relative roughness (e.g. Nicholas & Smith, 1999) with these difficulties resulting from the existence of an upper limit of k s for a given near-bed cell thickness (Nicholas, 2001) and (iv) there is the basic problem of setting the reference height of the bed in a numerical mesh: normally, it is assumed implicitly that the effective bed surface in mass conservation terms is the same as the bed surface sampled during field survey.

3 LARGE EDDY SIMULATION TURBULENCE CLOSURE

As discussed above LES can be viewed as a com

promise between DNS and RANS approaches. The

fundamentally important aspect of LES is that it cal

culates the properties of all eddies larger than the grid

size and models those smaller than this scale by a

sub-grid scale (SGS) turbulence transport model. A

cut-off point must be drawn in the spectrum of tur

bulent scales, and in the Smagorinsky sub-grid scale

(SGS) model used in this research, it is based on the

average local grid spacing. Thus, eddies capable of

being resolved by the computational grid are allowed

to evolve according to the Navier Stokes equations

and a turbulence model (Smagorinsky, 1963) is only

employed to represent the effects of turbulence at

sub-grid scales (SGS).The mixing length, l, is the char

acteristic length of the unresolved eddies, defined as:

l-min(C s h,κ.d wall) where C s is the Smagorinsky con

stant (0.17), κ is the von Karman constant (0.41) d wall

is the normal distance to the nearest wall and h is the

representative mesh interval:

where ∂x, ∂y, ∂z are the local mesh dimensions in the three co-ordinate directions.Therefore, grid resolution should be sufficient that the scales of interest. Obvi ously with this formulation, an anistropic mesh will cause the ambiguity in the definition of the SGS length scales, and therefore the mesh shown in Figure 1 will not provide a satisfactory spatial discretization for a LES closure.

Therefore, a development is required where Carte sian meshes can be used where complex topography can be represented both for fast and efficient numerical solution which are numerically stable both for RANS and LES closure turbulence schemes. An approach which fulfils this criteria is outlined below.

4 NUMERICAL SCHEME AND EXPERIMENTAL DESIGN

The numerical scheme involves a finite volume solu tion of the full three-dimensional Navier-Stokes equa tions in a Cartesian co-ordinate system. The initial simulations use a Renormalised Group theory (RNG) κ-ε turbulence models. These results are used as initial conditions for the LES simulations where a standard Smagorinsky sub-grid model was applied. The LES simulations are run at a frequency of 10 Hz for 102.4 seconds. 4.1 Porosity treatment and modification of drag terms Recent research (Lane & Hardy, 2002; Lane et al.,

2002; Lane et al., 2004; Hardy et al., in review) has developed a method for incorporating complex river-bed topographies into regular structured meshes, without the need to use boundary fitted co-ordinates. It uses a porosity based method based upon that identified by Olsen & Stokseth (1995). This involves the use of regular structured grids, in which all control volumes are orthogonal, in both computational and Cartesian space, with the bed topography specified using cell porosities (P); P= 1 for cells that are all water; P= 0 for cells that are all bed; and 0<P< 1 for partly blocked cells. Hardy et al. (in review) have developed the Olsen & Stokseth method to address issues that were not resolved in the original Olsen & Stokseth study, notably through the inclusion of relevant drag terms (e.g. Wen et al., 1998) in the momentum equations in combination with the porosity treatment. The only modification to the momentum equations is a scaling of the drag term derived from the law-of-the-wall to represent the effective exposed area of the surface. With a first approximation of flow direction, the drag exerted by a given cell is augmented according to the change in porosity in the flow direction, and is achieved by the up-scaling of z o . The scaling is based upon the effective (equivalent) surface area and all drag is assumed to be exerted along the base of cells, other than for the side walls of the channel. A surface is then fitted to the 3 × 3 matrix of elevations centered on cell for the four surrounding cells into which the flow is entering. The scaling factor (s ij) is then applied to the roughness height in the wall function using. This approach has been successfully validated upon digital particle image velocimetry (DPIV) as applied to a complex but regular, cuboidal surface and (Hardy et al., in review) and for the case of flow over rough gravel beds (Lane et al., 2004). The flow over rough gravel bed is reviewed later. The development of this method has allowed an understanding of the way in which a complex gravel-bed surface interacts with the associated flow field and provides the opportunity for understanding the interaction between gravel-bed topography and the associated 3D flow field. The second advantage of this scheme is that it maintains a constant filter length throughout the domain and allows LES simulations to be undertaken. 4.2 Boundary conditions Boundary conditions were specified at the upstream inlet and downstream outlet, at the side walls and at the free surface. The upstream inlet is specified from experimental data (see below) and the downstream outlet is specified as a fully developed flow profile with the hydrostatic pressure set at the surface at the

downstream outlet. At the free surface, the method applied by Bradbrook et al. (2000) has been adopted, which uses a symmetry plane at the surface across which all normal resolutes are set to zero. The bed was represented by the porosity algorithm while no-slip conditions were specified at the walls. The standard RNG theory k-ε turbulence model is not modified at the side-walls or the bed and the equilibrium wall func tion is used. The time averaged simulations are used for the initial conditions for the LES simulation. In this application we use the standard Smagorinski sub-grid scale model.

4.3 Numerical solution

The numerical scheme solves the full three dimensional Navier-Stokes equations discretised using a finite-volume method. The interpolation scheme used is hybrid-upwind, where upwind differences are used in high convection areas (Peclet number >2) and central differences are used where diffusion dominates (Peclet number <2). Although this scheme can suffer from numerical diffusion, it is very stable. The pres sure and momentum equations are coupled by applying SIMPLEST, a variation on the SIMPLE algorithm of Patankar & Spalding (1972). This convergence can proceed either smoothly or with damped oscillations to

the final solution. To achieve relaxation either: (i) real
istic maximum and minimum values may be imposed
on the solution; or (ii) relaxation may be used to limit
the amount of change allowed in any variable at a
given iteration. Weak linear relaxation was used for the
pressure correction, while weak false time step relax
ation was used for the other variables.The convergence
criterion was set such that the residuals of mass and
momentum flux were reduced to 0.1% of the inlet flux.

4.4 Experimental design: laboratory

The experimental geometry used for model develop
ment and validation is based on water worked gravels.
A bulk sample of sediment from the River Affric,
Scotland was placed in the flume and water worked
until a stable bed (no sediment transport) with a realis
tic structure (Butler et al., 2001) was obtained. Table 1
described the hydraulic conditions.

Once the gravels had been water worked, the surface
morphology was measured using two media digital
photogrammetry (see Butler et al. (2002) for full
explanation). The experimental set-up allowed gener
ation of DEMs at a spacing of 0.001 m. These DEMs
have been subject to intensive data quality tests, in
terms of point precision and accuracy and surface pre
cision and accuracy (e.g. Butler et al., 1998, 2001,

2002). For the topography had a mean surface error

was 0.0008 m and the standard deviation of error

was ±0.0017 m. For the computational experiment a domain was constructed which was regular in the x, y and z directions, with a grid resolution of 0.002 m. The topographic data was transformed into porosity data. An Acoustic Doppler Velocimeter (ADV) measuring 0.01 m intervals above the bed was used to set the inlet conditions and to obtain validation data. Data were collected at 25 Hz for 120 s and subject to basic screening following Lane et al., (1998). 4.5 Model geometry and boundary conditions For the purpose of these experiments, a 0.7 m long and 0.2 m wide section of river gravel was used to define the bed geometry. The computational domain was regular in the x, y and z directions, with a grid resolution of 0.002 m. In the z direction, to allow inclusion of topography data using the porosity treatment, the maximum extent of the domain was set at 0.24 m. Thus, the computational grid was sized at 350× 110× 120 (4 620 000 grid cells).Although validation data did not exist two other domains were constructed identical to the 24 cm domain except that the height of the domain was decreased to 12 cm and 6 cm. This was undertaken in order to asses the effect of flow depth of flow structure generation. The inlet boundary conditions were scaled appropriately. 4.6 Model validation Model validation used an automated correspondence algorithm to match ADV measurement locations to corresponding grid cell locations. The size of the model grid cells was 0.002 m by 0.002 m by 0.002 m. The ADV measures in a 0.08 m diameter cylindrical sampling volume, with a height of 0.010 m. Thus, it determines a spatially-averaged velocity that corresponds approximately to 5 by 5 by 4 grid cells. In the presence of strong shear in the flow, this opens up the possibility of high velocity variability in model predictions that will not be captured in the ADV measurements. Thus, the average, standard deviation and range of model predictions corresponding to each ADV measurement location were determined. Table 1. Basic hydraulic data for the flume experiment. 5 RESULTS

5.1 Validation of the porosity scheme against flume data

Figure 2 shows a comparison of vertical variation of the downstream variation of velocity above the bed for a velocity profiles taken from an ADV location within the computational domain. The results are extremely encouraging. First, and most importantly as compared with previous experiments (e.g. Nicholas, 2001), the model is especially effective at predicting strong shear, generally between 0.1 and 0.2 z/h above the bed. Although this study differs from Nicholas (2001) in that we do not ensemble model predictions and field data, but consider velocity profiles at specific locations, Nicholas (2001) found that a wall function approach failed to reproduce the shear because: (1) the necessary roughness height required excessively coarse mesh sizes at the bed, reducing resolution of the variation of velocity with elevation above the bed; and (2) the wall function does not represent the larger clasts that protrude into the flow. The porosity approach deals with both of these problems in that it allows application of the wall function to be restricted to grain-scale roughness, permitting much finer grid cells at the bed. When coupled to the specification of the bed using high resolution digital photogrammetry, it also allows representation of the influence of downstream variation in elevation asso

ciated with protruding clasts, and hence reproduces

both situations where high velocities extend to the bed

at the top of protruding clasts and where there is flow

separation, both upstream and downstream of large

particles. Comparison of model predictions with the

CFD with smooth bed experiments (c.f. Bradbrook et al.,
1998). 5.2 Time dependent flow fields over gravel surfaces
The results presented below have been simulated a frequency
of 10 Hz for 102.4 seconds. The only boundary conditions
difference to the RNG simulations is that cyclic boundary
conditions are used. Figure 3 shows a series of w-component
velocity plots for the centre line for the 0.12 m
simulation. Each image is spaced 1 second apart, with the
lighter colour representing positive upwards and darker
regions representing the negative downwards velocity. In
Figure 3a-d positive upward flow can be observed as the
flow interacts with the first large clast (x/l= 0.27) and
shows similarities to classic junction vortex flow.
However, after this object the periodic nature of the flow
is observed with both positive and negative flow Figure 3.

oscillating over high topographic features. For example in the deepening section of the flow (x/l= 0.8) a periodicity between positive and negative flow can be observed at a region of potential uplift. In this type of environment, and would be predicted by a RANS closure model, would be a region of uplift. However, the application of LES enables the prediction of these time dependent structures which appear to be very similar to the fluid wedges which have previously been observed in gravel bed rivers. Although this is qualitative visual validation, the initial results are encouraging in that we are simulating naturally occurring flow structures.

Figure 4 plots the correlation between downstream (u ′) and vertical (w ′) velocity deviations against dimensionless distance down the centre line of the model simulations for four dimensionless elevations above the bed. This has a notable pattern: up to x/l= 0.21, the strength of correlation increases with elevation above the bed. At x/l= 0.27, the correlations have similar values, in the range-0.28 to-0.36.

Between x/l= 0.27 and x/l= 0.61, the patterns are reversed, with very strong negative correlations near the bed, and much weaker correlations higher in the flow. This pattern reverses at x/l= 0.61, with the exception of data at x/l= 0.70. Figure 3 also shows how these changes are related to large-scale bed ele vation. The first three locations (to x/l= 0.27) are in a zone of flow shallowing, with stronger correlations higher in the flow.The three locations that follow (up to and including x/l= 0.50) have stronger correlations at the bed and correspond to a zone of generally shallow flow. The flow then deepens and the highest correlations are found higher in the flow. The exceptional point (x/l= 0.70) is associated with a single clast high point within this deepening zone and, again, this local flow shallowing produces highest correlations close to the bed. This implies that in the shallow flow studied here, the nature of the flow structure is strongly forced by flow shallowing and flow deepening. This leads to the detection on coherent flow structures in the deeper regions. Figure 5 shows how these correlations are linked to changes in the percentage of events found in each quadrant. We have used the standard definition of quadrants: i.e. quadrant one= outward motions; quadrant two= ejection; quadrant three= inward motions; and quadrant four= sweeps.As expected in a turbulent boundary layer, quadrant two (ejection) and quadrant four (sweep) events. Close to the bed (h/z= 0.2, Figure 5a) up until x/l= 0.27, the distribution of events is relatively similar, with quadrant two (ejection) and four (sweep) events weakly dominant. From x/l= 0.21, the percentage of quadrant two (ejection) and four (sweep) events increases, with them strongly dominant from x/l= 0.46, initially in quadrant 2 (ejection), and later in quadrant 4 (sweeps). As with the correlation, there is a switch back at x/l= 0.61, with the exception of data at x/l= 0.70. This is mirrored, but to a lesser degree, at h/z= 0.4 (Figure 4b). Higher in the flow (at h/z= 0.6 and h/z= 0.8, Figures 5c and 5d) the percentage of events in each quadrant is, in relative terms, more constant, with quadrant two (ejection) and four (sweep) weakly events

dominant throughout. Thus the correlation patterns shown in Figure 4 are related to a near-bed strengthening in the contribution of sweeps and ejections in shallowing flows: as the flow shallows, ejection events become dominant at the bed. Once the shallowest parts of the flow are reached, there is a transition from ejection events to sweep events becoming dominant. As the flow deepens the dominance of ejections and sweeps is reduced, except for localized points where individual clasts are found, and where ejections and sweeps are more dominant at the bed. Figure 6 shows example time-series for a 5 second period for a zone of flow shallowing (Figure 6a) and a zone of flow deepening (Figure 6b). From x/l= 0.21 to x/l= 0.27, the flow shallows, and the result is a reduction in the magnitude of vertical velocity fluctuations, coupled to stretching of the cyclicity in those fluctuations. At x/l= 0.21 (Figure 5a), flows closer to the surface (h/z= 0.8) lead flows at the bed. By x/l= 0.27, this lead is diminished, and the fluctuations are more synchronous as well as being of smaller magnitude. This probably reflects the growing influence of the bed as the flow shallows, with resistance having a greater effect closer to the bed, and fluctuations in velocity from upstream travelling slower 0 5 10 15 20 25 30 35 40 45 50 0 0.2 0.4 0.6 0.8 1 Distance (x/l) % Q1, h/z = 0.8 % Q4, h/z = 0.8 % Q3, h/z = 0.8 % Q2, h/z = 0.8 P e r c e n t a g e o f e v e n t s (d) 10 5 0 15 20 25 30 35 40 45 50 0 0.2 0.4 0.6 0.8 1 Distance (x/l) P e r c e n t a g e o f e v e n t s % Q1, h/z = 0.6 % Q4, h/z = 0.6 % Q3, h/z = 0.6 % Q2, h/z = 0.6 (c) 0 0.2 0.4 0.6 0.8 1 Distance (x/l) % Q1, h/z = 0.4 % Q4, h/z = 0.4 % Q3, h/z = 0.4 % Q2, h/z = 0.4

(a)

Figure 5. The percentage of events found in each quadrant downstream.

at the bed. As the bed shallows, the effects of resis

tance are more strongly felt throughout the flow, and

the fluctuations are more synchronous, and reduced in

magnitude. As the flow deepens (Figure 6b), the fluc

tuations are more variable in terms of magnitude and

time-scale and, as a result, less organized.

The level of organization is greater as the flow starts

to deepen (x/l= 0.50) than when it becomes deeper

(x/l= 0.61), with flow at the bed weakly leading flow

at the surface. As the flow enters the deeper zone,

the reverse of flow shallowing occurs, with the mag

nitude of fluctuations increasing and their time (and

length-scales) decreasing. However, these changes are

considerably less coherent than in the flow shallowing zone and this is associated with large-scale separation downstream from the region of very shallow flow (i.e. high bed elevations) such that flow re-circulation effects (including eddy shedding) are superimposed upon the effects of bed resistance upon flow structures. At elevations h/z= 0.4 and h/z= 0.6, the increase in magnitude of fluctuations can be greater and the compression can be greater. This is probably the zone of maximum influence from the eddy shedding process, and this results in highly irregular, variable magnitude and quite complex flow. In time-averaged measurements or models, this would correspond to the zone of maximum turbulent stresses where the main flow connects with the separation zone.

6 DISCUSSION

This paper has presented a new methodology which

enables the inclusion of complex topography within

a Cartesian framework. Furthermore, the numerical

algorithm provides the framework for the application

of LES over these gravel surfaces. In substantive terms,

the numerical simulations reported in this paper show

that there are two distinct scales of boundary influ

ence upon the shallow flow studied here. The first

is the large-scale, associated with clusters of parti

cles, that cause undulations in the bed surface. This

leads to water depth variation which, in turn results

in changes in the time (and length-scales) and mag

nitudes of the associated turbulence. In particular,

shallowing leads to a reduction in time (and length scales), but more coherent patterns throughout the flow depth. Deepening is much more complex, as the reduc ing boundary influence can also lead to near bed flow separation, which is superimposed upon the flow struc tures inherited from upstream.The second scale relates to processes associated with especially large or iso lated clasts which result in similar processes, but over a smaller length-scale. This emphasises that the mea sured flow variability at any one point in a natural river will contain both locally derived plus upstream inher ited flow structures, according to the range of scales of topography present.This will have significant implica tions for local derivations of bed shear stress. However, the modelling method developed herein opens up exciting possibilities for exploring this effect and using it to develop new methods for parameterising shear stress in sediment transport models.

Numerical simulation on development process of dunes and flow resistance

S. Onda

Graduate School of Civil Engineering, Kyoto University,
Kyoto, Japan

T. Hosoda

Dept. of Urban Management, Kyoto University, Kyoto, Japan

ABSTRACT: Flow resistance in rivers changes with development or attenuation of sand waves. Therefore, it is necessary to know how the flow resistance varies with transformation of sand bed in order to predict the water surface profiles. In this study, the numerical model to reproduce the formation processes of dunes and flow resistance was developed. A depth averaged flow model considering the effects of vertical acceleration and a non-equilibrium sediment transport model are combined. The calculated results on the temporal development processes of dunes, the shape characteristics and flow resistance are compared with previous experimental and theoretical studies.

1 INTRODUCTION

Over erodible bed, various sand waves are formed in response to hydraulic conditions and flow resistance changes with their development or attenuation. Predic tion of resistance law is important in river engineering and it is necessary to know how the flow resistance varies with transformation of dunes. So far, a number of experimental and theoretical studies on the forma tion processes of dunes and flow resistance have been carried out.

As one of the experimental studies on development processes of dunes, Nakagawa & Tsujimoto (1976,

1983) investigated the temporal variations of sand wave spectrum. It was pointed out that in evolution processes of dunes the spectrum peak formed in the generation process moves to lower wave number side with sand waves developed and that in equilibrium state the sand wave spectrum can be expressed as-3 power law. Engelund (1952) introduced the similarity assumption of the friction and explained that the grain shear stress is a function of the total bed shear stress in flows with same bed configurations. Comparing with other experiments, he derived the relationship between the grain and the total bed shear stress. Kishi & Kuroki (1972) showed that the grain shear stress is a function of the relative depth as well as the total bed shear stress and derived the resistance law for different bed configurations by modifying Engelund's theory.

On the other hand, Hosoda et al. (2002) developed the numerical model to reproduce the formation processes of dunes, incorporating the depth averaged flow model considering the effects of vertical acceleration and the non-equilibrium sediment transport model. However, flow resistance such as increase of the depth in development processes of dunes could not be reproduced. In this paper, the numerical model, which can also evaluate the flow resistance, is developed, applying the depth averaged flow model by Hosoda et al. The depth averaged flow model has advantages of simulating flows over the sand waves from a practical point of view. The formation processes of micro-scale sand waves such as dunes and antidunes are simulated and the calculated results on

the temporal development processes of dunes, shape characteristics and flow resistance are compared with previous experimental and theoretical studies. 2 BASIC EQUATIONS A depth averaged flow model considering the effects of vertical acceleration is applied to calculate the flow fields. The coordinate system and the hydraulic variables are illustrated in Figure 1. x U y h y b u

Figure 1. Explanation of symbols.

where x: spatial coordinate, h: depth, y b : bed elevation

from x-axis, q: flow discharge per unit width, U : depth

averaged velocity, τ bx : x component of bottom shear

stress, g: gravity acceleration, θ: bed slope, ρ: density

of water and α: coefficient of eddy viscosity (=0.05).

Equation (2) is used to evaluate the bottom shear

stress correctly in which the local velocity distribution

obtained by potential flow analysis and the accelerat

ing/decelerating effect near a bed are included (Hosoda

el al. 1997).

As the bed variation model, the non-equilibrium sedi

ment transport model is applied.

eter, λ: porosity of sand bed and A 2 , A 3 : shape coef

ficients of sand grain for two and three dimensional

geometrical properties, respectively (=π/4,π/6).

The pick-up rate p s is evaluated by equation (4)

proposed by Nakagawa & Tsujimoto (1980) and the

deposit rate p d is calculated combining the pick-up

rate and the probability density distribution function

of step length.

where σ: density of sand, τ ∗ : non-dimensional tractive

force, !: step length, s: distance from a point where a

sand particle is picked up. 3 NUMERICAL METHOD The numerical method Hosoda et al. (1994, 2002) used for simulating the undular bore and the flows over dunes is applied to calculate the water surface profiles. However, the flow resistance cannot be reproduced in their numerical results since the pressure distribution is assumed to be hydrostatics in case the depth gradient is greater than a standard value. To refine this aspect, the vertical acceleration terms of the basic equation are multiplied by the attenuation function locally in case the depth gradient is greater than the standard value. The procedures for calculating the water surface profiles are described as follows. (i) Each derivative term of the basic equations is descritized using the finite deference forms. (ii) The depths h k i at k-th step are supposed to be known. Substituting the depths h k i into the finite difference forms of Equation (1), the numerical errors er k i at each grid point are obtained. Using this numerical error and the following equations, the depths h k + 1 i at next step k + 1 are calculated. (iii) The procedure (ii) is iterated until the total error becomes small. (iv) The bed variation is calculated for 2s (t= 0.1s), using equations (3)-(5). Then, the iterative procedure for calculating the water surface profiles is performed. 4 HYDRAULIC CONDITIONS The model flume is shown in Figure 2 and the hydraulic conditions are listed in Table 1. While the flow discharge per unit width q and friction factor f is fixed as 200 (cm 3 /s/cm) and 0.01 respectively, the bed slope and the diameter of sand particles are varied as shown in Table 1. Since three boundary conditions on the depth h and gradient dh/dx are required for calculation of the water surface profiles, the following conditions are used. (1) The depth gradient dh/dx= 0 at upstream end. (2) The depth gradient dh/dx= 0 at downstream end. sand bed fixed bed fixed bed 0.4 m 7.2 m 0.4 m

(3) The depth h= the normal depth at downstream end in case of subcritical flow or the normal depth at upstream end in case of supercritical flow.

In calculation of the bed variations, sediment dis

charge is supplied from upstream fixed bed not to

change the bed elevation sharply between the fixed bed

and the movable bed. The bed elevations of the fixed

bed are made zero after calculating the bed variations.

5 RESULTS AND DISCUSSION

As the example of the numerical results, the temporal

variations of the water surface profiles and the bed ele

vations in RunD3 are shown in Figure 3. It can be seen

that the small disturbance generated from upstream of

the sand bed amplifies and propagates to the down

stream with the wave height developed and increase

of flow resistance is observed.

5.1 Formation processes of dunes

To discuss the formation processes of dunes in detail,

the temporal variations of the sand wave spectrum

in evolution processes of dunes are compared with -2 0 2 4 6 8 10 0 100 200 300 400 500 600 700 800 -2 0 2 4 6 8 10 0 100 200 300 400 500 600 700 800 -2 0 2 4 6 8 10 0 100 200 300 400 500 600 700 800 -2 0 2 4 6 8 10 0 100 200 300 400 500 600 700 800 (cm) y b y s (cm) y b y s (cm) y b y s (cm) y b y s x(cm) x(cm) x(cm) x(cm) (d) t = 18000 (s) (c) t = 5000 (s) (b) t = 3000 (s) (a) t = 1000 (s) Figure 3. As mentioned above, Nakagawa & Tsujimoto (1976, 1983) pointed out that the sharp spectrum peak is observed in initial stage and that the peak moves to the lower wave number side gradually in formation processes and in equilibrium state sand wave spectrum can be expressed as -3 power law. In the initial stage of the numerical results (Figs. 4(a), 5(a)), the spectrum peak is seen remarkably near the wave number $k = 0.1(cm^{-1})$. It is thought that these waves are equivalent to the sand waves with short wave length

(=10 cm) (Fig. 6 (a)) and corresponding to the sand

waves, which fulfill the resonance relation between the

water surface and the bed variation (the Airy relation).

range grows larger and the spectrum peak is gener

ated. This peak is equivalent to the waves with the wave length (L= 40–50 cm) (Fig. 6 (c)). After that it becomes blunt, as the spectrum in low wave number range gets bigger. On development time scale of dunes, Nakagawa & Tsujimoto (1976) reported that evolution of the wave length and wave height is proportional to the square root of non-dimensional time. In the calcu lated results (Fig. 7), it is found that the wave length is developed sharply from the initial stage to the develop ment processes, although the wave height is developed gradually. This is due to difference of development time scale in dunes formed in the initial stage and the formation processes.

In the equilibrium state (Figs. 4(d), 5(d)), the spec trum in the high wave number range can be expressed as −3 power law as pointed out by Nakagawa, Tsujimoto & Hino.

As for the time scale for fully developed sand waves, the numerical results are compared with the equation (7) proposed by Nakagawa & Tsujimoto (1981) (Fig. 8). Real time scale T D of the numerical results is obtained from the time that the wave gradient

is almost equilibrium. 100 1000 10000 10 4 10 5 10 6 10 7 dL dtu ∗ (a) Wave length dtu ∗ 0.1 1 10 100 10 4 10 5 10 6 10 7 dH (b) Wave height dtu ∗ 0.001 0.01 0.1 10 4 10 5 10 6 10 7 LH (c) Wave gradient Figure 7. expressed by equation (9). The numerical results are

in good agreement with equation (7).

5.2 Shape characteristics of dunes

Table 4 shows the averaged wave length and the aver

aged depth, which is obtained by using the numerical

results from x= 3.0 to 6.0 m. Since the wave length of

dunes is said to be five times of the depth in previous

works, the calculated results are almost reproduced.

Figure 9 shows the relation between the wave gradi

ent (δ=H/L) and the non-dimensional tractive force.

It can be seen that the numerical results agree with

equation (8) proposed by Fredsoe (1975) and equation

(9) by Yalin & Karahan (1979).

RunA2.

dunes and the peak is generated in some wave number.

Therefore, it turns out that the sand waves are formed

regularly.

5.4 Comparison of regions for formation of different bed configurations

Figure 12 shows comparison of regions for the forma

tions of different bed configurations. The reference

curves (Fig. 12) show the relationship between Froude 0.0 0.5 1.0 1.5 2.0 0 1 2 3 4 5 kh Fr Eq. (10) Eq. (11) RunD RunA Figure 12. Regions for formation of different bed configurations. number (Fr) and non-dimensional wave number (kh). These curves are expressed by equations (10) and (11) which indicate the minimum Froude number for antidunes and maximum for dunes (10) and the maximum possible Froude number for long-crested features (11), respectively (Kennedy, 1963). The calculated results are in good agreement with the regions described by equations (10) and (11). 5.5 Flow resistance Kishi & Kuroki (1972) developed Engelund’s theory and derived the resistance law for different bed configurations by arranging a large number of

the experimental data. The resistance law (relationship between friction factor and non-dimensional tractive force) for different bed configurations is described as follows:
[Dunes I] [Dunes II] [Transition] [Flat bed] 0 10 20 30 0.01 0.1 1 10 τ ∗

ϕ RunD RunA h/d =100 h/d =200 Eq. (12) Eq. (13) Eq. (14) Eq. (16) Eq. (15) κ = 0.2 Eq. (15) κ = 0.4

Figure 13. Comparison of friction factor.

[Antidunes]

where κ 0 & κ: Karman constant in flows only (= 0.4)

and flows with sediment transport, respectively.

The numerical results are compared with equations

(13)-(16) in Figure 13. As the relative depth h/d in

equations (13)-(16), 100 and 200 is used. Since it

is observed that the calculated results agree with the

resistance law, the numerical model in this study can

evaluate resistance law. In case of transition and flat

bed, further investigations are needed.

6 CONCLUSIONS

In this study the numerical model to predict the for

mation process of dunes and flow resistance was

developed, using the depth averaged flow model con

sidering the effect of vertical acceleration and the non

equilibrium sediment transport model. The numerical

results were compared with the previous experimental

and theoretical studies and it was indicated that this

numerical model can reproduce the formation process

Experimental study of bed-load grain size sorting near

incipient motion

on steep slopes

ABSTRACT: Flume experiments of bed-load transport on steep slopes were carried out using image analysis.

Many sets of experiments were performed, first with uniform materials, and secondly with mixtures of these uni

form materials, in order to assess the grain size sorting effects on bed-load. In each case, bedforms were observed.

Although input of water and sediments was stationary, large fluctuations of solid discharge were observed for

the non uniform material, associated with a varying slope around the equilibrium value.

1 INTRODUCTION

Research on bed-load solid transport and especially

on grain size sorting effects associated with bedforms

still remains an open and challenging issue. Experi

mental research on this topic makes full use of mobile

bed tilting flumes with mixtures of water and natural

sand-gravel material similar to those encountered in

rivers or torrents. In the work presented hereafter, the

toilsome and time-consuming manual sieving method

is replaced by a new technique called GDS using image analysis for measuring the grain size distribution and the solid discharge downstream of the experimental flume (Bigillon et al. 1999, Frey et al. 2003). Various sets of experiments were performed on an equilib rium slope of 9% to assess the grain size sorting effect on bed-load. A first set of experiment was performed using uniform materials and results are compared to non-uniform materials data obtained by mixture of the previous ones. In both cases observed fluctuations of the grain size distribution and the total solid discharge are presented and discussed.

2 EXPERIMENTAL SETUP

2.1 Description of the GDS system

The GDS (figure 1) allows to record images of grains flowing over a back-lighted transparent ramp located Figure 1. The image processing chain. at the outlet of the flume. Images were recorded with a frequency of 15 images/sec. From this series of 2D images as input, an algorithm using specific image analysis methods (with the help of WIMA software, Ducottet 1994) allowed to segment the particles, and permitted to calculate their axes dimensions. Considering the average grain velocity, the solid discharge and the grain size distribution were calculated each 3 second. The entire device was successfully validated with an error generally less than 3% on grain size curve parameters and less than 7% on solid discharge (Frey et al. 2003). 2.2 Materials and experimental flume Three uniform materials were selected by sieving natural sand-gravel materials with round meshes. Uniform

of a grain (g)

materials will be named in the following relatively

to these round meshes diameters (i.e. 2–3, 4–5 and

8–10 mm). Correspondences with square meshes are

reported in table 1.

The first aim of the study was to characterize the

behaviour of these uniform sediments close to the

incipient motion flow. This implied to work at low liq

uid and solid discharges. As 2D bedforms such as bar

formations were excluded from this study, it was also

necessary to have a low width to ensure that the super

critical flow occurred over the entire width with only

one-dimensional bedforms. The 9% steep flume used

for the experiment was 2.3 m long and 5 cm wide. The

flow rate at the inlet was regulated and measured by an

electromagnetic flow-meter. For each run, liquid and

solid discharge were maintained constant. There was

no recirculation neither solid nor liquid.

The solid feeding system was specifically devel

oped using a feeding tank and a conveyor belt whose

velocity allowed to control the solid discharge. This device was tested with the GDS and ensured a reasonable stable solid discharge even for very low values. In this case, the accuracy is plus or minus the order of magnitude of the grain average size. For example, working at 8 g/s with the 8–10 mm gravel which average particle weight is 1.3 g means an accuracy of ±15%, but becoming better with finer sediments (±5% for the 2–3 mm at 8 g/s). This device was also tested with a mixture of the 2–3/5–6/8–10 mm materials. Results are good and indicate that no sorting effects occur inside the tank, the average solid discharge for each classes remaining constant (figure 2). For this test at 11 g/s, quite large but very short in time fluctuations were observed mainly depending of the 8–10 mm average grain weight (since the average 8–10 mm solid discharge corresponds to 3 g/s).

2.3 Experimental conditions

At the beginning of each run, a 4 cm thick layer of sediment material was uniformly placed at the bottom of the flume to allow aggradation or degradation. Figure 2. Test of the feeding system with a mixture of 2–3/5–6/8–10 mm uniform materials. (a) total solid discharge Qs. (b) Contribution of the 8–10 mm fraction to Qs. (c) Contribution of the 5–6 mm fraction to Qs. (d) Contribution of the 2–3 mm fraction to Qs. Each run was performed at equilibrium state, meaning that, during the experiment, the changes in the bed elevation and the depth of the flow were small. The main hydraulic parameters for all runs are

reported in table 2, Q cr being the assessed incipient motion discharge, Q the liquid discharge, Qs the solid discharge obtained to stabilize a 9% equilibrium slope and H the estimated water depth.

3 MAIN RESULTS AND OBSERVATIONS

3.1 Bedforms and stable equilibrium slope with uniform materials

For each uniform material, antidune-like bedforms

were well observed close to the incipient motion liq

uid discharge (figures 3 to 5). These bedforms always

occurred on a constant equilibrium slope. When

increasing liquid and solid discharges with the same

equilibrium slope, the bedforms became more unsta

ble, almost disappearing at about twice the incipient

motion discharge.

Upstream moving of these bedforms was clearly

observed. Some characteristics measured through the

transparent wall of the flume are given in table 3.

Moreover a cyclic-like pattern seemed to occur sim

ilarly for the three uniform materials when observing

the bed evolution near the outlet as described on fig

ure 6. At this stage of the experimental development,

observations are only qualitative. In a further work

analysis of images from the side of the flume should

allow to improve our knowledge of bedform processes.

Figures 7 to 9 shows that solid discharges mea

sured with the GDS at the outlet only slightly fluctuate

around a constant average value.This is consistent with

a perfectly constant equilibrium slope. These fluctua

tions combine a noise (the entrance signal fluctuation
Figure 4. Bedforms in the 5-6 mm. Figure 5. Bedforms in the 8-10 mm. Table 3. Order of magnitude of the observed bedforms. Material Period Wave length Migration velocity (mm) T (s) λ (cm) U (cm/s) 2-3 4 8 1.7/2 5-6 10 10-15 1/1.5 8-10 40 40 1 and the measurement device accuracy) with what really happened inside the flume and is therefore not easy to analysed. More data are needed to perform spectral analyses of output solid discharge. Nevertheless a short analysis of the 8-10 mm output signal with bedforms conditions reveals the 40 s period which was measured confirming the cyclic pattern described on figure 6. 3.2 Bedforms and unstable equilibrium slope with the non-uniform materials Two experiments were performed with two nonuniform materials, mixtures of the previous uniform materials (table 4). Hydraulic conditions of these runs are given in table 2. For both experiments the measured incipient motion discharge appeared to be nearly the average of incipient motion discharges relative to the constitutive uniform materials of the mixture.

Figure 6. Cyclic like pattern occurring downstream from the flume.

Figure 7. Outlet solid discharge measured with the uniform

2-3 mm material.

Figure 8. Outlet solid discharge measured with the uniform 5–6 mm material.

Bedforms occurred for both experiments (figure 10) but in a completely different manner compared to what occurred with uniform materials. Many preliminary runs not presented here were performed under different hydraulic and sediment conditions but none permitted to obtain a stable equilibrium slope. Instead, a periodic-like fluctuation around the average equilibrium slope was observed, alternating periods of bed aggradation and degradation. Figure 9. Outlet solid discharge measured with the uniform 8–10 mm material. Table 4. Non uniform material used in the experiments. 2–3 mm 5–6 mm 8–10 mm Run 1% 50 50 none Run 2% 33 33 33 Aggradation was associated with bedforms and vertical and longitudinal sorting of the sediment with coarser grains progressively covering finer sediments. Observed wavelengths varied periodically with time and slope: (a) near the equilibrium slope, bedload is composed of a mixture of all grain sizes and bedforms are unstable.The order of magnitude of the wavelength corresponds to the coarser material. (b) when the slope increases, bedload is essentially composed of coarser grains, the finer being progressively buried. Bedforms are very similar to those observed with the corresponding coarser uniform material.

Figure 10. Bedforms in the 5–6/8–10 material.

Figure 11. Outlet solid discharge and slope for the non uniform material 2–3/5–6 mm figuring the 2–3 mm material contribution to the total solid discharge.

(c) when the slope is maximum quasi-stationary bedforms are observed. The bed is entirely armoured and the output solid discharge becomes negligible.

(d) the bed suddenly becomes unstable with armouring being

destroyed. A large amount of sediment stored in the bed is washed downstream of the flume leading to a very high solid discharge at the outlet.

(e) The erosion process leads to a rapid bed degradation down to a minimum slope inferior to the equilibrium value. During this period, the bed is flat with no bedforms.

(f) When reaching the minimum slope, short-life bedforms appear with a wavelength similar to that observed with uniform finer materials.

(g) These short bedforms quickly disappear by trapping the coarser material. Erosion is replaced by an aggradation process, and the cycle described before starts again with larger bedforms.

This cycle appears very clearly when considering

the solid discharge (GDS measurements) at the outlet

of the flume for the non-uniform 2-3/5-6 mm and 2-

3/5-6/8-10 mm materials (figures 11 to 15).

A quasi-binary signal is observed reflecting the

alternating phases of armouring and hyperconcen

trated bed-load flow. Both experiments show a low

frequency component corresponding to coarser sed

iments and high frequencies relative to the finer Figure 12. Outlet solid discharge and slope for the non uniform material 2-3/5-6 mm figuring the 5-6 mm material contribution to the total solid discharge. Figure 13. Outlet solid discharge and slope for the non uniform material 2-3/5-6/8-10 mm figuring the 2-3 mm material contribution to the total solid discharge. Figure 14. Outlet solid discharge and slope for the non uniform material 2-3/5-6/8-10 mm figuring the 5-6 mm material contribution to the total solid discharge. material. In both cases, the 2-3 mm contribution to the total solid discharge is equal to zero during the armouring process. For the 2-3/5-6/8-10 mm experiment, only the 8-10 mm participates to bed-load during that phase. Such phenomena of large fluctuations of solid discharge and slope have already been observed with natural sand-gravel material (Mizuyama 1977, Kuhnle et al. 1988, Suzuki et al. 1998,

Frey et al. 2003). In the meantime, no clear explanation is proposed

Figure 15. Outlet solid discharge and slope for the non uniform material 2-3/5-6/8-10 mm figuring the 8-10 mm material contribution to the total solid discharge.

which would permit to model the phenomenon, but, a systematic study using different uniform materials, and a second image processing device grabbing from the side of the flume will hopefully allow a better understanding.

4 CONCLUSION

With the help on an original image analysis device (GDS), contrasting results were obtained whether using uniform or non-uniform materials.

In the uniform case, bedforms occurred very close to the incipient motion discharge while disappearing at about twice that discharge. Solid discharges measured with the GDS at the outlet only slightly fluctuated around a constant average value, which was consistent with a perfectly constant equilibrium slope.

In the non-uniform case, using mixtures of the pre vious uniform materials, no stable equilibrium slope could be observed. Instead, the bed slope fluctuated around a mean equilibrium value, alternating periods

ABSTRACT: Conventional flow resistance equations are applicable to particular ranges of relative roughness (d/R). At many New Zealand river-gauging sites a marked increase in Manning's n is evident as flow decreases. It is suggested that the increase in n is partly caused by "out of range" application of the Manning equation rather than changes in channel boundary roughness. A full form of the log law, using Z o for boundary roughness, applicable to a wide range of d/R, is solved to give Z o values for flows measured at 78 sites on New Zealand rivers. This log law, with constant Z o for each of the sites, gives better velocity estimates over the range of measured flows than Manning's equation with a constant n. The influences of factors such as grain size, flow depth and shear stress on n and Z o are investigated.

1 INTRODUCTION

In a dynamic two-dimensional numerical model of a river floodplain, a resistance equation can be evaluated many millions of times to cover the range of depths that occur at each of the different computational nodes of the model. Flow resistance equations are also used for applications as diverse as converting flood marks into flows and aquatic habitat studies. In all such circum stances it is clearly advantageous to have a resistance equation that is applicable at both high and low flow depths.

A study of the roughness characteristics for 78 New

Zealand rivers (Hicks & Mason, 1998) reveals that for at least half of the sites, the measured Manning's n coefficient increases by more than 50% over the range from highest to lowest measured stream flows. Thus, errors of more than 50% could be introduced if a constant Manning's n were used to predict flow at these sites. Examples of this phenomenon are shown in Figure 1 for a small and large stream. Such behav ior is also reported by Griffiths (1981), Cao (1985), Jarrett (1984, 1990), and many others who have found that hydraulic resistance increases with a decrease in the ratio of hydraulic depth (R) to particle size (d). Smart et al (2002) show that common resistance formulae are applicable only to particular ranges of relative roughness (d/R). In the case of power law equations where U is depth averaged velocity, U * = √ (gRS), K is a constant and S is the energy gradient), the exponent m of (U/U *) = K(d/R) -m increases from around 0.17 for low (d/R) ratios to m = 0.5 or more at high (d/R) ratios. Consequently, poor results will be obtained if an inappropriate power law is used. It is postulated that the reported changes in Manning's n coefficients may be needed to compensate for the inadequacy of Manning's equation, when used over a wide depth range, rather than reflecting actual changes in hydraulic resistance. The proposition is investigated by seeking an equation with a roughness coefficient Loganburn R. downstream of gorge 0 0.01 0.02 0.03 0.04 0 Flow [m 3 /s] Flow [m 3 /s] M a n n i n g ' s n 0 0.01 0.02 0.03 0.04 Z o

that is more stable than Manning's n as depth changes

at a given site.

Assuming that roughness elements are fully covered

by the flow, that the origin of a logarithmic velocity

profile is a distance R below the surface and the profile

extends to the surface, integrating over the flow depth

(from height z = z o to z = R) gives:

where κ is von Karman's constant (~ = 0.4), and z o

describes the hydraulic roughness of the boundary

(the height above the z datum where the log profile

velocity= 0).

In situations where z o R, Equation 1 simplifies

to more common forms of the log law such as Equation

2, Nikuradse (1933) type equations (2a) or Keulegan

(1938) type equations (2b)

The equivalent sand grain diameter k s or a mea

sured grain statistic such as d 50 is also used in place of

z o with compensating changes in the equation coeffi

cients.An advantage of using z o is that it is a parameter

of the velocity distribution rather than a description

of the boundary material. Hence z o gives hydraulic

roughness, as seen by the flow, rather than relying on

a boundary characteristic such as bed material grain

size. Once z o is established it can be investigated in

terms of physical characteristics of the boundary.

For a smooth boundary, where ν is the kinematic

viscosity of water, z o is independent of bed roughness:

For rough boundaries z o can be established by pre

cise measurements of the velocity profile or by solving

Equation 1 using measured values of R, U and U∗.The

ratio U/U∗ of Equation 1 diverges from simplified

equations of type (2) by more than 1% when (U/U∗)

< 10 or (z o /R) > 0.007.

Equations of type (2) are suitable for low relative

roughness situations and are readily inverted to allow y = -0.5174x 3 + 2.0535x 2 - 0.5818x + 0.0451 R 2 = 1 0.0001 0.001 0.01 0.1 1 0 0.2 0.4 0.6 0.8 1/(1+κ(U/U ∗)) z o / R old log law Eq. (2) full log law Eq. (1) polynomial fit 1 Figure 2. Polynomial representation of z o /R equivalent to Equation 4. calculation of z o from measured values of U , R and U ∗ = √ (gRS). However, inverting Equation 1 gives: which is not readily solvable for z o . 2 METHOD As shown in Figure 2, Equation 5 can be accurately represented in polynomial form over much of its range. The dashed line in Figure 3 shows that the polynomial approximation is not applicable for z o /R < 0.005 but Equation 4 is suitable for this range. The polynomial is: Thus, given R, U and U∗, z o can be calculated for all R > z o , using (4) or (6). As z o is not known a priori, in such calculations x = (1+ κU/U∗) −1 gives a better criteria than z o /R for switching from Equation 4 to Equation 6. For x < 0.19 use Equation 4 and for x ≥ 0.19 use Equation 6. This log law resistance equation is now compared with Manning's Equation. 3 APPLICATION The above approach was used to calculate Z o for 566 gauging measurements made at 78 sites on y = 0.83 x + 0.103 R 2 = 0.89 for Zo y = 0.73 x + 0.164 R 2 = 0.75 for n 0 1 2 3 4 0 2 4 Measured velocity [m/s]

New Zealand rivers. The sites and data are based

on the raw measurements used in the New Zealand

Manning's n handbook (Hicks & Mason, 1998). A full

description of the sites and measuring techniques is

given in the handbook. All basic parameters are used

as described in the book. At this point it is important to note that some of the assumptions in the log law the ory are not necessarily applicable when cross-section averaged values of R and U are used to calculate z o . To preserve this distinction, an uppercase symbol is now used and Z o becomes a bulk roughness coeffi cient similar to Manning's n, which includes bed form and bank vegetation effects if they are present at a river section. This cross-section approach is also implicit in the Keulegan (1938) equation when it is applied to river reaches.

Z o values calculated as described above are also shown on Figure 1 along with Manning's n. At first glance n and Z o appear to show a similar variation over the range of flows measured at each of these sites. However, while velocity varies in inverse (lin ear) proportion to n in the Manning equation, the log law (Equation 2) shows that velocity varies as the inverse logarithm of Z o over much of the Z o /R range. In other words, velocity predictions are less sensitive to errors in Z o (with Equation 1) than to similar errors in n (when using Manning's equation).

Using Equation 1 with constant Z o may give better -100% -50% 0% 50% 100% 0.0001 0.001 0.01 0.1 d 50 [m] (U m e a s U p r e d) / U m e a s Manning Eq., site av. n Eq(1) with site av. Zo 1 Figure 4. Relative errors in velocity prediction are smaller for silt and sand bed rivers (d 50 < 2 mm). Nine outlying errors (as large as −400%) that are

due to external effects, are not shown. predictions of velocity for a site than the conventional practice of using Manning’s equation with a constant n value. This was tested by investigating errors in predicted velocities when using Equation 1 with constant Z o and Manning’s Equation with constant n values at each of the 78 New Zealand reference sites. The resistance coefficients used were the mean of the values measured at each site (e.g. for the Loganburn site, shown in Figure 1 at the top, values of n = .028 and Z o = .0036 were used). Figure 3 shows measured velocities in comparison with the velocities predicted using the average site resistance coefficient. Statistics on the errors are given in Table 1. It is apparent that using a site mean n or Z o results in many velocities being underpredicted. The outcome is especially pronounced when Manning’s equation is used. Equation 1 with constant Z o performs better than Manning’s equation with constant n. Relative errors are given in Figure 4. It is clear that, for this New Zealand data set, velocity prediction with a constant resistance coefficient causes appreciable errors, especially in rivers with median bed material coarser than sand sizes. Excluding the outliers described in the caption of Figure 4, the mean magnitude of the relative error using Manning’s equation with a site average n is 20%. Using Equation 1 with a site average Z o the equivalent mean error is 16%. 4 DISCUSSION Many factors can change flow resistance at a site. These include overbank effects, bank vegetation, bedforms, sediment loading, seasonal changes, backwater profiles and weed growth. Nevertheless, the above results show that if a constant resistance coefficient is to be used at a particular site, Equation 1 gives R/Z o

Figure 5. The relationship between Manning's n and Z o depends on relative roughness Z o /R.

better overall estimates of velocity than the Manning equation, especially in gravel, cobble and boulder bed channels. A problem with applying Equation 1 is that little information is available on Z o values for use in field situations.

Jacobs & Wang (2003) suggest Z o for floodplains can be adopted from atmospheric velocity profile measurements. While there is some information on atmospheric Z o for field crops it would be more straightforward if Z o could be calculated from bound ary properties such as grain size or related to the better known Manning's n values.

Eliminating U from the Manning equation using Equation 1 and $U* = \sqrt{(gRS)}$ gives a relation between Manning's n and Z o :

This relation is shown graphically in Figure 5.

While it is straightforward to calculate n values from

Z o and R using Equation 7, it is not obvious how to

calculate Z o from n and R except by way of iteration

or a chart such as Figure 5.

A second possibility is that Z o can be calculated

from channel properties such as grain size. To make

this study, measured n and Z o values are used (not

site averages) and logarithmic graph axes are shown

to display the wide range in the variables. Regression

lines and statistics refer to the raw (non-logarithmic)

data.

Figure 6 shows that there is a weak relation between

Z o and d 90 grain size (R 2 = 18%). The relationship

becomes progressively weaker if d 84 or d 50 is used.

No significant relationship between n and d 90 or d 1/6 90

was evident (as implied by the Strickler equation). y = 0.166x + 0.01 R 2 = 0.18 for Zo y = 0.08x + 0.044 R 2 = 0.03 for n 0.01 0.1 1 0.001 0.01 0.1 10 d 90 [m] M a n n i n g ' s n 0.00001 0.0001 0.001 0.01 0.1 1 Z o f r o m E q . (4) o r (6) measured n measured Zo 1 Figure 6. No significant relationship is evident between n and grain size of the river bed. A weak relationship exists between Z o and d 90 . y = 0.026x -0.175 R 2 = 0.05 for Z o 0.01 0.1 1 0.01 0.1 1 10 100 1000 10000 Flow [m 3 /s] M a n n i n g ' s n 0.00001 0.0001 0.001 0.01 0.1 1 Z o f r o m E q . (4) o r (6) measured n measured Zo y = 0.072x -0.15 R 2 = 0.05 for n Figure 7. A stronger relationship is evident between Manning’s n and flow than between Z o and flow. Conversely, when flow is used as the predictor, there is a power law relation between n and flow (R 2 = 26%) but little dependence of Z o on flow (R 2 = 5%). While there is weak power law dependence of n on R −0.25 (R 2 = 10%) there is no dependence of Z o on R. Both n and Z o depend on energy graident (n = 0.19 S 0.22 , R 2 = 25% and Z o = 0.29 S 0.46 , R 2 = 17%). From the above parameters, R, flow and

S, are most likely to vary at a given site. An ideal flow resistance coefficient should not vary with these parameters. The above statistics show that Z o has less variance depending on these parameters than does n. 5 CONCLUSIONS Many applications require a single equation with constant resistance coefficient to be used for flow resistance calculations at a given location. For the range of New Zealand river sites, power laws of (d/R) and Manning's equation do not satisfy these requirements.

It is suggested that measured changes in Manning's

n coefficient at a given site may be needed to compen

sate for the inadequacy of Manning's equation when

used over a wide depth range, rather than reflecting

actual changes in hydraulic resistance. An improved

flow resistance formula (Equation 1) which is based

on log law theory, gives better predictions of measured

velocity when used with a constant Z o than can be given

by Manning's equation with a constant n value.

While the new formula performs better than the

Manning equation for New Zealand river sites, guide

lines on Z o values are not readily available and further

work is required to either provide selection criteria

for Z o values, to allow conversion of n values into

Z o values or to make improvements to the Manning

equation.

Large-eddy simulation of flow over rough channel beds

T. Stoesser, W. Rodi & G.H. Jirka

Institute for Hydromechanics (IfH), University of Karlsruhe, Germany

ABSTRACT: In this paper we present the results of several large eddy simulations (LES) of the flow over

rough channel beds. The wall roughness is introduced via artificial 2-dimensional square bars, positioned along

the channel at varying spacing. The spacing is chosen such that the three roughness types, isolated roughness,

wake interference roughness, and quasi-smooth-wall roughness are represented. The vertical velocity profiles

exhibit the well known feature of turbulent flows over rough wall flows i.e. a shift of the logprofile above the

roughness crests. However, the increment of the shift depends strongly on the arrangement of the artificial

roughness elements. In addition, turbulent fluctuations and Reynolds stresses show a dependency on the type of

the roughness. Similar to previous experimental and numerical investigations the occurrence of flow into and out of the cavities is shown and vortices are shed into the outer flow. These vortices are associated with the occurrence of low and high speed streaks, a feature that is also found in smooth wall flows. However, the shape and length of these streaks depend strongly on the roughness type.

1 INTRODUCTION

Turbulent boundary layers over roughness elements have considerable engineering interest. Especially in the field of hydraulic engineering, nearly all practical flows are hydraulically rough, i.e. the roughness Reynolds number $Re_* = (u_\tau \cdot d)/\nu$ (where u_τ is the friction velocity, d is a characteristic roughness height and ν is the dynamic viscosity) exceeds a certain value ($Re_* > 70$) and the roughness affects the flow outside the roughness sublayer. This results in a mean velocity profile that differs considerably from the velocity profile over a smooth bed (e.g. Patel, 1998), since surface drag is significantly larger in comparison to a turbulent flow field over a smooth surface.As a consequence, the resulting turbulence characteristics should also reflect the nature of the surface.

According to Raupach (1981) the boundary layer over a rough surface is characterized by a surface layer that can be divided into an inertial or logarith

mic layer and a roughness sublayer. Within the inertial layer (IS) the vertical variation of the shear stress can be neglected and the vertical distribution of the flow velocity can be described by a logarithmic law (e.g. Perry et al., 1969). The region of the flow beneath the inertial layer is known as the roughness sublayer (RS) within which the flow is strongly influenced by the individual roughness elements and is therefore spatially inhomogeneous.

The effect of roughness however is not restricted to the mean flow properties. Flow visualizations and measurements (e.g. Grass, 1971, Grass et al., 1991, Djenidi et al., 1999 and many others) as well as recent DNS calculations over rough-walls (Leonardi et al., 2003, Miyake et al., 2002) indicate significant structural changes not only near the rough surface, but everywhere within the boundary layer. It was found that over rough walls the bursting phenomenon seems to be more intense than over smooth walls. Measurements over a series of roughness types reported by Antonia (1994), indicated that the Reynolds stresses are increased relative to a smooth wall. Leonardi et al. (2003) showed that due to surface roughness the size and shape of coherent streaks change drastically as a result of enhanced momentum exchange between the near wall region and the outer flow. Following the definition of Morris (1955) the effect of roughness is mainly due to the formation of wakes behind the roughness elements resulting in the production of turbulence and the dissipation of energy. According to Morris the longitudinal spacing w is of paramount importance in rough wall channel flow, classifying the roughness into three basic types (Figure 1): isolated roughness flow (k-type), wake interference flow (transitional) and quasi-smooth flow (d-type). However, the overall picture of the effect the roughness has on the near wall structure is far from complete and systematic studies on different types of roughness are rare. In this paper we show the results of several large eddy simulations (LES) calculations of an openchannel flow over an artificially roughened bed for the

Figure 1. Roughness types in rough wall channel flow according to Morris (1955).

above mentioned three roughness types. The main purpose of this study is to provide further insight into the turbulent flow over rough boundaries and to enhance the understanding of the effect of surface roughness geometry on the mean and instantaneous flow. Spatial and temporal averaging is used to quantify the effects of the three roughness types with regard to flow velocities, turbulent fluctuations and Reynolds stresses. Furthermore, we investigate the occurrence of coherent flow structures in dependence on the nature of the roughness and compare them to the equivalent structures on a smooth wall.

2 NUMERICAL METHOD

The LES code LESOCC developed at the Institute for Hydromechanics (Breuer and Rodi, 1996) is used to perform the LES simulations. The code solves the filtered Navier-Stokes equations on a curvilinear, block-structured grid discretised with the finite volume method. A non-staggered grid with Cartesian velocity components is used. Both convective and diffusive fluxes are approximated with central differences of second order accuracy. The SIMPLE algorithm is employed in order to conserve mass and to couple

the pressure to the velocity field. Time advancement

is achieved by a second order, explicit Runge-Kutta

method. LESOCC is highly vectorised and paralleli

sation is accomplished by domain decomposition and explicit message passing via MPI.The subgrid stresses of the filtered Navier Stokes equations are computed using the dynamic approach of Germano et al. (1991). The linear noslip (u + = y +) boundary condition is used for the walls and on the roughness elements, since the first grid point is placed in the viscous sub-layer (y + ≈ 7). 3 FLOW CONFIGURATIONS Three configurations with ratios of w/k = 10 (isolated flow), w/k = 7 (wake interference flow) and w/k = 3 (quasi smooth flow) are selected in order to simulate the three roughness types according to Figure 1. The boundary conditions and the Re number of 4200, based on half channel depth and bulk velocity, are chosen analogous to recent DNS calculations performed by Leonardi et al. (2003). This allows us to additionally perform a comparison LES – DNS and verify the mathematical model. The roughness Reynolds number Re* is approximately 400 based on the shear velocity u τ and the roughness height k . The ratio of roughness height to water depths is k/h= 0.2.The computational domain spans 8h in streamwise, πh in spanwise and 2h in vertical directions, respectively. Several simulations with different grid resolutions were carried out. In this paper we will only present the results from the finest grid consisting of 261× 61× 120 grid points in streamwise, spanwise and vertical directions, respectively. Periodic boundary conditions were applied in the spanwise and vertical directions. No-slip boundaries were applied on and between the roughness elements, representing the rough lower wall, and on the smooth upper wall. 4 RESULTS AND DISCUSSIONS 4.1 Time averaged flow field Figure 2 shows the time-averaged flow field above the three roughness types. The flow develops strong separation zones near the roughness elements causing a shear layer of different extent and a strong disturbance of the flow field in the vicinity of the elements. Whereas for the isolated and transitional roughness the flow reattaches in the groove, the separation zone for the quasi-smooth flow fully occupies the cavity that is formed by the roughness elements. The groove is filled completely with a stable eddy creating a pseudowall. As a consequence, the average flow field takes a more or less wavy form above the roughness elements for transitional and isolated roughness. Perry et al. (1969) attributed this roughness-induced streamwise distortion to standing waves, forming just above

the roughness elements. A more homogenous flow field above the crests (similar to a flow field above a smooth

a) isolated roughness

b) transitional roughness

c) quasi-smooth roughness

Figure 2. Average flow field for the three configurations (a-c).

wall) appears for the quasi-smooth flow.These features agree fairly well with the sketches from Figure 1.

Figure 3 shows the comparison of LES and DNS results for the three types at the top of the bar (left) and in the center of the groove (right side) for the three configurations. A fairly good match could be achieved and the differences can be regarded as insignificant for the further evaluation of the results.

Figure 4 shows the spatially (in streamwise and spanwise directions) averaged distribution of the streamwise velocity. It is apparent for all three rough ness types that the maximum of the velocity is shifted from the centre of the channel towards the upper, smooth wall. However, the shift is largest for the iso lated roughness and smallest for the quasismooth roughness. This is in accordance with the averaged mean velocity distribution.

A comparison of the second order statistics i.e. the rms values of the streamwise velocity fluctuations, at

the top of the bar and in the centre of the groove with the

direct numerical simulation (Figure 5) shows a good

match in the vicinity of both walls. There, the peak

of the turbulent fluctuations is reproduced to a very

satisfying degree. For the quasismooth wall the mag

nitude of u ′ u ′ is in a similar range in comparison to

the smooth upper wall. As w/k increases the strength

of the turbulent fluctuations increases and the intensi

ties are approximately 50% higher near the rough wall.

However, in the centre of the channel the fluctuations

are generally underestimated. Figure 5. Comparison of LES and DNS results for the

streamwise turbulent fluctuations u ′ u ′ above the bars (left)

and in the centre of the groove (right) for the three configu

rations (a-c). coarse resolution (the grid is stretched towards the walls) in this area, since only large scale fluctuations are represented within a LES. Hence, a finer grid, especially in the centre of the channel, is

desirable. However, the general features of rough wall channel flow, i.e. a fairly thick boundary layer and, as a consequence, a relatively large shift of the logarithmic region away from the wall is reproduced. Figure 6 furthermore clearly demonstrates that even for the quasismooth roughness the influence of the roughness elements seems to prevail up to approximately 2/3rd of the channel depth. The above mentioned standing waves also affect significantly the turbulence intensity distributions in the vicinity of the rough wall. Figure 6 shows the distribution of turbulent fluctuations u ′ , w ′ and u ′ w ′ normalized by the mean shear velocity at the top of the bar and in the centre of the groove. There is a significant increase in the Reynolds stresses in the groove compared to the top of the bars. The strength of the intensities again depends on the roughness type, being strongest for the isolated roughness and weakest for the quasi smooth flow. The influence of the rough wall can be seen in the magnitude of each stress component compared to the value of its smooth counterpart. While the difference for u ′ is rather small, the difference for both u ′ w ′ and w ′ is in the order of up to 4 times the value of the smooth wall.Also notable are the distortions of the stresses especially in the centre of the grooves. Furthermore, the strong distortion of the streamwise fluctuation u ′ at the top of the bar for both transitional and isolated roughness is apparent. This indicates a superposition of standing waves and suggests that a value of w/k = 10 might not be large enough to represent the fully isolated roughness regime. 4.2 Instantaneous flowfield Figure 7 shows instantaneous velocity distributions of the perturbation in streamwise direction i.e. u ′ , together with the perturbation velocity vectors (u ′ −w ′) in an x-z plane. It illustrates the presence of vortical motion, especially near the elements. It also shows that for the wake interference and the isolated roughness types the perturbation is much stronger than for the quasi-smooth flow, resulting in a more frequent and a stronger shedding of eddies into the flow. The Figure is an obvious reflection of the above mentioned distribution of mean velocities, turbulent fluctuations and Reynolds stresses. The turbulent boundary layer over a smooth wall is characterized by alternating high and low speed streaks, which lift up and break down during a burst cycle (see e.g. Kline et al., 1967, Robinson, 1991). For the rough wall cases streaky structures are also present just above the roughness elements as was u'w'/u(tau) 2 z / h -1.6 -1.6 -1.4 -1.4 -1.2 -1.2 -1.0 -1.0 -0.8 -0.8 -0.6 -0.6 -0.4 -0.4 -0.2 -0.2 0.0 0.0 0.2 0.2 0.4 0.4 0.0 0.0 0.2 0.2 0.4 0.4 0.6 0.6 0.8 0.8 1.0 1.0 1.2 1.2 1.4 1.4 1.6 1.6 1.8 1.8 2.0

shown by Djenidi et al. (1999) in a laboratory exper

iment with the help of dye. Figure 8 shows instan

taneous distributions of u ′ in a x–y plane just above the roughness bars for the three roughness configu rations and, for a comparison, near the smooth wall. Here, the presence of coherent high (indicated by the red colour) and low speed (blue colour) streaks alternating in the spanwise direction are visible. By increasing the spacing between the bars the strength of these streaks increases, which is due to increased momentum exchange with the outer layer. This is in accordance with observations from a quadrant ana lysis by Krogstadt and Antonia (1994). Furthermore, with an increase in the ratio of w/k the form of these streaks changes. While near the smooth and quasi smooth walls the streaks are elongated, they are shorter and wider for the isolated and transitional roughness. However, the streak spacing seems to be constant

irrespective of roughness type. a) smooth wall b) quasi-smooth roughness c) transitional roughness d) isolated roughness Figure 8. High and low speed streaks for the smooth upper wall (a) and the three roughness configurations (b–d). 5 CONCLUSIONS In this paper we have presented the results of large eddy simulations of open channel flow over artificially roughened channel bed for the three roughness types: isolated, wake interference, quasismooth roughness. A strong-form-roughness induced shear layer develops above the elements such that instantaneous and mean velocities differ significantly from the velocity distribution over smooth beds. Outflow from and inflow into the cavities are shown to occur for all roughness types. The shedding of vortices into the outer flow plays an

important role in producing/maintaining the boundary

layer. This is confirmed by the increase of turbulent fluctuations and Reynolds stresses above the rough wall in contrast to a smooth wall. An important role plays the nature of the roughness, being responsible for the magnitude of the stresses and the distribution of all turbulent quantities in the entire flow. This supports the statement of Djenidi et al. (1999) who underline the inadequacy of a roughness classification scheme based solely on the effect that the roughness has on the mean velocity profile. The present study showed that the type of the roughness is of significance espe cially in the formation of near wall coherent structures. Although streaks form above all types of roughness, their size and shape are different for each roughness regime.

ACKNOWLEDGEMENTS

This work is part of the research project funded by the German Research Foundation (DFG) under project number JI 18/10-1. The authors would like to thank Dr. Stefano Leonardi for the provision of the DNS data.

Flow over dunes with super-imposed smaller dunes. Turbulent coherent

structures and wall similarity hypothesis

M.T. Mattar

Water Resources Institute of the National University of
Santiago del Estero, Argentina

ABSTRACT: This paper shows the results of an experimental
work carried out on a glass wall flume with

dimensions 67 m× 1.5 m× 1.0 m (length×width× height)
installed in the hydraulics laboratory of the Litoral

National University, Argentina. The bed of the flume was
covered by a train of triangular bedforms, resembling

the typical dunes present on the bed of Parana river. The
point velocity measurements, aimed to estimate the

three components of the velocity vector, were performed by
means of an acoustic Doppler velocimeter (ADV).

The obtained values were processed and a study was carried
out in order to compare the turbulent characteristics

of the flow over dunes with the flow over a bed composed by
small dunes superimposed over large dunes. The

features analyzed were the reattachment length, coherent
events, characteristic spatial scales and, finally, it was

appraised the wall similarity hypothesis, by means of a
comparison between both bed conditions.

1 INTRODUCTION

Most of the flow which are present in nature are tur

bulent flows and so its mechanics has relevance in the

associated transport phenomenon.

In mobile bed when of the critic shear stress is

overcome processes of sediment transport take place,

generating new shapes when the stress is increased.

These turbulent transport processes are greatly influ

enced by the characteristics and by scale of the

turbulent coherent structure. These structures (phe

nomenon also called bursting) are manifested through periodic events of ejection and sweeps (Nezu, I and H. Nakagawa, 1993).

Nowadays there are many research works intended to evaluate how much the coherent events contribute to the Reynolds stresses though measures in open chan nels with rough-bed and smooth-bed as well as over totally developed form bed.

A less common bed is that which is formed by dunes with super-imposed smaller dunes (little dunes) like the one in the Parana River, near Villa Urquiza, Entre Rios State, Argentina (Amsler, M and M. Scheider, 1992). Nowadays, there is not a complete comprehen sion over the mechanics and the evolution of these little dunes. With the purpose of clarifying over some of these aspects, in the present work the influence of the turbulent coherent structures over Reynolds stresses, the characteristics scales and wall similarity hypothe sis are evaluated comparatively between a bed with a dunes train and another whit dunes with super-imposed smaller dunes. 2 EXPERIMENTAL PROCEDURE The measurements tasks of this work were carried out on a glass wall flume in the installed Hydraulics Laboratory of the Litoral National University, Santa Fe State, Argentina. This flume has the following dimensions: 1.50 m width, 1.00 m height and 67.00 m length. A bed's piece is formed by 16 bed forms, with a wavelength of 2.30 m and the bed form height of 0.05 m. Among the 16 dunes, 9 have super-imposed smaller dunes, called little dunes. These little dunes have 0.12 m

length and 0.005 m height. To measure the velocity, an Acoustic Doppler Velocimeter (ADV) was used for laboratories Sontek brand. This is an easyto-use, versatile instrument which can simultaneously measure the three components of the velocity at a measuring with sampling frequencies up to 25 Hz. This instruments averages a sampling volume of approximately 0.006 m width and changeable height: 0.0012 m, 0.0036 m and 0.005 m. The height of the sampling volume may be specified in the configuration file. In the present work a sampling volume height of 0.0036 m was used to carry out velocity measurements in a permanent uniform flow with a mean flow depth of 0.275 m. The velocity signal was recorded during a sampling time of 180 s (Mattar, M et al., 1999) using a sampling frequency of 25 Hz. The measurements were divided into two parts: Med1, the measurements were carried out over a uniform train of dunes, while in Med2 the measurements were carried out over dunes with super-imposed little dunes.

Figure 1. Med1 and Med2 scheme.

The measurements were carried out over 16 ver

tical profiles, each one with 14 points of velocity

measurements. The height in meters of the measure

ments point were the following: 0.002, 0.004, 0.006,

0.008, 0.01, 0.015, 0.02, 0.03, 0.05, 0.08, 0.11, 0.15,

and 0.20, measured from the dune’s profile. The pro

file number one was located over a crest of the dune

(progressive 0) the profile 16 was fixed in the next

crest in downstream direction (progressive 230). In

order to obtain a better description of the dynamics of

the flow, the vertical profiles for the measurement of

velocity were more closely spaced in the separation

zone downstream of the dunes. The Figure 1, shows

the measurement scheme.

3 COHERENT STRUCTURES

In order to determine the ejection and sweeps theAnal

ysis QuadrantTechnique (Lu, S.S and W.W. Willmarth,

1973; Nakagawa, H and I. Nezu, 1977a) was used in the

present work. This technique distinguishes the turbu

lent events according to the signs of fluctuation of the

velocities (u ′ and v ′) what gives origin to four
quadrant.

This technical assigns the outward interactions (ascen

dent movements of high velocity) to the first quadrant

(u ′ > 0 and v ′ > 0), the inward interactions (descen

dent movements of slow velocity) were assigned to the

third quadrant (u ′ < 0 and v ′ < 0) the ejections char

acterized by the transport of the fluid mass from the

wall generating a decrease of the shear stress were

assigned to the second quadrant and the sweeps events

are assigned to the fourth quadrant (u ′ > 0 and v ′ < 0)

which involve the flow transport to the wall increasing

the shear stress. This is shown in Figure 2.

At any point in stationary flow, the contribution to

the total Reynolds stress from quadrant i, excluding a

hyperbolic hole region of size H , is:

where ⟨u ′ , v ′ ⟩ i,H = contribution from quadrant i for a

certain threshold value H ; I i,H (t, H)= function that

registers the event and takes the following values:

1 If (u ′ , v ′) is inside the quadrant i, and if ❙ ❙ u ′

, v ′ ❙ ❙ ≤H ❙ ❙ u ′ , v ′ ❙ ❙

0 otherwise Interacciones internas 3 Barridos 4 v′ Eyecciones 5 2 Interacciones externas 1 u′ H Figure 2. Sketch of region in the u ′ v ′ plane. The stress fraction transported by the contribution defined is: And the time fraction during which this contribution is being made is: 3.1 Fractional contribution to the total Reynolds shear stress In the Table 1 the obtained values and the fraction of time of contributions for a profile located in the separation zone, to a height from the bed equal 0.05 m to Med1 is shown as an example. In the Table 1 it is shown that for a value of H = 8, while the second quadrant contributes 33.72% in a 2.7% of time, the contribution from the 4th quadrant is very little. In Figure 3 the contribution of the ejection for H = 2 and 4 (Q 2,2 and Q 2,4) in the whole wavelength (λ= 2.30 m) is shown, giving a wider vision of the transport dynamics of stress from the second quadrant. In Figure 4 the sweeps contributions are shown. Generally it can be said that when H increases the fourth quadrant contributions decrease more rapidly, while the ejection events continue generating stresses and the contribution fraction of time, T 4,H and T 2,H , from H = 4 become insignificant. This demonstrates that the process of transport is highly intermittent in the sense that it occurs during periods of great turbulent activity, what occupies a small fraction of time (Raupach, M.R., 1981). In Figures 5 and 6 the contributions of the ejection and sweeps respectively for the case of the bed with super-imposed little dunes can be observed (Med2). Table 1. Contributions and time fraction of the contribution to the Reynolds stress from the four quadrants. analysis of the interaction of the turbulence with the

mean flow.

The theoretical curve of the dimensionless spatial

macroscale, was determined according to the Nezu, I

and H. Nakagawa (1993).

The experimental values found in Med1 and Med2

are below the theoretical values. In Figure 8 the vari

ation of the macroscale in the two bed conditions are

observed.

4.2 Taylor's microscale λ

At Every point of each profile the value of Taylor's

microscale was calculated according to the Nezu, I

and H. Nakagawa (1993). The experimental data are

over the theoretical curve but they still keep a trajectory

almost parallel to it. In Figure 9 the found experimental

are shown.

4.3 Kolmogoroff’s Microscale η

The Kolmogoroff length microscale is the smallest one

manifested in the turbulence, this one decreases when

the dissipation increases.

This microscale is defined in function of the inward

variables ν and ε (Friedlander, F and L. Topper, 1962). Med1 Med2 y (cm) (m) 0 5 10 15 20 25 y (cm) 0 5 10 15 20 25 x (cm) 0.0000 0.0000 0.0001 0.0002 0.0003 0.0004 0.0005 (m) 0.0000 0.0000 0.0001 0.0002 0.0003 0.0004 0.0005 x (cm) 0 10 20 30 40 50 60 70 80 90 100 110 120 130 140 150 160 170 180 190 200 210 220 230 0 10 20 30 40 50 60 70 80 90 100 110 120 130 140 150 160 170 180 190 200 210 220 230 Figure 10. Curves of Ftke/U* 3 = 0.20; 0.30 and 0.40 for the two bed conditions. 5 WALL SIMILITUDE According to the wall similitude hypothesis, there exists a transport of Turbulent Kinetic Energy in dynamic equilibrium state towards the free surface verifying a constant value of Ftke in the intermediate zone (0.15< y/h p < 0.70). For high Reynold’s numbers, the dimensionless Kinetic Energy flow with the cubic shear velocity, is a constant value equal 0.30 (López and García, 1999). In the Figure 11 the experimentally found values were drawn. 6 CONCLUSIONS (a) The stele formed by the sweeps (fourth quadrant) in the zone of reestablished flow in Med1, has a thickness bigger than in Med2, whichshows that, apparently, the presence of the little dunes would increase the contribution are from the second quadrant (ejection) near the bed and specially near the crest. The predominance of the sweep events over the ejection ones in the bed proximity and consequently the total shear stress increase could influence in the resuspension elements and sediment transport in the mentioned zone. (b) In Med1 as well as in Med2, the values of Lx are below those previous studies of flow in open channels (Nezu, I., 1977a; Raichlen, F., 1967).

(c) The data of Taylor’s microscale obtained in this work are minor in a 50% than the ones found in previous studies about flow in open channels for high Reynold’s numbers and smooth bed (Nezu, I., 1977; Laufer, J., 1954; Raichlen, F.,

1967) and low Reynold's numbers and rough-bed (Nezu, I., 1977a; McQuivey et al., 1969).

(d) With regard to the wall similitude hypothesis, not in any of the two conditions of flow studies in the equilibrium area has been detected where, the production of Kinetic Energy is balanced with the local dissipation rate. Apparently in the case of a dune's train a dunes with super-imposed little dunes we would be in presence of an intermediate area vulnerable to the interactions between the internal and external area.

ABSTRACT: Many studies concern the influence of bed-load on flow resistance in wide open channels and

flumes. In this work the effect of bed-load concentration on the friction factor was investigated experimentally in

a narrow channel. Tests were performed both in clear water and sediment transport conditions, using a roughened

fixed bed.The present approach revises the Einstein side-wall correction procedure for the decomposition of flow

resistance between the bed and the walls, which are of different material and, consequently, different roughness.

From the velocity profiles, measured through micro-propellers, it was possible to obtain the bed shear velocities

and, then, the mean bed and wall friction factors. An equivalent friction factor was finally obtained. The effects

of the sediment concentration on velocities and resistance was analyzed. Also the influence of the walls on the

velocity distributions was observed and commented on.

1 INTRODUCTION

Many studies can be found in the literature about the

influence of bed-load on flow resistance in wide open

channels and flumes.

It is well-known that sediment transport requires

an energy expenditure from the flow, thus increasing

resistance and reducing velocities.

In the case of narrow channels, the influence of

the walls is exerted on the velocity distributions, and

in a different way in clear water conditions or in the

presence of bed-load.

In the following sections a quick review about the

friction factor is presented in both situations.

Revising the Einstein (1942) side-wall correction

procedure, in order to take into account the differ

ent roughness of bed and walls, an equivalent friction

factor is introduced.

1.1 Clear water friction factor

In steady, uniform turbulent open-channel flows on

a fixed bed, the velocity distribution law may be

expressed as follows: where u is the time mean velocity in streamwise direction, u ∗ the shear velocity, κ= 0.4 the von Kármán constant, z the height above bed, z 0 the turbulent length, which «describes the characteristic "hydraulic" friction length (or roughness) for the boundary» (Smart 1999). The shear velocity is a function of the shear stress, τ 0 : where ρ is the water density, g the gravity acceleration, R the hydraulic radius and S 0 the longitudinal energy slope, equal to the channel slope in uniform flow conditions. Introducing the friction factor in clear water conditions, f 0 , in the well-known Darcy-Weisbach form: U being the cross-sectional mean velocity, the following expression is obtained:

In the case of narrow channels, i.e. for B/h< 3.5,

where B is the top width and h the water depth (Song

et al. 1998), the border effects influence the veloc

ity distribution, which therefore does not present the

maximum value at the water surface, but below it.

In addition, the shear stress distribution is not con

stant over the bed (see, for example, Knight & Sterling

2000). Hence, the friction factor in narrow channels is

not expressible with Equation (3), where the hydraulic

radius is referred to the whole cross-section. In fact,

the shear stress assumes different values not only at the bed and the side walls, but also across the bed itself. Following the side-wall correction procedure first pro posed by Einstein (1942), for the correct computation of the friction factor in narrow channels it is necessary to subdivide the cross-section into three portions, one relative to the bed and two relative to the side walls: the central portion will be characterized by an average hydraulic radius R b and an average friction factor f 0,b , whilst the lateral portions by R w and f 0,w (Fig. 1). In the present work a laboratory test is presented, aimed at the determination of an equivalent friction factor, f 0,eq :

where P b and P w are the wetted perimeter of the bed and the walls, respectively; P=P b +P w is the total wetted perimeter.Analogously, f 0,b and f 0,w are the fric tion factors relative to the bed and walls, respectively: A b A w /2 A w /2 P b P w /2 P w /2

Figure 1. Ovoid section of composite roughness. The wet ted areas and perimeters relative to bed and walls are indicated with A b , P b and A w , P w , respectively.The fixed bed is made of a gravel layer glued on a PVC strip, as explained in Section 2. 1.2 Friction factor in the presence of bed-load In the presence of bed-load, an increment of resistance occurs (May 1982; Mayerle et al. 1991; Song et al. 1998; Gaudio & Miglio 2003; etc.). In this case, the friction

factor, f s , may be expressed as follows: where C V is the volumetric sediment concentration and d 50 the median grain diameter. In the following sections, some laboratory tests are presented, aimed to the determination of an equivalent friction factor, f s,eq : where f s,b and f s,w are the friction factors relative to the bed and the walls, respectively. 2 EXPERIMENTAL INSTALLATION Experiments were carried out at the Laboratory of Hydraulic Models of the Department of Soil Defense, University of Calabria, Italy. The facility was an 11.0 m-long semi-ovoid perspex channel (250 mm× 375 mm ovoid cross-section), bolted to a tilting truss with longitudinal slope variable from 0.00 to 5.00%. The channel bottom was made of a 140 mm-wide and 4.0 mm-thick PVC strip, set at the distance of 40 mm from the channel invert (Fig. 2). 11.00 m Flow direction Fixed bed A A a) Plan view A-A b) Cross section PVC Uniform fine gravel layer 47 mm 0.140 m h 0 140 mm Figure 2. Schematic diagram of the experimental channel. The uniform flow depth is indicated with h 0 .

The sediment used in the tests was a uniform fine

gravel, with a median diameter d 50 = 3.0 mm and a

specific weight γ s = 26.5 kN/m 3 .

Along the whole channel, a layer of sediment was

glued on the PVC strip.

The channel was fed through a 100 mm diameter

pipe. The water flowed into a tank at the upstream end

of the channel; a grid was inserted to minimize flow

disturbances at the channel inlet. The discharge was

measured with an ultrasonic flowmeter mounted on

the feeding pipe.

A restitution channel, with a Thomson weir for

calibration, receives the water flowing from the down

stream end of the experimental channel.

Water depths were measured with a digital point

gauge with an accuracy of ±0.01 mm, whereas local velocities with a micro-propeller. These instruments were mounted on a gantry manually moving on rails placed above the side walls of the channel.

Sediments were introduced into the channel through an Archimedes's screw fed from a 70 dm 3 hopper, with a chute attached. The screw is driven by a potentiometer, which permits setting a constant value of the screw rotation velocity; therefore, a uniform volumetric sediment discharge can be injected. The potentiometer was accurately calibrated versus solid discharge. The solid discharge is a linear function of the potentiometer frequency.

The maximum value of solid discharge was 1211 g/min.

The sediment transported by the flow was collected in a basket at the experimental channel outlet, properly dried and weighed, in order to verify that the solid discharge at the outlet was equal to the injected one.

3 TESTS

Six tests were performed in October 2003.

Test 0 was carried out in clear water conditions, tests 1 to 5 in the presence of sediment feeding.

Table 1 presents the hydraulic characteristics of tests, h 0 being the uniform flow depth. The ratio B/h 0

was always less than 3.5, confirming that the channel

can be considered as narrow. The solid discharge, G s ,

and the volumetric concentration, C V , are also shown.

Table 1. Hydraulic conditions of tests. S 0 Q h 0 B G s

4 0.010 11.4 68.6 214 3.12 1009 5.5 · 10 −4

5 0.010 11.4 69.2 214 3.10 1211 6.6 · 10 −4 No test presented deposit on the channel bed, also for the maximum value of bed-load (test 5). It is to be noted that the normal depth, h 0 , slightly increased in the presence of bed-load. In tests 3 to 5 a mobile layer much thicker than d 50 was observed (thickness about 8 mm). According to Sumer et al. (1996), it can be said that a sheet flow layer occurred. The presence of the layer justifies the water depth increment. For the measure of water depth and local velocities, the middle section, located 5.5 m downstream of the inlet, was selected. In fact, this section was distant enough from the end sections to permit the uniform flow conditions to be established, as verified through the acquisition of the water surface profile. In particular, for each test, the velocity profiles were acquired along three verticals, as shown in Figure 3. The left and right verticals were chosen symmetric respect to the centerline. Along each vertical, the first value was measured at the height of 10 mm above the gravel bed; the successive 5 measurements were acquired with a step of 2 mm, and the remaining measurements with a step of 5 mm (Fig. 3). At each position, the time mean velocity in streamwise direction, u, was acquired over a 30 s interval. 4 RESULTS Figures 4 and 5 show the experimental velocity distributions respectively at the centerline and the lateral verticals, where similar results were obtained, as expected in the present symmetric case. 20 mm 20 mm 50 mm 50 mm Right vertical Left vertical Centerline h 0 47 mm m Figure 3. Measuring section. Local velocities were measured at the positions indicated along the three verticals for a

30 s time interval.

Figure 5. Local time mean velocity distributions (lateral

verticals).

It is observed that the local velocities decrease as

the volumetric sediment concentration increases.

In addition, the C V increment produces greater

velocity gradients near the bed, as also observed by

Omid et al. (2003).

The influence of the walls in the narrow channel is

evidenced in the following findings:

1. the maximum local velocity is measured below the

water surface;

2. the velocities measured along the lateral verti

cals are less than the velocities measured along

the centerline at the corresponding distances from

the bed.

Figures 6 and 7 show the local time-averaged

It is observed the linear regression straight lines relative to the first seven points. The slopes of the straight lines were used for the determination of the bed shear velocities. The interpolated points fall in both the inner region (z/h 0 ≤ 0.2; Graf & Altinakar 1998) and the overlapping region (Smart 1999; Yen 2002). In fact, the relation expressed by Equation (1), which is rigorously valid only for the inner region, can be extended also to the overlapping region, where the velocity distribution is still logarithmic (Graf & Altinakar 1998; Smart 1999; Yen 2002). The bed shear velocities at the centerline, u ∗,bc , and at the lateral verticals, u ∗,bl , were obtained. Then the

following average value was computed:

The average bed hydraulic radius is determined as follows:

The mean bed and wall friction factors, f b and f w respectively, are obtained from Equations (6) and (7) for clear water conditions and analogously in the presence of bed-load.

In particular, the average wall hydraulic radius is determined as follows:

where the wall wetted area, A w , is the difference between the total wetted area, A (expressed as a function of the normal flow depth, h 0), and the bed wetted area, A b =R b ·P b (Fig. 1):

Eventually, the equivalent friction factor, f eq , is obtained from Equation (5) for clear water conditions and analogously in the presence of bed-load.

Results are presented in Tables 2 to 4. In particular, Table 4 reports the bed and the wall Reynolds number,

Re b and Re w respectively, the grain Reynolds number,

Re ∗ , and the Froude number, Fr, computed as follows: Table 3. Friction factors. where ν= 10 −6 m 2 /s is the water kinematic viscosity. The flow was fully turbulent and supercritical, as confirmed by the values of the Reynolds and Froude numbers, respectively: Re b > 2000, Re w > 2000, Re ∗ > 200 (see Graf &Altinakar 1998;Armanini 1999) and Fr> 1. Figure 8 shows the mean bed and wall friction factors and f eq versus the volumetric sediment concentration, C V . It is observed that the mean bed friction

factor increases with C V up to about 20%, whereas

the mean wall friction factor decreases down to about

48%. The equivalent friction factor, being a weighted

average value (with very similar values of the bed and

wall perimeters), is almost constant and presents a light

increment (about 7%) at the highest concentrations.

Figures 9 and 10 show the normalized velocity

differences, σ ij , between the time mean velocities mea

sured in the presence of bed-load (tests 1 to 5) and

the corresponding velocities measured in clear water

conditions (test 0) at the same height above bed: 0

Influence of macro-roughness arrangement on flow resistance

F. Canovaro, E. Paris & L. Solari

Department of Civil Engineering, University of Firenze, Italy

ABSTRACT: Experimental data on regular spaced strip arrangement of macro-roughness element are herein

analysed by means of a two-layer model, in order to evaluate flow resistance and drag shear stress. Seventytwo

experimental runs have been carried out in a glass walled tilting flume. Discharge was varied from 7.3 l/s to 13.5 l/s

and slope was varied from 1.0% to 2.5%.Three different pebble sizes with a median axis from 4.3 cm to 8 cm were

used as macro-roughness elements. Pebbles were placed on a granular plane bed to achieve a bottom geometry

configuration of transverse regularly spaced strips. Results underline a non-linear behaviour of Chezy coefficient

as a function of strip wavelength to height ratio, showing a minimum of conductance. Analogously, form induced

shear stress presents a maximum, around 80% of total bed shear stress. Even if the reproduced pattern appears to be not wholly representative of natural conditions, comparison of results with other field and laboratory data seems to indicate that a similar dissipative behaviour is recognisable in natural bed forms such as step and pools or dunes.

1 INTRODUCTION

Flow over macroscale roughness may occur in various situations, such as in mountain streams and vegetated channels. In the case of mountain streams, due to the presence of large rocks and boulders protruding from the channel bed and large bed slope, the flow depth is typically comparable with the size of the roughness. In these conditions the longitudinal velocity profile is known to deviate from the classical log law and the classical expression of flow resistance formulae elabo rated in the case of lowland rivers are no longer valid (Bathurst 1987).

In particular various Authors (Bathurst 1981, 1985, Baiamonte et al. 1995, Ferro 1999) suggest that flow resistance is a function not only of the relative sub mergence (defined as mean flow depth to charac teristic sediment diameter ratio) but also of further additional parameters related to the “roughness geo metry”, such as spatial density and arrangement of macro-roughness elements. In particular Baiamonte

et al. (1995) suggest, in case of absence of vegeta

tion, the following functional relationship for Chezy

coefficient:

where Re and Fr are flow Reynolds and Froude

numbers, k is relative submergence, '' is spatial

density, P 1 and P 2 are two parameters related to

the planimetric layout of macro-roughness elements (hereafter referred as pattern) and τ* is the Shields parameter. The influence on flow resistance played by Re, Fr, k, and τ* in the case of mountain streams, has been widely investigated by several Authors (Baiamonte 1995, Bathurst 1981, Colosimo et al. 1988, Ferro 1999, Graf 1984); while the role played by macro-roughness spatial density and pattern, is not completely clarified. Rouse (1965) indicates, in the case of a regular pattern, that there exists an optimum value of spatial density, ranging between 0.15–0.20, which produce the maximum of flow resistance. As pointed out by Morris (1971) for flow in closed conduits, Rouse findings may be explained in terms of a different behaviour of flow motion in relation to the spatial density of macro-scale roughness. For low values of density, when macro-roughness are “isolated”, motion might be regarded as a “non wake interfering” like, while for high values of density, wakes impact together and dissipation decreases. In order to study the effects of bedforms on flow resistance, a special type of pattern, formed by macroroughness elements arranged according to regularly spaced strips placed perpendicular to flow direction, has been investigated. In particular Davies (1980) and Wohl & Ikeda (1998), suggest that maximum of flow resistance occur when the spacing between the strips is about 10 times the height of macro-roughness elements. In the present analysis, we investigate flow resistance in the case macro-roughness elements placed according to regularly spaced strips across the plane

bed of a flume. The results obtained are discussed

and compared with those proposed by other authors

(Egashira & Ashida 1989, Aberle & Smart 2003)

interpreting flow resistance in natural bedforms such

as step & pool or sand dunes. Results indicates the presence of a maximum in flow resistance when the ratio strip wavelength to height is close to the val ues commonly observed in natural bedforms, such as step & pool bed forms.

2 THEORETICAL FRAMEWORK

Flow resistance is herein investigated by means of an analytical model, extended from Canovaro et al. (2003), according to which flow region, whose depth is indicated by Y , is divided in two layers.

A bottom layer, laying on the bed, containing part of macro-roughness elements, in which the flow is dominated by the loss of momentum due to the drag around the obstacles. In such layer of thickness d the flow velocity V b is relatively low and approximately constant.

An upper layer of height Y -d, where the mean flow velocity U is relatively high.

This velocity profile is defined by four variables: U , V b , Y and d. U and Y are obtained via experi ments, d and V b are unknowns determined by solving flow continuity and streamwise momentum balance equations. Steady flow and spatially averaged uni form conditions are here taken into account. In these conditions, governing equations read as follows:

Notations are given at the end of the paper.

In the streamwise momentum balance equation

(eq. 2) there are three components: the total water

weight along the streamwise direction F g , the resis

tance associated to the drag around macro-roughness

elements F d and the resistance due to the surface fric

tion of both granular and boulder surface F s . These

components read as follows: In the continuity equation (eq. 3), ψ denotes a reduction coefficient (always< 1) of flow velocity into the bottom layer to take into account the effective area occupied by the flow; thereforeψV b denotes the mean (apparent) velocity in the lower layer. For regular spaced strips the reduction factor has been defined as the ratio strip length (D l) to strip wavelength and reads as follows: Chezy coefficient is obtained from the following: where: 3 EXPERIMENTAL APPARATUS The experiments are carried out in a 10 m long, 36.5 cm wide and 50 cm deep glass-walled recirculating tilting flume. The measuring reach is 4 meter long with a bed covered by a layer of granular uniform material having a medium size of 7 mm. Over this granular layer (Fig. 1) the macroroughness elements (represented by pebbles) are disposed in order to roughly simulate natural macroroughness arrangement, such as bed forms or random distributions. In order to dissipate flow disturbances, before the beginning of the measuring reach a transition reach composed by little quarry rubbles is positioned (Fig. 2). In the experiments three different sets of pebbles are used, characterized by different medium axis values according to the Wentworth sedimentological scale, as presented in Table 1. Figure 1. Streamwise section of the velocity profile.

The pattern here investigated is represented by

“transverse rows” (Fig. 4) and it refers to a stream

wise sequence of strips. Each strip is made by pebbles,

placed over the granular layer with the long axis in

flow direction and the short axis perpendicular to the

bottom of the flume.

For each set of pebbles the “wave length” λ, i.e. the

spacing between two following strips, is varied from

15 to 80 cm. Experiments have been carried out with

different discharges from 7.3 to 13.5 l/s, and slope is

varied at 1.0 and 2.5 percent.

For each run both total water depth Y and mean

flow velocity U are measured. Several time-averaged

values of water depth and flow velocity are taken for

each run along the measuring reach.

Water surface elevation is measured by means of a

set of 19 piezometers, placed below the granular layer,

Flow velocity is taken in 33 different points along a wavelength across the middle strip, by means of a micro propeller meter (Fig. 5). Each value is the result of a 400 velocity time-averaging readings, corresponding to a measurement time of 10 seconds. As for the water depth measurement, one space-time averaged velocity value is obtained for each run. At the end of the experimental activity we have collected 47 runs divided in 5 experiments, each experiment is characterized

by different strip height, slope or discharge. A summary of the performed experiments is reported in Table 2. Figure 4. Arrangement of the “transverse rows” pattern. Figure 5. 4 RESULTS

Results concerning drag shear stress, dimensionless

Chezy coefficient and equivalent roughness are here

presented and compared with experimental findings

proposed by other authors, on both geometric strip

patterns and laboratory step-pool bed forms.

In Figure 6 the ratio between drag induced shear

stress and total bed shear stress, τ d /τ g , as a function

of the λ/D s ratio is presented.

τ d /τ g ratio presents two asymptotic values: ~0.15

when λ/D s → 1 (maximum packing) and 0 when

λ/D s →∞ (no macro-roughness). Far from these two

asymptotic values, it appears that the drag component

fraction is always over the 50% of the total bed shear

stress, reaching a maximum of about 80% when λ/D s

ratio is around 10. This value of λ/D s corresponds to

a pebble areal concentration ranging around 0.20.

A comparison between present results and the ones

obtained from Canovaro et al. (2003) in case of “ran

dom” pattern is presented in Figure 7. It appears that

for a similar value of pebble concentration, even the

“random” pattern exhibits a maximum, of relatively minor intensity, of τ_d/τ_g.

This result may indicate that regular strips have a deeper influence on flow dissipative mechanism than random elements. From equation (2):

it appears that the surface shear stress τ_s is a small fraction of total bed shear stress τ_g, being τ_s/τ_g ranging around (0.20–0.40), when λ/D_s ratio is around 10.

In Figure 8 is a plot of Chezy coefficient behaviour as a function of λ/D_s ratio. Analogously to τ_d/τ_g ratio also Chezy coefficient behaviour is not monotonic, showing a minimum at the same λ/D_s value at which the relative drag shear stress reaches a maximum. Chezy coefficient is also affected by discharge and slope, increasing as Q increases and S decreases.

The presence of a maximum in flow resistance in case of regular spaced strips has been demonstrated by several Authors.

Wohl & Ikeda (1998) through an extensive experimental activity employing regular spaced strips, obtained a Chezy coefficient behaviour in agreement with the results herein presented, as shown in Figure 9. In particular it can be noted that Chezy coefficient is minimum when λ/D_s is around 10.

Such behaviour is also confirmed by a compar

ison with results obtained by Johnson & LeRoux

(1946) regarding the relative roughness, in the case

of geometric strips (Fig. 10). The comparison shows a

maximum when λ/D s ≈ 10, again in agreement with

results herein presented. Figure 6. Ratio of drag induced shear stress τ d to total bed shear stress τ g as a function of ratio of wavelength λ to strips height D s . Figure 7. Ratio of drag induced shear stress τ d to total bed shear stress τ g as a function of pebble concentration, as from present experiments and experiments from Canovaro et al. (2003) in the case of “random” pattern. Figure 8. Dimensionless Chezy coefficient as a function of ratio of wavelength λ to strips height D s .

Figure 9. Comparison with Wohl & Ikeda (1998)

experiments.

Figure 10. Comparision with Johnson & LeRoux (1946)

experiments. In our case the t/H ratio is around 2, with

t corresponding to D l and H corresponding to D s .

Even if “transversal rows” pattern is only a geo

metrical schematisation of natural situations, it seems

reasonable to consider some general analogy between

flow resistance in natural streams and in laboratory

flumes.

In particular other Authors (Abrahams et al. 1995,

Chin 1999) have observed that λ/D s attains values

around 10 in the case of natural streams with slope

ranging between (0.01–0.025). The latter result may

indicate that step-pool streams evolve toward an

arrangement of steps that maximizes resistance to

flow, increasing the form resistance despite of the

surface resistance, in the way to reach a stable arrange

ment (Abrahams et al. 1995).

In the light of the above findings, it seems reason

able to assume that the “transverse rows” pattern is able

to reproduce the fundamental dissipative mechanisms Figure 11. Comparison with Aberle & Smart (2003) formula.
occurring in natural streams with a step-pool morphology.The validity of such assumption is discussed in the following. Aberle & Smart (2003) derived an empirical formula for the flow resistance in a step-pool morphology from experimental data obtained by Koll (2002) and Rosport (1997). The experiments were carried out in a tilting flume with slopes of 2, 4, 8 and 9.8%, employing two different coarse sediment mixtures, in the way to obtain real step-pool structures.The empirical formula in terms of Chezy coefficient reads as follows: In Figure 11 equation (11) is shown and compared with the present results. It appears a good agreement even if Aberle & Smart formula tends to slightly overestimates the Chezy coefficient. This behaviour is probably due to the fact that Aberle & Smart have employed a mixture of sediments obtaining a rather smooth step-pool profile. Finally, the formula proposed by Egashira &Ashida (1989) to evaluate flow resistance in presence of steppool bed forms, has been compared in Figure 12. The formula reads as follows: The comparison shows a good agreement of experimental data with equation (12), especially for λ/D s values around greater than 6-7.This behaviour is probably due to the fact that below this value the wavelength of the strips is too small to be interpreted by Egashira & Ashida formula.

Figure 12. Comparison with Egashira & Ashida (1989)

formula.

5 CONCLUSIONS

An extensive laboratory experimental activity has been

carried out in order to investigate the influence on flow

resistance of a regular spaced pebble strips arrange

ment, in the case of various flow conditions and strip wavelengths.

Experimental measurements are analysed by means of an interpretative extended model, derived from a previous paper (Canovaro et al. 2003). The model allows to investigate the behaviours of Chezy coef ficient and relative drag shear stress as a function of the strip wavelength.

Results suggest that when dimensionless strip wavelength (λ/D s) is around 10, Chezy coefficient and relative drag shear stress (τ d /τ g) present a min imum and a maximum, respectively. In particular the minimum of Chezy coefficient is substantially smaller (about 60%) than in the case of a bed completely cov ered by macro-roughness elements; at the same time drag shear stress is around 80% of total bed shear stress.

A comparison between present results and the ones obtained from Canovaro et al. (2003) in the case of “random” pattern suggests that, even if both patterns displays similar behaviors, “transverse rows” pattern have a deeper influence on flow dissipative mechanism than random elements.

The presence of a minimum of Chezy coefficient, when λ/D s is around 10 has been also pointed out

by other Authors (Wohl & Ikeda 1998; Johnson &

LeRoux 1946); moreover an overall good agreement

with present and latter Authors results is displayed.

An analogy between flow resistance in natural

streams and in laboratory flumes has been discussed;

in particular it seems that “transverse rows” pattern is

able to reproduce the dissipative mechanisms occur

ring in a natural step-pool morphology. In particular observations of other Authors (Egashira & Ashida 1989; Abrahams et al. 1995; Chin 1999; Aberle & Smart 2003) show both that λ/D s attains values around 10 in the case of natural streams with slope ranging between (0.01-0.025), and that Chezy coefficient behaviour associated to natural steppool configurations is in agreement with results herein presented. The above findings may indicate that step-pool streams evolve toward an arrangement of steps that maximizes resistance to flow, increasing the form resistance despite of the surface resistance, in the way to reach a stable arrangement (Abrahams et al. 1995).

The effect of bed roughness on velocity profile in open channels

A. Mahdavi & M.H. Omid

Dept. of Irrigation and Reclamation Eng., Tehran University, Tehran, Iran

ABSTRACT: The effect of bed roughness and bed load movement on flow velocity profile in an open channel

with uniform flat-bed is experimentally investigated. Experiments were performed in a tilting channel of glass

sides and smooth bed made of Perspex, and of rectangular cross-section 250 mm wide and 12.5 m long. Two

different grain sizes with diameter of 0.5 and 2.84 mm were used for the roughening of the bed and sediment

injection. Sediment injection was performed with the same size of particles used for roughening the bed. Point

velocities were measured by a 10 mm propeller current meter. The results indicate that the logarithmic law for

velocity profile is valid for different bed conditions and bed load concentrations. However, lower part of the

profile is influenced by the bed roughness resulting steeper slope of the profile in logarithmic region. Since the

slope of this profile increases, shear stress and consequently friction factor increases, affecting the bulk of flow

to reduce the mean flow velocity.

1 INTRODUCTION

The velocity profile is closely related to the friction

factor and boundary roughness, though the connec

tion had received relatively little attention until 1980.

Because the friction factor can be estimated from the

bulk measurements without having to obtain the veloc

ity profile, earlier works until 1980 had tended to

consider the two separately, in many cases ignoring

the velocity profile altogether since the friction fac

tor is often of more direct engineering interest. The

renewal of interest in the characterization of velocity

profiles due to work of Itakura and Kishi (1980) and

particularly Coleman (1981, 1986) had led to further

debate concerning the friction factor.

In open-channel flow the velocity is not uniformly

distributed. In this research, only vertical velocity pro

file is studied. In case of gravel bed and turbulent flow

the vertical velocity profile is often assumed to be loga

rithmically distributed (e.g. Chow, 1959; French, 1986;

Graf 1998 and Ferro, 1999). Logarithmic velocity

profile can be shown by:

where u= velocity [m/s] in distance y [m] from the

bed; u * = the shear velocity [m/s]; κ=Von Karman

constant; and y 0 = the integral constant.

The flow can be hydraulically either smooth or

rough. Hydraulically smooth flow occurs when the surface irregularities are so small that all roughness elements are entirely submerged in the laminar sub layer (Chow, 1959). Therefore, the bed roughness will not affect the velocity distribution. According to Graf (1998) and Schlichting and Gersten (2000) the flow is smooth if: where ν= kinematic viscosity [m 2 /s]; and k is the roughness height [mm]. Substituting y 0 for smooth channel in equation 1, one gets: The flow is rough when bed roughness is so large that it produces eddies close to the bottom (Liu, 2001). There is no viscose sub layer and the velocity distribution is affected only by bed roughness. According to Graf (1998) and Schlichting and Gersten (2000) the flow is hydraulically rough if: Substituting y 0 for rough channel in equation 1, it follows:

In this equation the roughness element k s , may be con

sidered as the sum of the skin roughness, and sediment

transport roughness (suspended load and the bed load

transport).

In studies of flow with suspended sediment, two

concerns often raised are the effects of suspension on both velocity distribution and flow resistance. Based on the experimental results of Vanoni (1946), Einstein and Chein (1955) and Elata and Ippen (1961), as the sediment concentration increases, the Von Karman constant becomes progressively smaller than that of the clear water value of 0.4. However, this view is not universally endorsed. Imamoto, et al. (1977) found that κ increases with sediment concentration in their exp eriments while Fukuoka (1980) and Itakura and Kishi (1980) suggested that the value of κ does not change. Coleman (1981) analyzed his own data and reexam ined the data from earlier experiments to show that the change in κ, which was found in the earlier works, were due to incorrect application of logarithmic velocity distribution to the outer flow region where the logarith mic law is really not valid. By applying the logarithmic law only to the region close to the bottom boundary, Coleman found that the presence of suspended sedi ment has no effect on the value of κ. The value of κ was found to conform to the law of the wake which was introduced by Coles (1956) for boundary layer flows. It appears that Coleman (1981) has presented the most convincing argument to date on the effects of sus pended sediments on the velocity distribution in open

channels.The general velocity profile given by the log arithmic law plus a wake function seems to be valid for all of the flow depth outside of viscose sub layer.

In comparison to suspended load transport, a few studies were found in the literature regarding the effects of bed load movement on flow resistance and velocity distribution. The generally accepted view is that bed load extracts momentum from the flow which causes a reduction of flow velocity and increase of apparent roughness length (Ryckoczi, 1967; Kennedy, 1969; Wang & Chien, 1985; Mclean, 1992; Song et al., 1998; Begeron et al., 1999). But some researchers believe that bed load movement has no effect on flow resistance (Einstein & Barbarosa, 1952; Vanoni & Nomicos, 1960; Yang & Hirano, 1995).

In this research, the effects of skin roughness and bed load movement with different concentrations on flow resistance and velocity profile are experimentally investigated.

2 EXPERIMENTAL SET UP AND PROCEDURE

Experiments were performed in a tilting channel of glass sides and smooth bed made of Perspex, and of rectangular cross-section 250 mm wide and 14 m long. The downstream end of the channel is provided with a sediment trap with a collecting basket and the weight of sediments

collected in the basket is continuously measured by a digital weighing scale. Downstream of the sediment trap is a tailgate consisting of a set of horizontal rotating flaps to provide various degrees of opening for the water to flow through. The tailgate is used to adjust the depth of water in the channel without causing undue backwater effects into the channel. In each of the experiments clear water is supplied at a steady rate from an overhead constant head tank. For experiments with the rough bed, a single layer of uniform sand was glued onto the Perspex bed. The same size of sand was injected to the flow using a screw feeder system to produce bed load at the beginning of the flume. Two different grain sizes d = 0.5 2.84 mm were used in the experiments. Point flow velocities were measured by a 10 mm propeller current meter. The experiments were carried out with (i) clear water over smooth and rough beds, and (ii) sediment laden flows over smooth and rough beds. In the first series, a number of preliminary experiments were carried out to determine the friction factor f , for smooth and rough rigid beds. Various slopes of the channel and velocities of flow were considered in these experiments. This information was then used to set the depth of flow before injecting sediment at the upstream end in the main experiments. Prior to the experiments with sediment-laden flow, for a given slope of the channel and discharge of water, a uniform flow without sediments was first obtained by adjusting the tailgate to attain a prescribed depth. Different concentrations of sediments were then injected into the flow at constant rate at the upstream end of the flume. The rate of sediment supply was kept constant by adjusting the feeder and keeping the sand level coinciding with the top level of the container. Flow measurements were made for various injection rates less than the rate at which initiation of sediment deposition on the bed was observed. Bed load particles were collected in the sediment trap provided at the downstream end of the flume to be removed periodically. For each injection rate I expressed in terms of mass rate, the corresponding volumetric concentration of sediment C is simply where Q= the water discharge and S s = the sediment density, is taken to be 2650 kg/m 3 . The experimental conditions are summarized as follows: • sediment diameters used: 0.5 and 2.84 mm • sediment concentration: 0.0025–0.0075 • water depth: 25–250 mm • mean velocity: 0.35–1.2 m/s • bed slopes used: 1:1000, 2.5:1000, 3:1000

For each sediment concentration, two or three flow

velocity profiles were measured along the vertical cen

terline of the cross-section of flow at a position located 8.0 m downstream from the location where sand particles were injected into the flow. Starting from 10 mm above the bed, which was dictated by the size of the current meter, velocities were measured at vertical intervals of 5 mm up to 20% of water depth and then at 10 mm intervals up to the water surface. The measured velocity profiles were then averaged to obtain the mean velocity profile corresponding to a particular sediment concentration. The mean bulk velocity U of each averaged profile was then obtained by integrating the profile over the whole flow depth. The shear velocity u* and the friction factor f were then calculated from the averaged velocity profile using the equations for velocity profile in rough turbulent flow and shear velocity.

3 RESULTS

Figure 1 shows the velocity profiles in normal and semi-log scales for clear water condition. These profiles are presented to show how the experimental results fit the logarithmic law given by equation 2.

3.1 Effects of bed roughness on velocity distribution

Two sets of velocity distributions related to the same discharge and bed slope are shown in Figure 2a and 2b to show how bed roughness changes the velocity

distributions.

Figure 2a shows velocity distributions for discharge

of 30 lit/s on smooth and rough bed. It can be seen that

with the same slope, as the bed roughness increases, 0 4 8 12 16 50 60 70 80 90 100 u (cm/s) y (c m) y = 0.0799x + 0.6739 u ∗ /k = S = 0.0799 u ∗ = 0.0799*0.4 = 0.0032 m/s 20 30 40 50 60 70 80 90 100 -1 0 1 2 3 Ln (y) u (c m / s)

Figure 1. Velocity profile related to clear water on smooth bed. the velocity decreases especially in lower part of the velocity profile. In other word, the amount of decrease in the lower part of the profile is more than the upper part. The velocities related to the bed roughness of 2.84 mm are higher because the slope of these experiments is more than the others. The amount of this increase in the upper part is more than the lower part. We can also see these results in Figure 2b that is due to discharge of 40 lit/s. As it can be seen from the figures, changes in discharge and bed slope affect the upper part of flow region while when the bed roughness is changed, the lower part is more affected.This makes the logarithmic part of velocity distribution steeper resulting higher shear velocity. So we expect more friction factor in rough beds. This is shown in Figure 3. This figure shows the logarithmic part of velocity profiles presented in Figure 2 in a semi-logarithmic scale (a is line slope). As shown in Figure 3, when the bed roughness increases, a and u ∗ are increased. This increase together with a reduction in mean velocity will increase the friction factor f , according to equation 7. in which U =mean flow velocity. 3.2 Effects of bed load roughness in velocity profile Figure 4a and 4b show the effect of size and concentration of injected sediments on flow velocity distributions. Figure 4a shows the velocity distributions related to smooth bed (clear water and rough bed with diameter Q = 30 S = 0.002, h = 16 cm S 2.84 = 0.005, h = 13.5 cm Clear Water 0 4 8 12 16 20 40 50 60 70 80 90 100 110 u(cm/s) y (c m) Rough Bed, d = 2.84 Smooth Bed Rough Bed, d = 0.5 Q = 40 S = 0.002, h = 20 cm S 2.84 = 0.004, h = 18 cm Clear Water Rough Bed, d = 2.84 Smooth Bed Rough Bed, d = 0.5 0 4 8 12 16 20 40 50 60 70 80 90 100 110 u(cm/s) y (c m)

Figure 6. Effect of sediment injection with different concentration on flow velocity in smooth bed.

of 0.5 and 2.84 mm). It shows that the increase of

diameter and concentration causes a reduction in flow

velocity.

Figure 4b shows the velocity distribution related

to smooth bed (clear water and sediment injection

(d = 0.5 mm) with two sediment concentration. It is

clear that sediment injection causes a reduction in

velocity especially in lower part of velocity profile.

It also shows that increasing sediment concentration causes more reduction of velocity in lower part of velocity distribution profile.

The logarithmic parts of the velocity profiles of Figure 4 are plotted in semi-logarithmic scales in Figure 5 to show the effect of sediment injection on the lower part of the velocity profile. It shows that sediment injection caused an increase in slope of logarithmic part of velocity distribution and shear velocity. Further, this shows increase of concentration also causes more increase in shear velocity. Figure 6 show the effect of different concentrations on velocity distribution related to rough bed. Figure 6a shows velocity distributions related to rough beds with d = 0.5 mm (clear water and two different concentrations of sediment injection with d = 0.5 mm). It can be seen that, first, sediment injection causes a reduction in velocity, especially in lower part of profile. Second, increase of concentration has increased this effect.This is also shown in Figure 4b which is due to sediment size d = 2.84 mm. The velocity profile of Figure 6 is also plotted in a semi-logarithmic scale in Figure 7 to see the effect of sediment injection with different concentrations on shear velocity. It can be seen that the sediment injection increase the shear velocity. Q = 45.13 S = 0.005 h = 17.5 cm Rough Bed d = 2.84 a = 1 0 . 7 7 a = 1 3 . 2 6 a = 1 8 . 6 6 a = 2 1 . 6 8 a = 1 2 . 4 5 a = 1 2 . 9 3 50 60 70 80 -0.5 0 0.5 1 1.5 ln(y) u (c m / s) Q = 40.2 S = 0.002 h = 20 cm Rough Bed d = 0.5 Clear Water c = 0.0026 c = 0.0037 Clear Water c = 0.0026 c = 0.0095 50 60 70 80 90 100 -0.5 0 0.5 1 1.5 2 ln(y) u (c m / s)

Figure 7. Mean velocity against ln(y) for logarithmic part of velocity profiles in Figure 6.

4 CONCLUSION

The effect of bed roughness and bed load movement on flow velocity profile in an open channel is experimentally investigated. Following are the conclusions:

- experimental results of smooth and rough bed fit the logarithmic law of flow velocity distribution profile,

- changes in discharge and bed slope influence the upper part of velocity profile,

- increase in roughness elements (skin roughness and bed load roughness) affect the lower part of profile making the logarithmic part of veloc ity profile steeper. Since the slope of this profile increases, shear stress and consequently friction fac tor increases, affecting the bulk of flow to reduce the mean flow velocity.

3D turbulent flow over irregular bed surfaces

W. Czernuszenko

Institute of Geophysics PAS, Warsaw, Poland

A. Rylov

Institute for Water and Environmental Problems, Barnaul, Russia

ABSTRACT: Features of 3D velocity field in an open channel with smooth and regular rough bed are suf

ficiently known and understood by civil engineers, whereas flows over irregular bed surfaces are still not fully

known. The paper deals with 3D rough turbulent flows in straight open channel with irregular bed roughness.

The bed of the channel is characterized by roughness elements which can be uniform or non-uniform in sizes,

and which can form regular or irregular surfaces of channel bed. It is assumed that the turbulence structure

above the viscous sublayer, over regular and non-regular bed roughness is the same and the logarithmic law

(Log-Law) describes this structure. This structure is scaled with height (distance from bed), friction velocity, the

absolute size of the elements forming the bed roughness and the coefficient designated by letter “B”. An open

channel turbulent flow is described by the Reynolds equations with simple turbulent model, which is based on the

assumption of isotropic but not homogeneous eddy viscosity at a cross-section.The eddy viscosity is described by

an enhanced mixing length hypothesis. The model also takes into account the non-isotropic character of normal

turbulent stresses at the channel cross-section. The Reynolds equations with the continuity equation for steady,

parabolic 3D turbulent flow in open channel are solved for irregular and different height of rough elements

forming the channel bed. It is shown how to define the boundary conditions for this bed and how to estimate the

parameters defining the turbulence structure over this bed. The numerical simulations show the disturbances in

velocity distribution due to the boundary irregularities. To smooth these disturbances the spatial average oper

ation is applied to get the equivalent Log-Law velocity profile, i.e. the equivalent shear velocity, the equivalent

size of roughness elements and equivalent coefficient B. It is shown that the boundary conditions defined by

this equivalent velocity give reasonable good prime velocity distribution as well as the secondary flow pattern.

1 BASIC HYDRODYNAMIC EQUATIONS

Three-dimensional, steady turbulent flow in an

open channel is governed by the Reynolds-averaged

Navier-Stokes equations. The continuity and momen

tum equations for incompressible turbulent flows may

be written in the Cartesian tensor notation in the forms:

continuity equation:

momentum equation:

where U i is i-th component of the time average veloc

ity (i= 1, 2, 3), p is the pressure, ρ is density and F= (g sin α, g cosα, 0). A notation of x for horizontal (longitudinal), y for vertical (downwards) and z for lateral coordinates as well as U, V, W for corresponding velocity components will be used also in the paper. 1.1 Turbulence model An applied turbulence model is simplified version of models presented by Czernuszenko & Rylov (2000) and Czernuszenko & Rylov (2003). The model describes the turbulence structure in the case of anisotropic normal turbulent stresses and the isotropic shear stresses in the form:

where u i is the ith component of turbulent velocity

vector, l is the mixing length, D ij is the deforma

tion rate tensor and quantity S is defined by formula

(Czernuszenko & Rylov 2000)

For the open channel flows the right-hand sum in Eq. 4

may be reduced to two terms containing derivatives of

streamwise velocities in lateral and vertical directions,

respectively.The other terms in the sum above contain

ing the lateral and vertical components of the mean

velocity vector do not exceed 1-2% of the streamwise

component. To solve Eqns. 1 and 2 the total turbulent

stress tensor must be known, i.e. the normal and shear

turbulence stresses at any point of the cross-section

should be prescribed. The normal turbulent stresses

and the shear turbulent stresses are defined according

to Czernuszenko & Rylov (2003).

1.2 Hydrodynamic model

Consider the tilted open channel with bed slope

defined by an angle . The flow is steady with aver

age velocity components (U, V, W) directed in x, y

and z directions, respectively. Turbulent transport of

momentum in x-direction is assumed to be negligi

ble. Therefore, the terms involving second derivatives

with respect to x may be omitted. This kind of flow

is usually called parabolic in longitudinal direction.

The basic equations describing the 3D-velocity field

in open channel flows are the continuity 1 and momen

tum equations 2. Substituting Eq. 3 into Eq. 2 and

neglecting higher order terms produces the momentum

equations in the form: where p is the pressure, S is defined by Eq.4. Details on the enhanced mixing length model can be found in Czernuszenko & Rylov (2003). Boundary conditions which accompany previous equations (Eqns. 5-7) need to be specified along solid boundaries, water surface and up-stream cross-section bounding the calculation domain. Since parabolic flows are considered, boundary conditions do not need to be given at the downstream end of the calculation domain. It is assumed that the flow is uniform with constant width and depth (rigid lid approximation, Rastogi & Rodi 1978). The conditions at the solid boundaries were specified using wall functions technique proposed by Launder & Spalding (1974), i.e., the conditions are specified at a point near a wall which lies outside the laminar sublayer and satisfy the logarithmic portion of the universal law of the wall where (a) for smooth channels $k^* = \nu/U^*$, $B \equiv B_s = 5.5$, (b) for rough channels $k^* = k_s$, $B \equiv B_r = 8.5$; U^* friction velocity, y distance from the wall, ν molecular viscosity, B coefficient and k_s the equivalent sand roughness. Normal velocity components at the solid boundaries and free surface are set to zero. The free surface boundary conditions were specified following the approach of Rastogi

& Rodi (1978), which considers free surface acting as a plane of symmetry. Therefore, the gradients of U and V in y-direction are zeros. The condition at the initial cross section x= 0 for longitudinal velocity U was taken along with logarithmic distribution. Components V and W were set equal to zero. The essential problem with the boundary conditions is in specifying the logarithmic velocity profile, which in the case of rough, irregular bed surface is not clear. 2 VELOCITY PROFILE OVER REGULAR (SAND) BED SURFACES Uniform, turbulent flow in the vicinity of a smooth and regular rough (sand) bed is to be considered. If the geometry of the bed roughness is specified, then the flow can be completely defined by the physical properties ρ andμ of the fluid, by the mechanical state of the fluid motion (which is completely determined by the shear velocity U ∗), and by the absolute size (height) k of the elements forming the bed roughness. The velocity profile Eq. 8 is defined for y in the range: y min < y≦ h, where y min is either equal to the thickness of the viscous sublayer or to the height of the roughness, whichever is larger. Coefficients k∗

Figure 1. Relation between Bs and Re (after Schlichting,

1968).

and B depend on the regime of turbulent flow, which is

defined by non-dimensional number (U ∗ k s /ν), so that

1. For (U ∗ k s /ν)<≈ 5 the regime is called hydrauli

cally smooth flow. Velocity distribution does not

depend on the size and nature of the roughness,

k ∗ = ν/U ∗ and B is the universal constant equal to

5.5 (see Yalin 1977) (Nezu & Rodi (1986) suggest

B= 5.29).

2. For (U ∗ k s / ν)>≈ 70 the regime is called rough tur

bulent flow. Velocity distribution does not depend

on the viscosity for this type of flow, k ∗ = k s and

B is the universal constant equal to 8.5 (see Yalin

1977).

3. If the non-dimensional parameter ($U * k_s / \nu$) is in the range from 5 till 70, approximately the flow is in the transitional regime. In this regime velocity distribu tion depends on roughness and the value of B which must be estimated from experimental data, Figure 1, Nikuradse's graph (seeYalin 1977) where, index "s" stands for sand roughness.

Two straight lines displayed in Figure 1, namely S 1 and S 2 lines are received from the non-dimensional analysis (see Yalin 1977). Their validity limits are established from measurements carried out for rough ness formed by equal size and grains tightly glued on the bed. The problem is how to establish the Nikuradse relation between the Reynolds's number ($U * k_s / \nu$) and coefficient B in the regime of rough turbulent flows over irregular bed roughness.

3 FLOWS OVER IRREGULAR BED SURFACE

In the case of roughness having the average height k and geometry that is different from the geometry of the sand roughness, the curve B will differ from the curve B_s (Fig.1). However, this difference will mainly be in respect to absolute values and not in "the char acter" (overall shape) of the curve. It is obvious that the straight line S 2 that does not depend on the nature

of roughness must be common for any roughness, which means that all B-curve must “sooner or later” merge into the same straight line S 2 and the constant B= 5.5 must be valid for any geometry roughness. Also, it is clear that curve B may become parallel to the abscissa starting from some “large” Re * . This threshold value may be different than the one for the curve B s (U * k/ν= 70). Its value might be different than 8.5. Let’s consider now a rough turbulent flow over irregular surface gravel bed defined by the granulometric curve (cumulative size distribution) of the bed material. The flow is steady with a unit discharge q and it can be treated as two-dimensional (x–y space). As it was assumed, the velocity distribution along any vertical in the flow is assumed to be logarithmic one but with various friction velocity and parameters, k and B. The question arises, whether it is possible to create “equivalent” velocity profile for an open channel with regular surface bed which gives the same unit discharge q. If the answer is positive, then the velocity profile exists with parameters U *,e , k e and B e and these parameters are coupled by Eq. 8. Integrating Eq. 8 over the vertical and introducing the unit discharge (mean velocity), one can easily get the following relationship where U *,e is the equivalent friction velocity for considered open channel, that can be different from local friction velocity over irregular bed. The relationship is only valid for the flows in rough turbulent regime, i.e. for Reynolds numbers (U * k/ν)>Re *,cr . It is plausible to assume that the equivalent velocity profile can be created by averaging of velocity profiles over the suitable area in the plane (x, y= const, z). As a result one could get the averaged velocity profile that matches the logarithmic law with equivalent parameters U *,e , k e and B e in any range of y. The process of space averaging of velocity profiles over fixed area needs a new theoretical formulation of the problem, which is the objective of the next section. 3.1 Theoretical formulation The tensor of momentum flux density for turbulent flows can be written (see Landau, Lifshitz 1986) where p is the density, u i the component of velocity vector, p the pressure and μ the viscosity coefficient. The overbar denotes ensemble (time) average and subscript t denotes departure from the average; usually called the turbulent fluctuation.

It is clear that ensemble averaged flow, at least

in the close neighborhood of irregular rough bound

ary, is strongly spatially heterogeneous. Boundary

irregularities originate perturbations in ensemble aver
age flow which we call “boundary disturbances” and
which have been already detected experimentally in
the steady flow as well (see Raupach et al. 1991).
The velocity profiles are essentially determined by the
effects of these disturbances. In order to define the
boundary disturbances of flow and to smooth out
the flow irregularities, a special, spatial averaging
operation denoted by the symbol <> is introduced.
where u i overbar represents the ensemble averaged
velocity and the domain D(x, y, z) is the part occu
pied by fluid of a fixed region of the plain y= const
(assumed parallel to mean bed) centered at the point
(x, y, z) and which has an area A w . The area is large in
comparison with the characteristic wavelength of the
disturbances u i –u i . Using the spatial averaging Eq. 12,
the ensemble average velocity can be split up into an
overall mean and a boundary disturbance (subscript b)
according to
After space averaging of Eq. 10 the tensor of
momentum flux density takes the form (see for details
Gimenez-Curo and Lera (1996):
3.2 Nature of shear stresses
Fluid flows in the vicinity of smooth, impermeable,
plane surface are usually classified as laminar or tur

bulent flows. In laminar flows the shear stress arises exclusively from direct action of molecular viscosity. In turbulent flows the shear stress is essentially due to ensemble mean (or time mean) momentum flux of ran dom turbulent fluctuation, also called Reynolds stress. In this kind of flow a very thin layer of fluid adjacent to the wall exists, in which viscous stress predominates since turbulence goes to zero at the boundary. Let us restrict ourselves to 2D, horizontal and uni form (space averaged) mean motion over an irregular surface.The mean velocity has a component only in the x direction , then U=U(y),V=W= 0, where now y is measured vertically upward from an arbitrary datum. It is assumed that an area integration domain D(x, y, z) is very large in comparison with the characteristic wavelength of the disturbances in order to guarantee that the resulting averaged value varies over length scales large enough as compared with those of the disturbances. The spatially averaged shear stress equation can be directly and easily obtained from Eq.14 for the region of fluid over the crests of roughness as When comparing with the corresponding equation for flow over a smooth surface, we observe that Eq.15 introduces one extra term, which we call “forminduced stress” or simply “form stress”. If the fluid flows over an irregular surface, the form stress (τ f), added to the mean viscous (τ v) and mean Reynolds (τ t) stresses creates a total shear stress. The maximum bed shear stress has therefore three components τ ov , τ ot , and τ of and it appears at the roughness height. Gimenez-Curo & Lera (1996) show that the form stress is fundamental and both other stresses are negligibly small comparing to it, therefore the friction velocity is much larger in the case of the form stress occurring in the turbulent flow. 3.3 Log-Law for rough flow over irregular bed surfaces The problem of reconstruction of the Nikuradse graph for flows over irregular gravel river bed can be reduced to establishing the equivalent Log-Law parameters, i.e., U ∗,e , k e and B e . These parameters represent the equivalent

velocity profile that can be received by space averaging all of profiles belonging to the domain of averaging. In the considered case, this area is equal to W×L, where W is the width of channel and L is the range of calculation. It is reasonable to assume, that the space averaged velocity profile has the same turbulence structure as the profile over sand roughness. It means, we can assume that for some distances from the bed and at some large Reynolds numbers the logarithmic portion of Log-Law distribution exists. We must define only those distances at which Log-Law is valid, the equivalent friction velocity, the roughness height and the coefficient B. The distance from the wall at which the Log-Law is valid depends on the geometry of roughness elements and is difficult to be estimated. Experiments of Kirkgöz (1989) show that for uniform, rough surfaces with d 90 = 2.36, 5, 10 and 20 mm the Log-Law starting at the distance from the wall defined by inequality: U * y/ν≥ 40-50.The equivalent friction velocity can be estimated when the general flow parameters like the depth and the energy slope are known. For uniform

flows the relationship holds

The remaining two parameters can be established only

based on some field data (measurements) or special

numerical simulations. Below there is a proposition

such numerical calculations.

4 NUMERICAL SIMULATIONS

The hydrodynamic model (Eqns. 1, 5-7) was applied

to simulate the 3D mean stream velocity distribution

in turbulent flow in a rectangular channel. To solve the

above set of equations the numerical parabolic proce

dure known as Patankar-Spalding algorithm is used. It

solves the set of above equations for three components

of velocity U, V, W and pressure P, at each forward

step in longitudinal direction. The continuity equation

(Eq. 1) is solved for the pressure using the well known

Patankar-Spalding (1972) algorithm. The scheme has HYBRID pattern approximation of convective terms (Leschziner 1980). However, due to insignificant sec ondary velocities it has actually the second order of accuracy. A series of numerical simulations have been performed in order to verify the possibility for finding values of parameters which define this velocity distri bution near the bottom as well as within the whole flow. These parameters occur in the Log-Law (8), namely, U_*, k and B.

In order to get a sample of real-life distribution of parameters k and U_* across the bottom in a bed form with irregular roughness, a series of random val ues for k was generated. This parameter is responsible for roughness modeling across the channel bed when rough turbulent regimes take place as it was discussed before. An example of the distribution of k across the channel bed is depicted in Figure 2.

Knowing the distribution of roughness the local friction velocity has been computed from Eq.9 using the assumption that discharge is uniformly distributed across the channel width and B= 8.5 (the same as for regular roughness).

Table 1 contains the other flow data which pertain to the case of a flow over the bed with irregular roughness

(case 1). Computed streamwise velocity distribution

as well as secondary currents pattern are shown in

Figures 3 and 4.

Streamwise velocity profile of fully developed

turbulent flow allows to re-assess parameters k, B

incorporated into the Log-Law formula (8). Having

velocity profile near the bottom, we are able to find the

values of those parameters using least squares method

for several verticals close to the channel centerline.

Velocity profile at one of them is shown in Figure 5. 1.5 2.5 3.5 4.5 5.5 Figure 2. Distribution of roughness (mm) over the channel bed. Table 1. Data for numerical calculations. by the same simulation using equivalent regular rough ness parameters.

5 SUMMARY AND CONCLUSIONS

1. The logarithmic law is valid also for the rough tur bulent flow over irregular distribution of roughness elements but with the coefficient B that is different (usually less) from 8.5 (the case of regular size of roughness).

2. For any turbulent flow over irregular roughness ele ments the equivalent velocity profile can be found with parameters U *,e , k e and B e .The equivalent pro file represents flow over regular bed roughness and gives the same discharge as the considered flow over irregular roughness.

3. The equivalent velocity profile can be treated as the result of space averaging of all profiles over area which is large in comparison with the characteris tic wavelength of the disturbances. The area can be

Negative eddy viscosity in river bends

R. Booij

Faculty of Civil Engineering and Geosciences, Delft University of Technology, the Netherlands

ABSTRACT: Flows in river bends are very shallow and mildly curved free surface flows. The shallowness and

the curvature of the flow lead to a few specific flow features that are difficult to reproduce with numerical models.

An example is the second counter-rotating secondary flow cell that is observed along steep outer banks in river

bends. This second cell has important consequences for the undermining of the outer bank. Another feature is the

sign of the shear stress component that transports main flow across the channel. If this shear stress is expressed

as a gradient type of momentum transport, then a negative eddy viscosity appears. The negative eddy viscosity

can be understood by looking at the mechanism that creates the shear stresses, in this case parcels of water that

move upwards and downwards over the flow retaining a substantial part of their original momentum. This can be

described with a kind of vertical mixing length model. In contradistinction to gradient type turbulence models,

large eddy simulation (LES) reproduces both features correctly.

1 INTRODUCTION

Flows in river bends are shallow turbulent free surface

flows. In these flows the important horizontal length

scales of the flow are one or more orders of magni

tude larger than the flow depth. River bends have large

aspect ratios {W/h ≥ O(50)} and curvature ratios

{R/h≥O(50)} generally, where h, W and R are the

depth, width and radius of curvature respectively. In

laboratory models these large ratios are not feasible in

most cases. Often the models used are hardly shallow

(e.g. models of meandering rivers with aspect ratios of

2 to 4). This leads to a defective modelling of the shal
low flow and/or a very restricted insight in the physical
processes in shallow flow (Booij, 2003a).

An important aspect of the flow in river bends is
the secondary flow. Because of this the largest flow
velocities in mildly curved shallow free surface flow
are found at the outside of the curved flow, e.g. the
outer bend in curved river flow. The mechanism that
makes the flow velocity at the outside of the curvature
increase at the expense of the velocity at the inside
is differential advection, which can be understood as
follows. In mildly curved shallow flow the main flow
velocity profile over the vertical is almost logarithmic.
Hence the centrifugal force due to the curvature of the
flow is larger in the upper part of the flow than near
the bottom.

On the average this centrifugal force is compen
sated by the pressure gradient due to a surface slope
towards the outer bend. The resulting force is directed

to the outward side in the upper part of the flow and to the inward side near the bottom and hence leads to a secondary flow to the outside in the upper part and to the inside near the bottom (see Figure 1). The main flow and the secondary flow together form the helical flow observed in curved shallow flow. In mildly curved shallow flow the amount of water flowing outward is more or less equal to the amount of water flowing inward. However the main flow velocity is larger in the upper part of the flow than in the lower part, hence more main flow momentum is transported outwards in the upper part of the flow than

inwards in the lower part. This leads to a net transport of main flow momentum in outward direction and consequently to higher flow velocities at the outer bend. z z helical flow lateral force velocity Figure 1. Mechanism of differential advection.

In view of the shallowness of rivers and tidal

channels the preference for 2-D horizontal numerical

models is understandable. However, the momentum

transport by differential advection (i.e. from the region

of low velocity at the inside bend to the region with

high velocity near the outside bend) requires the imple

mentation of a negative eddy viscosity, which will

lead to stability problems. In 3-D computations the

secondary flow is computed and hence its advection

effects are included, without the necessity of a negative

eddy viscosity.

Extensive measurements of the main flow and of the

turbulent stresses in a model of a curved shallow free

Figure 2. Sketch of two cell system of the secondary flow

in a river bend with steep outside bank.

Figure 3. The curved flume of Delft University of Technology (Top view and cross-section). surface flow (Booij and Tukker, 1996) showed another negative eddy viscosity phenomenon. If the shear stress component that transports main flow momentum across the channel is expressed as a gradient type of momentum transport, then again a negative eddy viscosity appears. This negative eddy viscosity and the mechanism of momentum transport that explains this negative eddy viscosity form the main subject of this paper.The apparent negative eddy viscosity means that 3-D computations with gradient type turbulence models (e.g. eddy viscosity or k-ε models) can never yield such a stress component with the correct sign. Another feature of the shallow curved river bend flow that is difficult to

reproduce is the second, counter-rotating, secondary flow cell observed in river bends with steep sides, see Figure 2 (Vriend, 1981). For relatively deep laboratory model flows this second cell is easy to reproduce with Reynolds average numerical simulations (RANS), but not for real shallow flow conditions (Booij, 2003b). 2 EXPERIMENTAL SETUP The measurements discussed in this paper were obtained in the curved flume of the Laboratory for Fluid Mechanics of Delft University of Technology (DUT) (see Figure 3). The flume is a compromise

between real river bends and the possibilities in a

laboratory. The cross-section of the flume is rectan

gular and the measures of the flume are h= 52 mm,

W = .50 m and R= 4.10 m. Hence the flume is a model

of a relatively shallow (W /h ≈ 10) and mildly curved

(R/h≈ 80) river bend. An advantage of this layout is

that the flow becomes almost uniform in the second

part of the bend (>90 ∘), which makes the flow more

appropriate for theoretical investigation and validation

of numerical models. A flow of about 5.2 l/s was used,

corresponding to an average velocity of about 0.2 m/s

over the cross-section.

All measurements discussed here were executed in

the nearly uniform flow region at the cross-section

of 135 ∘ with a 3D laser Doppler velocity meter

(LDV) system, measuring through the glass bottom

of the flume. The measurements were executed with a

DANTEC 3-colour fibre optics system with a 4-Watt

Coherent Ar-ion laser and DANTEC BSA processors.

The optical system used was a combination of a 2

dimensional probe and a 1-dimensional probe, see Figure 4. The velocity components measured with the 2-D probe (directions 2 and 1 in Figure 4) are the velocity component in transverse direction v and a combination of tangential and vertical velocity components u and w. Combination of the last one with the velocity component (direction 3 in Figure 4) measured with the 1-D probe yields u and w. The relatively large angle (60 ∘) between directions 1 and 3 allows for a relatively precise determination of w with this beam configuration. Identity of the measured particles is assured by requiring arrival time coincidence.

To simplify aligning of the many laser beams a water-filled prism, with sides perpendicular to the optical axes of the two probes, was attached under the measuring cross-section, see Figure 4. The refraction by the glass-plates forming the bottom of the flume and the top of the prism, which were at an angle to the optical axis, complicated the creation of overlapping measuring volumes for the different beam pairs. This refraction effect of the glass plates could be effectively compensated for by a small air-filled slit between them. The measuring system can be traversed in yand z-direction

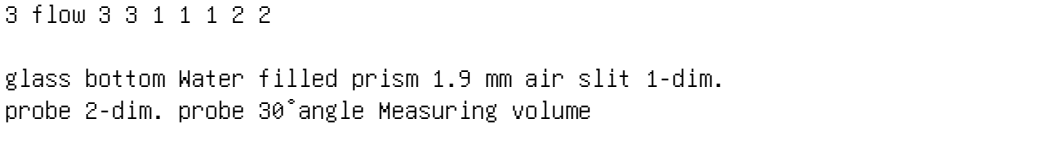

Figure 4. The 3-dimensional LDV beam configuration.

and the two probes independently in the x-direction (see Figure 3). This combination of 4 movements is required to be able to execute measurements over the cross-section without having to align the beams between measurements. A small measuring volume of the order of .1 mm in all three directions was realized. The measuring time in each point was 6 minutes. 3 SECOND COUNTER-ROTATING SECONDARY FLOW CELL The measurements clearly showed the existence of a counter-rotating secondary flow cell along the outer bank (see Figure 5), which was earlier mainly reported from measurements in relatively deep and sharply curved flumes (Blanckaert and Graf, 2001). Standard RANS models can reproduce the main characteristics of the main flow and of the secondary flow patterns. However, the reproduction of the second, counter-rotating cell depends on the sharpness of the bend. In sharp river bends (R/h< 20) it is relatively easy to compute this second cell with several RANS models. However for more realistic gentle bends (R/h> 50) the second cell is not reproduced (see Booij, 2003a). In Figure 6a the result of a computation of the flow in the DUT-flume with a k-ε model is shown. The counter-rotating cell is not reproduced. A 3-D large eddy simulation (LES) did succeed in reproducing the second cell (see Figure 6b) in spite of the for LES unfavourable aspect ratio W/h≈ 10 of the flume, leading to very unequal sides of the computational cells (Booij, 2002). However, 3-D LES is not yet applicable for the computation of more realistic river layouts. Blanckaert & Graf (2001) indicate a protecting effect by the second cell. They reason that the second cell displaces the maximum main flow velocity away from the vertical outside wall. In case of more realistic less steep banks the second cell may displace the maximum main flow velocity in the direction of the underside of the outside bank, leading to enhanced undermining. It is clear that a correct computation of the secondary flow pattern is important for the prediction of the morphological development of a river bend. 4 NEGATIVE EDDY VISCOSITY In Figures 7 and 8 the measured time-averaged velocity profiles and shear stress profiles in the cross-section are plotted. Remarkable is the positive value of the shear stress τ xy = ρu ′ v ′ over the lower half of the vertical in the centre part of the flume. This shear stress transports main flow momentum across the flume.

Figure 5. Measured secondary flow field, showing a counter-rotating cell along the upper outside wall. a) the complete

cross-section, b) the outside part (blown up for clarity).

Figure 6. The computed secondary flow field in the outside part of the cross-section at 135 ∘ . a) k-ε model; b) LES

computation, showing the counter-rotating cell along the upper outside wall.

If gradient-type momentum transport is assumed for

the different shear stresses, values for the related

eddy viscosities can be obtained using the following

relations:

where the used approximations are allowed (but not too

close to the sidewalls) because of the uniform flow in this section of the flume. The obtained values for the eddy viscosities in the centre of the cross-section are plotted in Figure 9. Related to the positive value of τ xy is the negative value of the corresponding eddy viscosity ν xy . This negative eddy viscosity applies for a large part of the cross-section (see Figure 10). For comparison the theoretical parabolic eddy viscosity profile for wide straight uniform flow (corresponding to a logarithmic velocity profile) is included in the plot of Figure 9. As curvature is assumed to suppress this vertical momentum exchange, another profile with lower κ (= 0.3) is

Figure 7. Vertical profiles of the measured time averaged velocity components. (The velocity scale for the middle of the

cross-section, y= 0, is given at the bottom. The scales for the other verticals are displaced, see the top of each plot. The vertical

lines indicate U = 0.2 m/s, V = 0.0 m/s and W = 0.0 m/s. …….. = approximate and/or extrapolated part of the profile.)

(. . . .= approximate and/or extrapolated part of the profile).

added. Because gradient type momentum transport

models require positive eddy viscosities, the nega

tive value obtained from the measurements explains

the inability of this kind of models to reproduce cor

rect shear stresses. This in contra-distinction to LES

computations where the velocity and hence also the

velocity fluctuation is computed directly.

The plotted results are henceforth restricted to the

vertical in the middle of the cross-section. In Figure 11

the measured shear stresses (From Figure 8) for this

vertical are given. In Figure 12 the computed shear Figure 12. Computed shear stress profiles. Top: k-ε model; bottom: LES computation. stress profiles are plotted, respectively the results of a k-ε model (top) and the result of a LES computation. The k-ε model does indeed not succeed in computing a correct shear stress τ xy , in contradistinction to LES. For the shear stress results obtained by LES over the complete cross-section see Booij (2003b). 5 EXTENDED MIXING LENGTH CONCEPT The sign of the shear stresses can be understood if a totally different

mechanism is assumed to be responsible for the turbulent velocities in this part of the flow. Parcels of water that move upward from near the bottom arrive at a higher level in the fluid with a positive value of w and relatively low values of u and v, implying a positive w′ and negative u ′ and v ′ . Downward moving parcels have analogously a negative w ′ and positive u ′ and v ′ . Both kind of parcels give a negative contribution to u ′ w ′ and v ′ w ′ but a positive contribution to u ′ v ′ .The positive value of u ′ v ′ has then evidently nothing to do with a gradient of u across the flume as is basic in the gradient type transport theory. This idea can be worked out using an extension of the mixing length theory of Prandtl. Turbulent parcels of water that move upward through a certain level are assumed to originate from an average distance, l m , the mixing length, below this level. They have consequently a slightly different velocity, fitting to the level of origin of the parcel, which deviation can be estimated by u ′ =-l m ∂U/∂z and v ′ =-l m ∂V/∂z. The vertical velocity component w ′ is positive and is generally assumed to have roughly the same magnitude as u ′ so w ′ = l m |∂U/∂z|. A parcel going downward has correspondingly u ′ = l m ∂U/∂z, v ′ = l m ∂V/∂z and 1 2 3 3 2 1 l xz l xy l yz theoretical = 0.4 Bakhmetev = 0.4 = 0.28 l m [mm]

Z

[m

m] linear l yz l yz l xy l xy l xz

Figure 13. Mixing lengths corresponding to the three mea

sured shear stresses in the center of the flume.

w ′ =-l m |∂U/∂z|. Averaging over all particles in this

model yields consequently

This concept can be evaluated by inspection of the

values of l m obtained from the three measured shear

stresses and the gradients of the time-averaged veloc

ity components, see Figure 13. Here the mixing length

obtained from the measured shear stress τ xz is notated

l xz , etc. The three mixing lengths are compared in

Figure 13 with the theoretical Bakhmetev distribu

tion l m = κz √ (1- z/h), which applies for a straight,

wide and uniform free surface flow when a logarithmic

velocity profile (with κ= 0.4) and a linear shear stress

distribution are assumed. In the upper part of the flow

the time-averaged velocity and the shear stresses devi

ate strongly from those in a straight flume because

of the curvature of the flow. Moreover the velocity

gradients and shear stresses are small in that region.

Therefore the mixing lengths in the upper half of the

flow can hardly be determined. In the lower half the

three mixing lengths are all of the same order of mag

nitude. Moreover they compare well to the Bakhmetev

distribution, or the linear distribution expected in the

near wall region (see Figure 13), especially if again a

slightly lower value of κ (= 0.28 is optimal) because of

the suppression of the turbulence due to the curvature

is assumed.

The agreement between the different mixing lengths

for the three shear stresses obtained from the mea

surements corroborates the extended mixing length

concept. It may be a promising tool for other flows with

Figure 14. 3-Dimensional correlation of the measured turbulent velocity components. The majority of the measurements falls within the concerning curve. large velocity gradients over the depth and a strongly depth-depending flow direction. In LES computations the movement of fluid parcels itself is computed, which

explains the good result of the LES computation for all three shear stresses. 6 CORRELATION OF VELOCITY FLUCTUATIONS The concept of the vertical movement of water parcels, which transport horizontal momentum of both directions, can be checked by means of the 3-dimensional correlations of the turbulent velocity components. Here it is used that only LDV-measurements in which all three velocity components could be measured simultaneously were allowed. In Figure 14 three different groups of those measurements are distinguished. - Measurements showing a large value of w ′ , which means a measurement in a parcel of water that moves relatively fast upwards. - Measurements showing a large but negative value of w ′ , which means a measurement in a parcel of water that moves relatively fast downwards. - Measurements showing a small value of w ′ , which means a measurement in a parcel of water that hardly moves in vertical direction. The curves in Figure 14 indicate where most of the measurements of the horizontal velocity fluctuations can be found. For the positive value of w ′ most measurement fall within the dashed curve, corresponding to negative values of u ′ and v ′ . For a negative value of w ′ most measurement fall within the dotted curve, corresponding to positive values of u ′ and v ′ .This confirms the assumed mechanism on which the extended mixing length theory was based. 2014 16 1810 12 u' v' w' arrival time (s) 0 40 -40 -40 -40 40 40 0 0 V e l o c i t y f l u c t u a t i o n s (m m / s)

7 CONCLUSIONS

• The shallow curved free surface flows in tidal chan

nels and river bends show certain flow features that

are difficult to model numerically.

• RANS (e.g. k-εmodel) computations can reproduce

the main characteristics of the main flow and the

secondary flow in a river bend.

• However they fail to give satisfactory reproductions

of the complicated secondary flow field in a mildly

curved river bend with a steep outside bank: e.g.

the second counter-rotating secondary flow cell and

shear stresses of the proper sign.

• 3-D LES correctly reproduces the shear stresses and

other flow aspects, but is not yet applicable for the

computation of more realistic river layouts.

• An extended vertical mixing length model appears

to be promising for flows with a depth-dependent

flow direction as above the bed in tidal channel and

river bends.

• 3-Dimensional correlations of the velocity fluctua

Turbulent flow over mobile and molded bedforms: a comparative

field study

ABSTRACT: The paper presents some results of a field study designed to examine flow structure over bedforms.

It also quantitatively compares these results to previous laboratory investigations of flow over fixed bedforms. In this study measurements of turbulence were obtained in a small river in Illinois, USA over a fine spatial grid of sampling points above a mobile sand wave and a molded replica. Flow remained attached to the riverbed within the troughs for both bedforms, but pattern of stacked wakes, similar to that observed in laboratory studies, was clearly evident in the vertical profiles of turbulence statistics. The spatially non-uniform flow over the mobile bedform appeared to approximate more closely turbulence equilibrium than the flow over the fixed bedform. In as much as propagation velocity of bedforms is an index of transport rates of bed material, results of field and laboratory studies should be compared only for similar bed-material transport rates.

1 INTRODUCTION

The development of mobile bedforms in natural rivers complicates accurate predictions of sediment trans port, channel erosion and deposition and flow resis tance. Many laboratory and theoretical studies have been conducted in a search for essential mechanisms of bedform development, propagation and interaction with overlying turbulent flow. Because field studies have proven laborious (Korchokha 1968; McLean & Smith 1979; Grinvald & Nikora 1988; Kostaschuk & Villard 1996) and complex (Carling et al. 2000), they are limited both in number and in the level of mea surement detail. For the most part, laboratory investi

gations and theoretical analyses have served as the primary means of studying the problem of bedform flow interaction. To evaluate the relevance of results of such studies for bedform dynamics in rivers and streams, a need exists for comparisons of findings of field studies with results of laboratory investigations and theoretical analyses.

Laboratory studies often focus only on the structure of turbulent flow over fixed bedforms that replicate the equilibrium forms (Nelson et al. 1993; Lyn 1993; Bennett & Best 1996) that develop on an erodible bed under the same bulk-flow conditions (Guy et al. 1966). In particular, separation and reattachment of flow over bedforms was revealed to be a peculiar property with important dynamic implications for such flows, and recent theoretical efforts have concentrated mainly in incorporating these aspects in the formulation of more advanced models (McLean & Smith 1986, Nelson & Smith 1989). Although presumed as essential mechanism, flow separation is paradoxically a rare phenomenon observed in natural streams (Kostachuk & Villard 1996) with minor effects, as reported in several field studies (Carling et al. 2000). Various reasons have been proposed for the discrepancy between laboratory and field observations; however, to date, none has been rigorously evaluated. To a great extent the lack of comparative analyses can be attributed to technical limitations. Hot-wire, hot-film anemometers, and laser doppler velocimeters have been used in laboratory studies for about four decades, whereas analogous devices suitable for field studies (acoustic doppler velocimeters or ADV) only became commercially available a decade ago (Kraus et al. 1994). In the field, the need to simultaneously monitor the evolution of mobile bedforms while performing flow measurements has been an additional problem.

Recent developments in echosounding technology (Nikora et al. 1997) and progress in application of

ADV measurements to studies of river turbulence (Sukhodolov et al. 1998; Sukhodolov & Rhoads 2001) have opened new possibilities for coupled field studies of flow-bedform dynamics. In this study we take advantage of ADV and echo-sounding technology to: (1) explore simultaneously flow structure over bedforms and the morphological characteristics of bedforms in a mobile-bed natural stream and (2) compare flow structure over mobile bedforms to that over an artificial fixed bedform with a shape derived from the characteristic form of mobile prototypes. This paper presents some preliminary results of the study and qualitatively compares these results to laboratory observations of flow over bedforms. The results contribute to the understanding of basic mechanisms governing flow-bedform interactions in alluvial channels.

2 FIELD MEASUREMENTS

2.1 River reach

The study is based on measurements conducted in the Embarras River, 15 km south of Urbana-Champaign in the east central Illinois. The stream is contained within the bottom of a trapezoidal drainage ditch. During the period of measurements (June 5–7, 1998) the bulk characteristics of the flow were: discharge Q= 0.783 m 3 /s, mean velocity U = 0.44 m/s, river

width B= 5.2 m, average depth h= 0.35 m, water slope S = 0.00132, corresponding shear velocity U ∗ = 6.7 cm/s, Froude number Fr= 0.24, and Re= 1.4×10 5 .

2.2 Measuring systems and equipment

Measurements of riverbed elevations were performed with a multi-channel microsounder system SH-1M (Nikora et al. 1997).The system consists of six sensors ported at a processing block interfaced to a portable computer and operated either in manual or automatic mode.The system permits synchronous measurements at a sampling rate up to 2 Hz with a spatial resolution of about 2 cm and an accuracy of 1–2 mm for a depth range of 6 to 100 cm.

Records of instantaneous 3-D velocity components were collected using an acoustic doppler velocimeter manufactured by Sontek, Inc. This instrument consists of an ADVLab probe mounted to submersible field electronics. The sampling volume of the probe is located 5 cm from the sensors and is <0.25 cm 3 in size. The resolution of the ADVLab is 0.1 mm/s with a noise level of 1% of the velocity range at a sampling frequency of 25 Hz.

A special measuring platform was constructed to enable precise positioning and traversing of the sensors (Fig. 1). The platform consists of a square 3× 3 m Figure

1. The measuring platform in the Embarras River. wooden frame mounted on metal uprights. A wooden traversing bar containing a metal mount for the ADV sensor was placed on the wooden frame. Wires were stretched beneath the platform, and parallel to the main direction of current, to support a light aluminum frame oriented in the cross-current direction and housing six echosounding probes placed 10 (1–2), 15 (2–3), 20 (3–4), 25 (4–5), and 30 cm (5–6) apart. A system of tapes stretched along the frame allowed for precise positioning of the traversing bar within the dimensions of the 3× 3 m wooden frame. The ADV probe was mounted on a tip of 1.5 m long metal rod aligned with the principal axis of the probe. The vertical alignment of the rod was controlled by a bubble level on the metal ADV mount and by geodetic instruments. 2.3 Measurements and data processing The experimental program for the study comprised: (1) measurements of riverbed morphology and kinematics of mobile bedforms; (2) measurements of velocity and turbulence characteristics over natural mobile sand waves, and elevations of the riverbed; and (3) measurements of velocity and turbulence characteristics over an artificial concrete bedform created from a mold representative of natural bedform characteristics. The characteristic spatial structure of bedforms within the study reach was determined by moving the array of echosounding probes along several parallel 30 m-long traverses in the streamwise direction and collecting depth readings every 5 cm.To estimate characteristics of bedform propagation the sensors were positioned at a closely spaced series of fixed locations in the streamwise direction and depth readings were collected at a sampling interval of 10 s over a sampling period of 16 hours. In site processing of the spatial riverbed measurements allowed portraying a

typical bedform. A mold corresponding to the dimen

sions of that form was manufactured – and filled with

the concrete, and sand extracted from the riverbed was

used to create the bedform surface exposed to the flow.

The concrete was left to set while other measurements

were performed.

Velocity measurements in the flow over the mobile

bedform were obtained at four vertical profiles. Each

profile consisted of 15–17 measurements spaced about 2 cm apart. The sampling duration at each measurement location was 200 s at sampling rate 25 Hz. Prior to collecting the velocity data for a specific vertical profile, riverbed elevations were monitored by traversing the array of echosounding probes within the experimental frame (3 m) and recording depths at 5 cm spatial intervals.

The artificial bedform was then exposed to the flow at the same location where a moveable bed form was observed before. Velocity measurements were taken at three verticals along the length of the bedform and topographic profiling of the riverbed profiling was performed once prior to velocity measurements.

Monitoring of water levels was performed on two gauges located 10 m upand downstream of the frame. Levels were recorded every hour and the variation was less than 0.7 cm for the whole period of measurements.

The software package ExploreV 1.5 (Nortek USA) was used to process the ADV data. Prior to computations of the statistical characteristics of turbulence, each record was inspected visually to identify possible problems, such as spikes, trends or abrupt discontinuities in the time series. Post-processing of the data involved removal of the defective portions of the time

series using the data clipping capabilities of the soft

ware, spikes detection with a set of criteria imple

mented in ExploreV and replacement of extreme values

produced by interruption of the acoustic beam by

floating debris with linearly interpolated values.

3 RESULTS

A coordinate system with a streamwise x direction,

a transverse y direction, and a vertical direction z,

originating at riverbed and directed toward the free

surface is adopted herein. The corresponding velocity

fluctuations are u ′ , v ′ and w ′ , respectively; the mean

streamwise velocity is denoted U .

3.1 Spatial-temporal characteristics of bedforms

The longitudinal profile of bed topography along the

flow centerline obtained from the echosounding device

illustrates the morphology and abundance of sand

waves on the channel bed (Fig. 2a).Averaging of a total

of six separate longitudinal profiles resulted in a char

acteristic form 2 m long and 8 cm high with a lee-side

angle of 12 ∘ and a stoss-side angle of 5 ∘ . Comparison 0 10 20 30 x, m 0 10 20 z , m a) 16 12 8 4 0 time, hr 0 5 10 15 z , c m b) 0 25 45 70 Figure 2. a) Example of a longitudinal profile of bed elevations along the flow centerline (dashed box indicates the position of the measurement platform), and b) temporal change in bedform profile at fixed verticals within the measurement frame (numbers indicate spatial lags in cm). of the longitudinal profiles at different locations across the stream indicated that bedforms were approximately two-dimensional in the central part of the stream and did not change substantially

in shape over transverse distances on the order of two times the depth of flow. Successive temporal records of riverbed elevation at fixed locations provide insight into kinematics of bedforms (Fig. 2b). From these records, it is possible to estimate the propagation velocity C for a typical bedform as the distance of movement of the lee side of the bedform divided by the time of movement, yielding a mean value for propagation velocity C of 6.5× 10 −5 m/s. 3.2 Individual bedforms When measuring velocity and turbulence profiles over an individual mobile bedform, prior to the start of each vertical profile the riverbed was surveyed with the echosounding device. This scheme allowed precise determinations of the position of each vertical and of the locations of individual sampling volumes relative to the instantaneous morphology of the channel bed (Fig. 3). Successive measurements of a propagating bedform indicated that its shape and dimensions generally remained constant. However, small-scale secondary forms (length of 25–50 cm and height 3–5 cm) superimposed on the large sand wave developed, propagated and disappeared on an irregular basis (Fig. 3a, d). Successive bed profiles 250 200 150 100 50 0 x, cm 0 10 20 30 40 50 h , c m Profile 1 time: 00:20 a) 250 200 150 100 50 0 x, cm 0 10 20 30 40 50 h , c m Profile 2 time: 02:10 b) 250 200 150 100 50 0 x, cm 0 10 20 30 40 50 h , c m 250 200 150 100 50 0 x, cm 0 10 20 30 40 50 h , c m Profile 3 time: 03:52 c) Profile 4 time: 05:10 d)

Figure 3. Instantaneous riverbed profiles and locations of ADV’s sampling volume during velocity and turbulence

measurements (arrows indicate the direction of flow).

were spatially averaged to account for temporal lags

associated with bedform motion. The spatial-temporal

averaging yielded a characteristic time-averaged

shape of the individual mobile bedform (Fig. 4a)

and allowed the velocity profiles and ADV sampling

locations to be determined precisely relative to the

phase-shifted motion of the bedform.

Subsequently, the molded replica of the charac

teristic bed form (Fig. 2a), was carefully placed in

the channel by removing bed material and manually constructing smooth transitions between the artificial bed form and its natural surroundings. The resulting riverbed topography was then surveyed and a longitu dinal bed profile that included the artificial bed form was obtained (Fig. 4b).

There is a difference in the shape of the spatially temporally averaged bed form (Fig. 4a) and the arti ficial bedform (Fig. 4b). The difference is explained inasmuch as the artificial bed form was copied from the instantaneous pictures of the bed forms (Fig. 2a, Fig. 3) that looked steeper than their averaged patterns, which incorporate the secondary small-scale structures. 3.3 Mean velocity profiles The time-averaged values of the streamwise velocity components over the mobile and artificial bedforms show that velocities gradually increase toward the surface in a log-law-like pattern (Fig. 5) No flow separation could be detected within the troughs of either bedform. The main differences between the two velocity profiles are the relatively steep slope of the profile for the artificial bedform and the deviation of two nearbed points from the shape of the profile over the stoss side of the artificial bedform. 3.4 Turbulent stresses Distributions of the primary components of the turbulent stresses – u ′ w ′ presented in Figure 6. (McLean & Smith 1986), including the effect of upstream bedforms, can be observed from the distri bution of Reynolds stresses (Fig. 6). The distributions exhibit distinct segmentation marked by abrupt dis continuities in vertical trends of shear stress. These discontinuities occur consistently among all verticals and can be traced from one shear-stress profile to the next over the bedform. The dashed lines shown in Figure 6 depict the segmented configurations of a flow over bedforms. A notable characteristic of the stress profiles for both the mobile and fixed bedforms is the highly irregular pattern of shear stresses over the trough compared to the pattern of near-bed shear

stresses over the crest and stoss side of the bedform. -50 0 50 100 150 200 250 x, cm 0 10 20 30 40 50 h , c m a) 0 50 100 150 200 250 300 x, cm 0 10 20 30 40 50 h , c m b) U scale, cm/s 0 60 Figure 5. The spatial distribution of k can be used to identify zones of high turbulence kinetic energy, which often represent zones of turbulence production (Rhoads & Sukhodolov 2001). Distributions of k suggest that production is greatest over the trough of mobile and fixed bedforms (Fig. 7). 0-50 50 100 150 200 250 x, cm 0 10 20 30 40 50

in the flow over moveable (a) and fixed (b) bedforms, dashed

lines depict the boundaries of layers and crosses indicate

locations of the profiles and zero values of stress.

The high values of k over the troughs are indicative of

a shear layer marking the upper boundary of an inter

nal boundary upper boundary of an internal boundary

layer within the trough. Turbulence kinetic energy is

distributed fairly uniformly over the gently rounded

crest of the mobile bedform (Fig. 7a). In contrast, the

layer of high k is more clearly developed and extends

farther upstream over the fixed bedform, suggesting

that its high roughness and steep stoss and lee slopes

enhances internal shearing of the flow as it moves over

this artificial bedform (Fig. 7b). -50 0 50 100 150 200 250 x, cm 0 10 20 30 40 50 h , c m a) 0 50 100 150 200 250 300 x, cm 0 10 20 30 40 50 h , c m b) k scale, (cm/s) 2 0 40 Figure 7. existence of which was defined by relationship

The patterns of dissipation rate measured over the

mobile bedform (Fig. 9a) are similar to the distribu

tions of turbulence kinetic energy (Fig. 7a), indicating

that local equilibrium of turbulence energy may be

approximated in at least some portions of the flow over

bedforms. Upper portions of profiles of k and ε exhibit

the greatest similarity. Near the surface of the bedform,

vertical patterns of k and ε begin to diverge, espe

cially for the fixed bedform.Thus, flow in this near-bed

region departs substantially from equilibrium. Overall,

however, rates of dissipation are highest over the lee

side of the bedform where values of k also are highest. -50 0 50 100 150 200 250 x, cm 0 10 20 30 40 50 h , c m a) 0 50 100 150 200 250 300 x, cm 0 10 20 30 40 50 h , c m b) scale, cm 3 /s 2 ε 0 10 Figure 9. Dissipation rate (circles) distributions in the flow over moveable (a) and fixed (b) bedforms, crosses indicate locations of the profiles and zero values of dissipation rates. 4 DISCUSSION AND CONCLUSIONS Field studies of turbulent flow structure

over mobile bedforms have inherent limitations that are difficult if not impossible to accommodate completely. Point measurements of turbulence characteristics require relatively long periods of record to ensure accuracy of high-order statistical moments. To resolve structural properties of the flow at specific locations along the entire length of bedforms, data should be collected over a fine grid involving a large number of

measurement points. At the same time, the total dura

tion for the set of measurement should not exceed

the time scale over which the bedform substantially

changes shape or position. Refinement of field stud

ies can be achieved through predictions of the total

time required for measurements of turbulence relative

to the time scale of bedform propagation.

The propagation speed of bedforms depends on

their length, with small secondary bedforms moving

rapidly over large slower-moving primary forms. The

propagation speed C of bedforms recently has been

characterized in the semi-empirical formulae (Nikora

et al. 1997)

Applying bulk parameters of the flow measured in

the Embarras River (Section 2.1) to the equation (3),

and using average bedform length l= 2.0 m (Sec

tion 3.1) yields C = 4.5× 10 −5 m/s. This predicted

value matches the measured value of 6.5× 10 −5 m/s

(Section 3.1) with an accuracy within 30%.Thus equa

tion (3) can be recommended for planning of bedform

measurement programs.

Flow separation on the lee side of bedforms, a characteristic phenomenon almost always reported in laboratory studies, usually is recognized by a signifi cant reduction or even reversal of mean downstream velocity. This effect, however, was not pronounced in the mean downstream velocity distributions reported in this study (Fig. 5). For both the mobile and fixed bed forms, flow remains attached to the riverbed within the trough. Observed bedforms were characterized by lee side slope angles not exceeding 12 ∘ -relatively gentle slopes compared to laboratory bedforms with angles of approximately 30 ∘ (Nelson & Smith 1989), values close to angle of repose for sandy material. The lack of flow separation raises some important questions: Why were the bedforms observed in the Embarras River not highly asymmetrical in shape? Given the differences in bedform morphology in field and laboratory stud ies, to what extent are the results of these two types of investigations comparable?

Obviously, since the motion of bedforms reflects sequential erosion and deposition, and the angle of repose controls the accumulation of the riverbed mate rial at the crests of bedforms, the asymmetric shape with lee-side angles of 30 ∘ is characteristic of bed forms with high transport rates. Inasmuch as propa

gation velocity of bedforms is an index of transport rates of bed material, the results of laboratory and field studies of bedforms should be compared only for similar bed-material transport rates. Simple com putations using equation (3) and the data by Nelson & Smith (1989) give an estimate of propagation veloc ity of 6.3× 10 −4 m/s, a value one order of magnitude

Depth-averaged modelling of overbank flow in meandering channels

P. Rameshwaran

Centre for Ecology & Hydrology, Wallingford, Oxfordshire, UK

K. Shiono

Department of Civil and Building Engineering, Loughborough University, Leicestershire, UK

ABSTRACT: A quasi two-dimensional model for calculating depth-averaged velocity and boundary shear stress

in meandering channels for overbank flow is developed for a complex cross-section.The model numerically solves

the depth-averaged equation for the streamwise motion of flow in a curvilinear coordinate system. The input

model coefficients – friction factor, eddy viscosity and advection term – are calculated from the experimental data obtained from the UK Flood Channel Facility. The predictive ability of the model is assessed against experimental data and results from two and three dimensional numerical models with regard to distributions of depth-averaged velocity and boundary shear stress. The results show that the quasi two-dimensional model produces a reasonable simulation of the flow field when appropriate input coefficients are used.

1 INTRODUCTION

Accurate prediction of flow and boundary shear stress for overbank flow in a meandering channel is required by engineers and scientists in order to understand bank erosion, sediment transport behaviour and river ecosystems. There are a number of methods predicting inbank velocity and boundary shear stress in meandering rivers in the literature (e.g. Chang, 1988), but it is difficult to apply such methods to overbank flow since the flow structure is very different to that for inbank flow (Shiono and Muto, 1998). Recently, Rameshwaran and Shiono (2002, 2003) and Rameshwaran and Naden (2003) used two dimensional (2D) and three-dimensional (3D) numerical models to predict velocity and boundary shear stress in a meandering channel for overbank flow; however, these models take a long time to reach a solution

even with the computer power available today. There are one equation depth-averaged 2D models which are much simpler and quicker to solve. Two of these are based on the model developed by Shiono and Knight (1991) for a straight compound channel. They are proposed by Ervine et al. (2000) and Spooner and Shiono (2003) for a meandering channel. Ervine et al. (2000) simply use the straight channel equation with out considering the radius of curvature and the model developed by Spooner and Shiono (2003) model is only applicable to flat bed cases.

The main objective of this paper, therefore, is to investigate the feasibility of simulating overbank flow in a two-stage meandering channel with a complex cross-section using the one equation 2D model (i.e. quasi 2D model). A model for calculating depthaveraged velocity and boundary shear stress in meandering channels for overbank flow is developed for a complex cross-section. The model equation is solved numerically. In order to solve the equation, friction factor, eddy viscosity and advection terms are required. These are obtained from the experimental data obtained from the UK Flood Channel Facility (UK-FCF). The performance of the quasi 2D model is evaluated by a comparison with the detailed experiment data obtained from the UK-FCF together with results from 2D and 3D numerical models (Rameshwaran and Shiono, 2002 & 2003 and Rameshwaran and Naden, 2003). 2 EXPERIMENTAL DATA A brief description of the experimental set up for the UK-Flood Channel Facility (UK-FCF) programme is given here. The detail of the programme has been described by Ervine et al. (1993) and Lorena (1992). The UK-FCF flume is 60 m long and 10 m wide, with a maximum discharge of 1.1 m 3 s −1 . Experiments were performed in two-stage meandering channels consisting of flat floodplains with straight floodplain walls and a sinuous main channel, as shown in Figure 1. The top width of the main channel was 1.2 m and the bank slopes were 45 ∘ with a bank-full depth of Inner radius=2143mm Outer radius=3343mm 6000 mm 2 5 0 0 m m 1 9 4 7 m m 290 mm

150 mm. The shape of the meandering channel cross

section was either trapezoidal or ‘natural’.The‘natural’

channel cross-section (Figure 2) was modelled from

seventeen natural river bends and the detail of the Table 1. Flow conditions. Case Sinuosity Main channel h max (mm) Q (m 3 s −1) A 1.374 Natural 165 0.0580 B 1.374 Natural 200 0.2250 C 1.374 Trapezoidal 200 0.2500 D 2.043 Natural 200 0.1790 channel design was given by Lorena (1992). The lower sinuosity (1.374) channel, was used with both the trapezoidal and natural channel cross-section, but only the ‘natural’ channel cross-section was employed for the higher sinuosity (2.043) channel. The channel slope was 0.996× 10 −3 for the lower sinuosity channel and 1.021× 10 −3 for higher sinuosity channel. Detailed measurements of horizontal velocity and bed shear stress were made under steady uniform flow conditions for all four cases considered in this study (Table 1). The flow angle was recorded by a vane connected to a rotary potentiometer and the horizontal velocity was measured using a miniature propeller meter.The shear stress was measured by a Preston tube on the bed. 3 MODEL EQUATION The equation for the streamwise component of momentum on a fluid element combined with the continuity equation for steady uniform flow using curvilinear coordinates is: where x, y and z are the streamwise, transverse and vertical directions respectively, U , V and W are the temporal mean velocity components corresponding to x, y and z coordinate directions respectively, ρ is the density of water, g is

the gravitational acceleration, S 0 is the bed slope gradient, τ is the Reynolds stress in the respective planes, r in is the radius of curvature of the meandering channel inner bank and y mc is the distance across the meandering channel from the inner bank. The depth-averaged momentum equation can be obtained by integrating equation (1) over the water

depth, H , provided W (H)=W (0)= 0 (Shiono and

Knight, 1991):

where subscript d indicates a depth-averaged value,

τ b is the bed shear stress and s is the bank slope

(1:s – vertical : horizontal). At the apex cross sec

tion, assuming ∂H (U 2 d)/∂x≈ 1 and ∂H (τ xx) d /∂x≈ 1

because streamwise velocity is dominant, equation (2)

can be written with some manipulation as:

where U d is the depth-averaged velocity, f is

the Darcy-Weisbach friction factor, (ε xy) d is the

depth-averaged eddy viscosity, U ∗ is the local

shear velocity and λ is the dimensionless eddy

viscosity.

When r in →∞ (i.e. straight channel), equation (3)

takes the same form as the Shiono and Knight (1991) equation when expressed in a Cartesian co-ordinate system: Shiono and Knight (1991) defined the secondary flow term as " and found constant values of " in the main channel and on the floodplain using the experimental data from the FCF straight compound channel experiments. The secondary flow term " can be written as: Ervine et al. (2000) assumed that the secondary flow term (U V) d could be expressed by the stream-wise depth-averaged velocity squared. Using this assumption regarding the secondary flow term: where K is a function which depends on channel geometry and bed roughness values, equation (5) becomes: Equation (3) with either of equation (5) or (7) can be solved numerically. In this study, a finite difference discretisation is used. The

discretised equations are solved with a Gaussian elimination method. When using equation (5), the value of " needs to be defined and when using equation (7), the value of K needs to be defined. In this paper, the value of " is used. 4 INPUT MODEL COEFFICIENTS In order to solve equation (3) with equation (5) for the depth-averaged velocity U d , the model coefficients of local friction factor f , dimensionless eddy viscosity λ and secondary flow term " across the apex cross-section are required as input data. These model coefficients are estimated as follows. 4.1 Friction factor The formulation for estimating the friction factor across the channel is given below using the roughness height, k s , or skin friction of the channel surface. The channel surfaces in all the experiments

were composed of smooth cement mortar. The skin

friction of the channel surface was measured in a

calibration exercise using a straight wide trapezoidal

channel and gave a Manning coefficient n of 0.01

(Ackers, 1991). The equivalent sand grain rough

ness height, k s , is 0.3 mm, which was calculated from

the relationship n= k 1/6 s /(8.25 √ g) (Ackers, 1991).

Using k s = 0.3 mm, the Colebrook-White equation (C

W equation) can be used to calculate a local friction

factor f at any location in a cross-section with depth

of water H :

where Re is the local Reynolds number defined as:

Using U ∗ = √ gHS 0 and f = 8U 2 ∗ /U 2 d , equation (8) can

be re-arranged as:

This equation can be used to estimate the friction

factor f . The validity of this equation was assessed

by comparison with the experimental data. The exper

imentally calculated values of local friction factor,

f (=8τ b /(ρU 2 d)), based on the measured bed shear stress and depth-averaged velocity, and the predicted values using equation (10) are shown in Figure 3 for cases A, B, C and D. The figure shows that the friction factor calculated with equation (10) agrees reasonably well with the experimental data for the cases A, B and C despite the complex flow structure in the main chan nel. However, the friction factor is under predicted for the large sinuosity case D for most of the cross-section. The discrepancies in the large sinuosity case are largely caused by secondary flow which generates a complex flow structure in the main channel and distorts the ver tical profile of velocity from the 2D logarithmic profile assumed in the C-W equation.

4.2 Dimensionless eddy viscosity

Figure 4 shows the dimensionless eddy viscosity val ues λ(=(ε xy) d /(√ τ b /ρH)), obtained from the results of the 3D model study by Rameshwaran and Naden (2003) and the standard depth-averaged value for two dimensional open channel flow (i.e.λ= κ/6= 0.0683, where κ is the von Karman constant). Dimensionless eddy viscosity λ across the apex section. the modelled dimensionless eddy viscosity values on the floodplain are close to the standard value but, in the main channel, the modelled values are much higher than the standard value. Although the dimensionless

eddy viscosity varies across the main channel, initial

runs of the quasi 2D model using the non-dimensional

eddy viscosity as modelled by the 3D model showed

little effect on the solution.The 2D model study carried

out by Rameshwaran and Shiono (2003) also showed

only a slight effect of the eddy viscosity on the solu

tion for the cases considered here, while Spooner and

Shiono (2003) also demonstrated this using experi

mentally determined eddy viscosity. However, for flow

in a straight compound channel, this eddy viscosity

could be significant as demonstrated by Shiono and

Knight (1991). For a meandering compound channel

case, the model is insensitive to the value of dimen

sionless eddy viscosity used. Thus the standard value

of 0.0683 was used for the whole cross-section.

4.3 Advection term (Secondary flow)

Spooner and Shiono (2003) demonstrated that the

value of '' for equation (5) varies across the main

channel with a constant water depth (i.e. flat bed). In

this study, the channel bed level varies, and the equa
tion for '' obtained by Spooner and Shiono (2003)
may not be applicable to the cases considered here.
An investigation of '' was carried out using the mea
sured data. With the measured bed shear stress and
velocity distributions across the channel and with the
assumed non-dimensional eddy viscosity of 0.0683, ''
was estimated using equation (3). The following geo
metrical and roughness non-dimensional parameters,
while not unique, are sufficient to describe the sec
ondary flow function '' in non-dimensional form in
the main channel at the apex cross-section:
where C is a constant, a to e are unknown exponents,
k mc and k fp are the equivalent sand grain roughness
heights in the main channel and on the floodplain
respectively, r is the sinuosity, MBW is the meander
belt width, FW is the floodplain width, y bf is the main
channel at bankfull level, h mc is the local main chan
nel flow depth and h max is the maximum main channel
flow depth.
The constant C and exponents a to e have to be deter
mined empirically. The available limited data have
been used to define equation (11). As k mc /k fp = 1 for
all cases considered here, the following equation was
obtained: (a) Case A (a) Case B (a) Case C (a) Case D

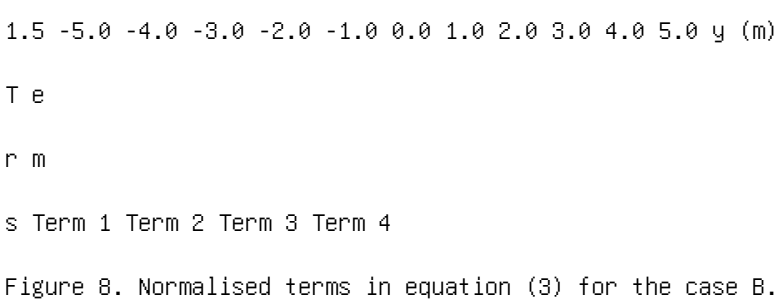

Figure 8. Normalised terms in equation (3) for the case B.

is under predicted on the floodplain for the shallower flow case A. For the deeper flows in cases B, C and D, it is under predicted on the left floodplain and over predicted on the right floodplain. By comparison, the Q2D results show a good prediction in the main channel and a reasonable prediction on the floodplain.

A sensitivity analysis was carried out by normalising equation (3) by pgHS 0 . Figure 8 shows the separate terms in equation (3) for case B. Term 1 is the '' term, Term 2 is the gravity term, Term 3 is the bed stress term and Term 4 represents the transverse shear stress terms. It was found that the magnitude of the transverse shear stress was negligibly small as found by Spooner and Shiono (2003). It can also be seen from Figure 8 that the bed stress term at the deepest point in the main channel is relatively small but the advection term '' is significantly larger and almost the same magnitude as the gravity term. This indicates that the determination of '' is very important.

The data available in this study were very limited

in the range of geometrical and roughness parameters covered and equation (12) is essentially for demonstration purposes only. The main flow mechanism contributing to the advection term is the secondary flow.The basic principles behind the generation of secondary flow for overbank has been reported by Shiono and Muto (1998) and Shiono et al. (2001). The main factors involved are the angle of the floodplain flow to the main channel flow and the ratio of the main channel water depth to the floodplain water depth. These are represented in equation (12) by the sinuosity and water depth ratio respectively. The values of the exponents in equation (12) confirm that these are the dominant factors. However, the general validity equation (12) will be dependent on additional data. When a larger set of field and experimental data becomes available it will, therefore, be important to re-examine the equation for the advection term in the main channel and to develop a similar equation for the floodplain advection term.

When using equation (7) to solve with equation (3), the value of K may be similarly expressed by dimensionless groups and determined by experimental and

ABSTRACT: Experimental results are presented concerning boundary shear stress and force distributions in

a compound rectangular channel comprising one main river channel and one or two symmetrically disposed

smooth floodplains. A comparison is made between the boundary shear stresses on the main channel bed for

channels having either rigid or mobile beds of the same geometry. The influence of the main channel mobile bed

on the momentum transfer between the main channel and the floodplains, and on the boundary shear stresses

and forces acting on different elements of the compound channels are investigated. The mobile main channel

bed causes the boundary shear stress values on the main channel bed to increase once overbank flow takes place

for a given flow depth, and all values are always greater than those in an equivalent rectangular channel i.e. the

isolated floodplain case. The rigid main channel bed case shows the opposite trend to the mobile bed case, in

that the boundary shear stresses decrease once overbank flow occurs.

1 INTRODUCTION

The flow structure in an open channel is directly related

to the distribution of boundary shear stress around

the wetted perimeter of the channel. Many investi

gations have been made into boundary shear in open channel flow, and it has been established that many factors, such as the shape of the cross section, the variation in surface roughness in both longitudinal and lateral directions, the longitudinal variation in planform geometry and sediment concentration, all influence the boundary shear stress distribution (e.g. Christensen & Fredsoe, 1998; Kartha & Leutheusser, 1970; Khodashenas & Paquier, 1999; Knight, Yuen & Alhamid, 1994; Lundgren & Jonsson, 1964; Yang & Lim, 1997; Zheng & Jin, 1998).

Many investigators have especially studied bound ary shear stress distributions in compound channels or ducts, since these types of channel are useful for flood conveyance and also feature in river restora tion projects (e.g. Lai, 1987; Myers and Elsawy 1975; Myers 1978; Rhodes, 1991; Shiono & Knight 1991; Knight & Shiono 1996; Sear et al., 2000).

Boundary shear is particularly important for two reasons. Firstly, the resistance to flow is directly related to the global boundary shear stress, τ_o, and secondly, the mean bed shear stress τ_b (or bed shear velocity, u_* is generally required in many sediment transport equations. Thus being able to predict the boundary shear stress distribution is an essential element in morphological studies and in designing sustainable river channels (Abril & Knight, 2002 & 2004a&b; Atabay, 2001; Knight, 2001). In flood conditions, in which overbank flow occurs the channel becomes a ‘compound one, and both the effects of a mobile channel bed on the boundary shear stress distributions, and

on the momentum transfer between main channel and floodplain, have to be understood.This paper describes an experimental study in which measurements were made of the boundary shear stress in two compound channels, of the same geometry, but with either rigid or mobile beds in the main channel section. 2 EXPERIMENTAL PROCEDURE The experiments were undertaken at the University of Birmingham in a non-tilting 22 m long flume with a compound working section length of 18 m. The flume was 1213 mm wide, 400 mm deep and configured into a two stage channel with a 398 mm wide rectangular mobile main channel and two 407.3 mm Adjustable wall B

Figure 1. Cross section of 18 m flume.

wide smooth floodplains at an elevation h= 50 mm

above the mobile bed, as shown schematically in

Figure 1.The sand bed of the main channel was covered

with a smooth PVC sheet when rigid bed experiments

were to be undertaken, with the height of the flood

plain, h, kept at the same value of 50 mm as in the

mobile bed experiments.

At the end of the flume a series of three adjustable

tailgates were located to produce uniform flow con

ditions in the 18 m test length. Water surface profiles

were measured directly using pointer gauges. The tail

gates were calibrated so that the mean water surface

slope and the mean longitudinal bed slope could be

set equal to the valley slope of the floodplains, fixed

at 2.204× 10 −3 for any required test discharge.

Velocity measurements were made at 0.4 of the local

depth using a Novar Nixon miniature propeller cur

rent meter with a propeller diameter of 13 mm. Local boundary shear stress measurements were made using a Preston tube (Preston, 1954) with an outer diame ter of 4.77 mm. This indirect technique (Winter, 1977) was developed originally for smooth boundaries and is essentially based on a Pitot tube in direct contact with the boundary. The Preston tube thus consists of a static tube, closed to the flow that records pressure due to the static head, and a dynamic tube that is placed within the boundary layer facing into the flow that records the total pressure head. The pressure differ ence between the static and dynamic tubes, p, may be converted into boundary shear stress using Patel's cali bration equations for smooth boundaries (Patel, 1965). In order to measure the low pressure differences, an inclined manometer with an angle of 13.7 ◦ was used. Further details of the apparatus and experimental procedures may be found in Atabay, 2001.

3 EXPERIMENTAL RESULTS

3.1 Boundary shear stress distributions

Experiments were carried out for the three test config urations: inbank flow with the side walls, overbank flow with an asymmetric cross-section and over bank flow with a symmetric cross-section. Inbank and overbank flow experiments were carried out in 0.00 0.20

0.40 0.60 0.80 1.00 1.20 1.40 0.00 0.20 0.40 0.60 0.80 1.00 1.20 Distance, m Experimental data Channel boundary τ b , N m 2 Figure 2. Typical boundary shear stress distribution in a rigid symmetric compound channel. channels with both mobile and rigid main channel beds in order to make direct comparisons between them. This paper focuses on the effect of the mobile main channel beds on the boundary shear stress data and on the momentum transfer between various zones within the cross section. Results concerning stagedischarge relationships, velocity and boundary shear stress distributions, resistance, bed forms and sediment transport rates are presented elsewhere (Atabay, 2001; Atabay & Knight, 1999 & 2002; Tang & Knight, 2001). A typical boundary shear stress distribution for the symmetric rigid compound channel is shown in Figure 2. Data on all other channel configurations and depths are given in Atabay (2001). Figure 2 shows a remarkably symmetric data set, with the floodplain values decreasing continuously towards the outer edges due to the relatively large depth and narrow floodplain width in this particular experiment. The main channel values are more uniform in the central region, with evidence of only weak secondary flow cells being present. Given the spatial resolution of the data it was possible, by integration of appropriate values, to obtain high quality mean boundary shear stress and force values for the individual wall elements 1–5, shown in Figure 1. The average errors in the overall shear stress between the mean integrated experimental value and the theoretical value (τ o = ρgRS) were within –2% and +1.0% for all the rigid compound channel tests. The measured data were all corrected by these small amounts in order to standardise all data to what was regarded as the ‘correct’energy slope value.The velocity data were likewise compared with the mean value obtained from direct measurement by a Venturi meter, and any small differences used to adjust the individual measurements accordingly. For the mobile compound channel tests, unlike the measured velocity data, the measured boundary shear stresses data were only obtained on smooth boundary

surfaces, as time did not permit bed freezing to take place for all experiments. Bed freezing would have enabled boundary shear to be measured over many dune formations in order to determine a mean value for the main channel bed. Instead, the local boundary shear stress measurements were accepted as measured, without any correction, because of the absence of data on the bed of the main channel. Given the small errors cited earlier for the rigid bed cases, this was not thought likely to introduce any serious error.

3.2 Boundary shear data

The effects of the mobile main channel bed on the

boundary shear stress can easily be explored by com paring all the main channel bed data together, as shown in Figure 3.

This Figure clearly shows that for a given flow depth the boundary shear stress on the mobile main channel bed is always greater than that on the rigid main chan nel bed. For a given flow depth the total shear force (=pgA total S f) in the mobile and rigid compound chan nels of same geometry will be the same. It therefore follows that if the shear force in the main channel is increased, due to the mobile bed, the shear force on the floodplain must consequently be reduced. These data need to be read in conjunction with the correspond ing stage-discharge data, shown in Figure 4, and the resistance data shown in Figures 5 to 7.

As can be seen from Figure 3, for a given flow depth the boundary shear stress values on the rigid main channel bed decrease once overbank flow takes place, and are always less than those in an equivalent rectangular channel, i.e. the isolated floodplain case. It should also be noted that the boundary shear stress values for the rigid symmetric compound channel case are less than those for the rigid asymmetric compound channel case for a given flow depth. Furthermore, Fig ure 3 shows that the boundary shear stresses on the

mobile main channel bed show the opposite trend to

the data from the rigid bed case. Figure 7. Variation of zonal Manning's n with depth, H, for main channel and floodplain in symmetric compound channels.

For inbank flows (H < 0.05 m) and a rigid-bed, Manning's n values are more or less constant at around 0.0091, consistent with values at these Reynolds numbers for the smooth PVC sheets. The corresponding inbank mobile-bed values are much higher, beginning at around 0.018, decreasing with depth to 0.013 at bankfull (H = 0.05 m). The higher roughness at very low depths is attributed to higher viscous shear close to the boundary. For high inbank flows (H > 0.05 m), n increases with flow depth, as the height of the bed forms increase.

At the bankfull stage (H = 0.05 m), Figure 5 shows the apparent reduction in global n values due to the sudden decrease in hydraulic radius. The estimated global Manning's n values at the bankfull level have also been added to Figure 5, assuming that for flow just above bankfull level, the floodplain perimeter is included in the calculation of the section perimeter,

but the floodplain area is not included in the section area, thus influencing values of R, and hence n & f as follows:

Values of hydraulic radius, R, were calculated as 0.040 m at bankfull level and 0.022 m (asymmetric) & 0.015 m (symmetric) for the level just above bank full, giving apparent reductions in n of 33% and 48% due to the reductions in hydraulic radius of 45% and 62% respectively. Thus for the symmetric mobile-bed compound channel, Manning's n drops from a value of 0.0134 just below bankfull to a value of 0.0070 just above bankfull, a reduction of 48%. Likewise the fric tion factor, f , drops from 0.0410 to 0.0158, a reduction of 62%.

For overbank flows, global n values increase further, and Figure 5 indicates that at high depths n becomes more or less constant, at around 0.0091 (sym-smooth) and 0.0124 (sym-mobile). The first value indicates that at high depths the compound channel starts behaving again like a single channel, whereas the second value indicates that the smooth floodplains have become a greater proportion of the overall channel wetted perimeter, even compensating for the increased roughness in the main channel with a mobile bed. Figure 6 shows the corresponding global f Re (Darcy-Weisbach-Reynolds number) relationships, along with the smooth law of Prandtl. For inbank flows in smooth rigid-bed channels, as the flow (or Re) increases, f decreases and follows Prandtl's smooth law until the bankfull stage. At this stage, both f and Re are discontinuous, with f values dropping suddenly when the flow is just out of bank. The f values thereafter start increasing again, eventually following the same trend as the smooth law of Prandtl. The mobilebed cases show a somewhat similar trend, with f initially decreasing until

the bankfull stage, thereafter increasing with Re. Similar relationships, obtained from large-scale experimental work, are shown in Shiono & Knight (1991), Knight et al. (1999), Myers et al. (1999) and Knight & Brown (2001). Figure 7 shows the ‘zonal’ n values for the symmetric mobile-bed channel, with SCM ‘global’ values added from Figure 5 for comparison. The zonal values were calculated from integrated velocity measurements in each zone, using imaginary vertical division lines at the main channel and floodplain interface, excluded from the calculation of wetted perimeter for each zone. Inter-facial shear forces, due to lateral momentum transfer, were likewise not taken into account. The zonal main channel n values vary between 0.013–0.018, whereas the floodplain values are more or less constant at a value of around 0.0096. These zonal values are important, since they are frequently required in divided channel methods to calculate the correct discharge in each sub area (Knight et al., 1989). Figure 7 shows that the main channel zonal n values, calculated by a divided channel method (DCM) are larger than the n values calculated by the single section method (SCM), whereas the floodplain values are smaller than the SCM values. Since these experimentally determined zonal n values include the effects of any momentum transfer arising from lateral shear and vortex behaviour at the main channel/floodplain interface, it follows that if the global n value had been used in any DCM instead, it would lead to a significant over-estimate of discharge in the main channel. Furthermore, since the main channel carries the bulk of the flow at low floodplain depths, this indicates why the DCM overestimates the conveyance of compound channels. Similar relationships to those in Figure 3 have also been found in the experimental results from the UK Flood Channel Facility (FCF), a large

scale-experimental compound channel. Figures 8 & 9 show some boundary shear stress data for two compound channels of slightly different geometry, having either rigid or mobile main channel beds, taken from Phase A & Phase C studies of the FCF pro gramme respectively. See Knight & Sellin (1987), Knight & Shiono (1990), Shiono & Knight (1991), Knight (1992), Knight & Brown (2001) and Brown (1997) for further details. The differences in bound ary shear stress on the main channel bed are much greater for the FCF than for the Birmingham Univer sity flume, due to the much larger scale and bedform dimensions in the FCF. Figures 8 & 9 clearly empha size the effect of the mobile main channel bed on the shear stresses. Once again it is noted that the bound ary shear stress values for the three rigid symmetric compound channel cases in Figure 8 are all less than the corresponding inbank results for the same depth, whereas Figure 9 shows that for the mobile bed cases they are greater.

The measured mean shear stress on each rigid

boundary element was multiplied by the appropri

Shear forces acting on elements 2 & 4 for an asymmetric compound channel with a rigid or a mobile main channel bed. SF, acting on that element. In order to calculate this shear force, the wetted perimeter of the compound channel was divided into various boundary elements as shown in Figure 1. The mean shear force on the main channel bed for the asymmetric and symmetric mobile compound channel was then calculated from the appropriate force balance equation, Equations (2a) & (2b) respectively: 3.4 Apparent shear forces Due to the geometry of the cross section, the majority of the total shear force was carried by the main channel bed and floodplain bed elements. The shear forces carried by these boundary elements are shown plotted versus the relative depth in Figure 10 for the asymmetric compound channel case. This Figure shows that the shear forces carried by these elements increase as the relative depth increases. The same data are expressed as percentages of the total shear of the channel in Figure 11. As the flow depth increases, the percentage shear force on the main channel bed, SF 4 , decreases, while that on the floodplain bed, SF 2 , increases. Figure 11 also shows that for the rigid asymmetric compound channel case the percentage shear forces on the main channel and floodplain bed became equal when the relative depth is around 0.58. This Figure also helps to explain the effect of the mobile main channel bed on the boundary shear forces. Similar relationships between shear forces and relative depth were also found for the symmetric channel cases (see Atabay, 2001). The apparent shear forces, (ASF), acting on the vertical, and horizontal interfaces were calculated for all channel configurations since these forces are of interest when using any divided channel method for

conveyance estimation. For example, the apparent

shear force on any vertical interface, ASF v , in a depth

averaged model may be obtained by considering the

balance of forces on different elements of the cross

section. Typically a river channel cross-section may

be divided into any number of vertical slices in the

transverse direction, y, and the flow assumed to be

in the streamwise direction, x. The ASF acting on

any vertical interface within the cross-section is then

defined as the difference between the weight force

of those elements resolved in the streamwise direc

tion, up to that particular lateral position, y, minus the

integrated boundary shear forces around the wetted

perimeter up to the same lateral position.TheASF then

accounts for any momentum transfer effects across

that vertical slice, arising from turbulent shear, sec
ondary flows and planform vorticity. See Shiono and
Knight (1991). A similar procedure applies to where
the channel cross-section is divided into horizontal
slices.

The vertical interface was taken to be at the main
channel/floodplain interface, and the horizontal inter
face was taken to be at the bankfull level. In order to aid
comparison, these forces were normalised by express
ing them as a percentage of the total channel shear
force, %ASF v and %ASF h respectively. The data for
the asymmetric compound channel are shown in Fig
ure 12. It should be noted that the similar relationships
were obtained for the symmetric compound channels.

Figure 12 shows that the percentage apparent shear
force on the vertical interface for the rigid compound
channel is always positive and greater than that for
the mobile compound channel for a given relative
depth. This is explained by the fact that in the rigid
compound channels at low floodplain flow depths the
lateral momentum transfer is greater, due to dissimilar
velocities in subareas, with the slower floodplain flow
retarding the faster main channel flow. In the mobile

compound channels, however, the velocities in these 0.00

Horizontal interface Vertical interface Figure 12. Apparent shear forces on horizontal and vertical interfaces for asymmetric compound channels with smooth floodplains. sub-areas become more similar, because the mobile main channel bed reduces the flow velocity in the main channel sub-area, due to bedforms and the increased resistance. At high relative depths (around (H -h)/H > 0.35), the main channel flow actually retards the floodplain flow, indicated by the negative %ASF v for these mobile compound channels with smooth floodplains. In Figure 12, the negative %ASF h values on the horizontal interface (at bankfull level) between lower and upper main channel sub-areas, indicate that the upper region of flow is accelerating the flow in the lower main channel. The %ASF h for the channel having a mobile main channel bed is always greater than that for the channel having a rigid and smooth main channel bed. This indicates again that the effect of a mobile bed on the flow is obviously more than the effect of a rigid smooth bed, as might be expected from the increase in roughness due to bedforms. Simple empirical equations between the percentage shear forces carried by each boundary element and the relative depth were obtained for all channel configurations by Atabay (2001). These equations will be useful for further analysis of the resistance coefficients and the sediment transport rate for these particular symmetric and asymmetric compound channels. 4 DISCUSSION OF RESULTS In order to understand the effect of the mobile bed on the boundary shear in a compound channel, the shear forces carried by the main channel bed and the floodplain have been compared for different channel configurations having rigid and mobile main channel beds. Since the width of the main channel bed was fixed for all channel configurations, the shear forces correspond directly to the main channel bed shear stress, τ b .

The data collected from the 18 m Birmingham Uni

versity flume, shown in Figure 3 for both asymmetric

and symmetric compound channels, together with the

data collected from the large-scale FCF, shown in Fig

ures 8 & 9 for a symmetric compound channel, all point

to the same conclusion. It appears that the boundary

shear stress values for compound channels with a rigid

main channel bed show a decrease once overbank flow takes place, and that the values are always less than those in an equivalent rectangular channel at the same depth. For compound channels with a mobile bed and the same geometry, the opposite appears to be true, in that the boundary shear stresses on the main channel bed increase once overbank flow takes place.

In compound channels with a mobile main channel bed the boundary shear stresses increase significantly with flow depth, in contrast to the rigid bed case. This is due to the greater friction factor for a mobile bed compared with that for a rigid smooth bed. The behaviour of global resistance coefficients for com pound channels with either rigid or mobile beds is shown in Figures 5 & 6 to be more complex than for simple channels. Care thus needs to be exercised in assigning global values in any single section method (SCM), especially when the flow changes from being inbank to one in which the flow is overbank with a shallow floodplain depth.The pattern of the global f Re relationship shown in Figure 6 is similar to that found in natural rivers, as indicated by Knight et al. (1989). The global and zonal resistance coefficients shown in Figure 7 indicate the importance of taking into account momentum transfer at the main channel/

floodplain interface due to lateral shear and vor
ticity. Methods for estimating conveyance capacity
that ignore these effects, based on simple DCM
approaches, are therefore bound to be unreliable.
However, some improvements to the divided channel
approach have been made, notably by Ackers (1993),
who proposed the ‘coherence’ method (COHM), and
by Lambert & Myers (1998), who proposed the
weighted divided channel method (WDCM). Both
methods are reviewed in detail elsewhere by Atabay &
Knight (2004). The COHM and WDCM are shown
to give reasonable predictions of conveyance and
division of flow between the main channel and the
floodplains for homogeneously roughened compound
channels, but the WDCM cannot deal with boundary
shear and the COHM gives relatively poor predictions
of mean boundary shear stress in different sub-areas.
Since simple DCM approaches are not capable of pre
dicting boundary shear stress accurately, recourse is
usually made to methods based on the depth-averaged
form of the ReynoldsAveraged Navier-Stokes (RANS)
equations.
In such methods, the bed friction, lateral shear and
vorticity effects are modelled separately, and good pre
dictions may be obtained, not only for conveyance and
division of flow, but also for the lateral distribution of

boundary shear. SeeAbril & Knight (2004a), Knight & Abril (1996), Knight & Shiono (1996) and Shiono & Knight (1991) for application of the Shiono & Knight method (SKM) to various rivers and laboratory flumes. A numerical evaluation of the effects of secondary flow on lateral momentum transfer in overbank flow is given by Tominaga & Knight (2004). The apparent shear force data shown in Figure 12 indicate that ASF v for a mobile bed compound channel is different from the rigid bed case, in that it may become positive at high relative depths. Thus in extreme flood events with high depths, the main river channel resistance may become so large that the direction of the momentum transfer is reversed from the more common one in which the floodplain flows retard the main channel flow. However, this should not be taken as a general rule, since the bed regime may change further at even larger discharges, possibly into upper regime flow type, leading to negative values again at even larger depths. Thus the lateral momentum transfer depends significantly on bed shear in the main channel and its use in predicting lower or upper regime bed forms and the corresponding resistance. It is hoped that these unusual data from some experiments with a mobile bed compound channel will be of value to modellers attempting to simulate sediment motion in compound channels with overbank flow. 5 CONCLUSIONS The following conclusions may be drawn from this study: 1. Main channel bed shear stresses for compound channels with a rigid main channel bed show a decrease once overbank flow takes place, and are always less than those in an equivalent rectangular channel at the same depth. 2. Main channel bed shear stresses for compound channels with a mobile main channel bed show the opposite trend to the rigid bed case. 3. In compound channels that have a mobile main channel bed, the boundary shear stress increases more with flow depth compared to the rigid bed case. This is due to the greater resistance of the mobile bed than the smooth rigid main channel bed. 4. Particular care needs to be exercised in assigning global resistance values when estimating conveyance capacity by the single section method, especially when the flow changes from being inbank to one in which the flow is just overbank. 5. Zonal resistance coefficients indicate the importance of taking into account momentum transfer at the main channel/floodplain interface when estimating conveyance capacity by any of the divided channel methods.

6. Similar relationships were obtained from the exper

imental data using both large and small facilities,

the FCF and the Birmingham University flumes.

7. It is recommended that divided channel methods be replaced by methods based on the depth-averaged form of the Reynolds Averaged Navier-Stokes (RANS) equations when accurate estimates are required of boundary shear in compound channels.

Interaction processes in a straight compound channel with rigid and

flexible emergent floodplain vegetation

I. Schnauder

Institute for Water Resources Management, Hydraulic and Rural Engineering, Universität Karlsruhe (TH), Germany

ABSTRACT: This paper examines the interaction processes between main channel and vegetated floodplain

flow zones in an experimental study at the Theodor-Rehbock Hydraulic Laboratory in Karlsruhe. The physi

cal model was composed of a compound channel section in a 20 m long and 1 m wide flume. The floodplain

was roughened using both rigid and flexible idealised floodplain vegetation in the form of cylinders. They

were arranged at two different densities using a regular staggered configuration. Uniform flow experiments were conducted for different discharges and specifically for high relative flow depths to model extreme flood events. Instantaneous velocities in the longitudinal and cross-streamwise directions were measured using a two component LDV with a high spatial resolution measurement grid at different cross-sections in the longitudinal direction.

1 INTRODUCTION

Compound channels are characterized by a change of roughness and water depth across the channel sec tion resulting in strong lateral gradients of the mean flow velocity. The low velocity floodplain flows are dominated by the large roughness generated by the vegetation. Between these two sections a region with strong momentum exchange and production of coher ent turbulent structures occurs, where the velocities are decelerated in the main channel and accelerated on the floodplain. This region is known from lit erature as interaction zone or apparent shear layer. Many researchers have investigated the interaction phenomena see for example Naot et al. (1996). First, Zheleznyakov (1965) and Sellin (1964) visualized hor izontal vortices with vertical axes along the shear layer as the basic mechanism of transfer of momentum.

The dimensionless relative water depth h/H , where

h is the water depth on the floodplain and H in the

main channel, was found as dictating the degree of

the momentum exchange. Identical structures were

found in compound channels with cylindrical flood

plain vegetation in the experiments of Pasche &

Rouve (1985). Arnold et al. (1989) continued with

the latter researchers and suggested that the interac

tion mechanism induces helical secondary currents

with longitudinal axis. Experiments of Tominaga et al.

(1989), Onitsuka et al. (1999) showed that for a

rectangular compound cross section without vegeta

tion on the floodplains, that for higher water depths (h/H > 0.625) the influence of the horizontal vortices decreases and secondary currents and a strong 3D-vorticity dominate the exchange of momentum. The important role of floodplain vegetation for river restoration and the increased occurrence of extreme flood events demand a better understanding of the associated hydrodynamic processes. The recent study examines the flow processes in a laboratory model of compound channel flow with vegetated floodplains giving special regard to high relative depths and comparing rigid and flexible vegetation. 2 EXPERIMENTS 2.1 Experimental equipment: flume and LDV A 1 : 100 scale physical model of a half-trapezoidal compound channel was constructed at the laboratory facility.The rectangular flume employed for the experiments was 1.0 m wide, 20.0 m long and set at a fixed bed slope of 0.001. The main channel and floodplain were B= 52 cm and b= 48 cm wide, the floodplain elevation was z= 2.3 cm. The main channel bank slope was set at 1 : 1. The main channel as well as the floodplain were roughened homogenously with PVC granules of 3 mm diameter (k S = 3.6 mm). The LDV (LASER Doppler Velocimeter) measurements were carried out with an Aerometrics 300 mW Argon-Ion fibre-optical LASER system operating in backward scattering mode. The system in its downward looking

Figure 1. Schematic view of the flume cross section.

Figure 2. Schematic view of the measurement grid for the different sections.

mode measured the longitudinal and cross-streamwise velocity component. Feeding material (TiO2) was added to the flow to obtain valid sample rates within time steps of 60 seconds at each location. The probe head was mounted on a computer controlled rail car riage equipped with a two-axis traversing system to allow precise control in three directions. The LDV measurements were carried out in a way that separated the cross sections into three regions: main channel, interaction zone and floodplain.

The grid of measurement points was densest in the interaction zone (0.4 m< y< 0.56 m) with lateral and vertical distances of Δy=Δz= 1 cm increments (see Fig. 2). In the main channel (0 m< y< 0.4 m) and floodplain (0.56 m< y< 1.0 m) a higher increment of Δy= 2.5 cm and Δz= 1 cm was chosen. Further more, several cross sections in longitudinal direction (2 within the main channel and the floodplain, 4–6 in the interaction zone) were measured to analyze the longitudinal change in the velocities at different longitudinal positions relative to the cylindrical flood plain vegetation and hence attempt to examine the heterogeneous flow structure.

2.2 Floodplain vegetation and density

Two different types of cylinders were used in two dif

ferent densities. The first setup (s1) used rigid PVC

cylinders of d S = 1.0 cm diameter in a staggered pat

tern, in which each cylinder covered a projected area

of 100 cm 2 (x= 10 cm, y= 10 cm). For the sec

ond setup (s2), the rigid cylinders were replaced by flexible ones fabricated of foam rubber with sealed, air-filled pores that kept the cylinders emergent for all tests and allowed streamwise bending and lateral waving motions. The same rigid and flexible cylinders were used in setup (s3) and (s4) but for a higher density in which each element covered a projected area of 50 cm 2 (x= 5 cm, y= 10 cm). 3 EXPERIMENTAL RESULTS AND ANALYSIS 3.1 Longitudinally averaged mean velocities Figure 3 shows contour plots of longitudinally and time averaged longitudinal velocities. The plots refer to a discharge of 20 l/s to point out the influence of vegetation density and flexibility for a similar relative depth ratio (h/H = 0.83÷ 0.85). Generally, the cross section can be subdivided into three different zones according to the predominant hydromechanical process. First, in the main channel about y=-0.05 cm away from the right channel wall is a zone of free open channel flow (-0.2< y<-0.05), where the vertical velocity profiles can be well described by the logarithmic velocity law. Secondly, the floodplain regime between the left channel wall and the cylinder at the edge to the main channel (-1< y<-0.53), where the wakes generated by the cylinders dominate the flow by their additional production of drag forces and turbulent energy. In this zone the vertical velocity profiles are almost constant over the water depth, but vary in magnitude depending on the relative lateral and longitudinal distance from the cylinders. Only the first row of cylinders (y=-0.53 m) contributes to the exchange of momentum and deceleration of main channel velocities. From this point on the vertical floodplain profiles remain periodic in magnitude in the lateral direction. Due to their waving motions and bending, the floodplain contours in Figure 3 are less sharp for the flexible setups (s2 and s4) than for rigid (s1 and s3). Thirdly, the interaction zone which is characterized by a strong lateral exchange of momentum between the main channel and the floodplain (-0.53< y<-0.2) and the presence of coherent vortices and secondary currents. The strong

impact of the momentum exchange on the longitudinal velocities is clearly visible (see Fig. 3). Independent from the floodplain vegetation, all graphs show a near-bed intrusion of higher velocity components from the main channel towards the floodplain and vice versa in the upper regions of the flow. The strongest deformations occurred for the setups with flexible cylinders (s2 and s4) and increased with increasing relative depth ratios. Furthermore, the velocity maximum in the main channel was higher and laterally shifted towards the 0 m/s 0.02 m/s 0.04 m/s 0.06 m/s 0.08 m/s 0.1 m/s 0.12 m/s 0.14 m/s 0.16 m/s 0.18 m/s 0.2 m/s 0.22 m/s 0.24 m/s 0.26 m/s 0.28 m/s 0.3 m/s 0.32 m/s 0.34 m/s 0 0.04 0.08 s1 (rigid, low density) 0 0.04 0.08 0.12 s2 (flexible, low density) 0 0.04 0.08 0.12 s3 (rigid, high density) y [m] -1 -0.9 -0.8 -0.7 -0.6 -0.5 -0.4 -0.3 -0.2 -0.1 0 0 0.04 0.08 0.12 s4 (flexible, high density) z [m]

Figure 3. Measured isovelocity contours of temporally and longitudinally averaged velocities for a discharge of Q= 20 l/s.

right wall. This suggests that the influence of sec

ondary currents in the present compound channel is

remarkably high.

3.2 Longitudinal change of velocities

Measurements of 4–6 different cross sections in the

interaction zone were used to analyze the longitudi

nal change of velocities influenced by the position

relative to the cylinders. Figure 4 shows six mea

sured profiles exemplarily for setup s2q30 (flexible,

sparse, highest discharge Q= 30 l/s, h/H = 0.87). The

longitudinal contours show good homogeneity in the

main channel. For the region close to the cylinders

(–0.52 m< y<–0.55 m) peaks occur which result

from the wake structures and their local deceleration

and acceleration effects. Figure 4c refers to a posi

tion Δx= 5 cm in the wake behind a flexible cylinder

and shows the lowest velocities of $\bar{u}$= 0.035 m/s in the

interaction zone. However it should be noted, that the

cylinders were bent streamwise for about Δx= 4.5 cm

(at water level). Hence the contours are not exactly

vertical over the water depth.

The vector plots of transverse velocities $\bar{v}$[m/s]

in Figure 4 prove the presence of secondary cur

rents. To compensate for nonalignment errors of the

LDV, a correction procedure was applied, see Wilson

(2003).Assuming no net transfer of momentum in each

vertical, correction angles of the LDV head were deter

mined and the transverse and longitudinal velocities recalculated from the measured data. This affected mainly the transverse component, whereas the longitudinal component resulted in changes of less than 0.5%. The transverse velocities show a near-bed flow from the main channel towards the floodplain (z< 0.08 m) and a counter-directed flow from the floodplain towards the main channel close to the water surface (z> 0.06 m). This secondary flow is evident in all cross sections and reaches maximum velocities of about $\bar{v}$=±0.03 m/s (respectively 8% of $\langle\bar{u}\rangle$ max). The influence of the wake is also clearly visible in the vector plots of transverse velocities $\bar{v}$[m/s] in Figure 4c which refers to a position Δx= 0.033 m behind a cylinder. Due to the bending, the transverse flow is directed away from the cylinder (outer wake region) at lower water depths and inwards close to the water surface (inner wake region). 3.3 Standard deviation of longitudinal change In Figure 5 the standard deviations of time averaged velocities were calculated as a measure of their longitudinal change along the channel (using data of 4 cross sections in case s3 and s4, and 6 in s1 and s2). Depth-averaging was carried out because the influence of the water depth was found to have only a minor influence. The standard deviation is about three times higher for the

longitudinal component and shows a stronger -0.55 -0.5

Figure 4a–f. Measured temporally averaged isovelocity

contours of longitudinal velocity $\bar{u}$ [m/s] (left) and vector

plots of transverse velocities $\bar{v}$ [m/s] (right) for setup s2q30

(flexible, sparse, highest discharge, $< \bar{u} >$ max = 0.374 m/s).

The six diagrams refer to different longitudinal positions from

besides a cylinder (Fig. 4a, topmost) to right in front of the

following one (Fig. 4f, bottom). The distance between each

sheet was Δx= 1.661 cm.

impact of the cylinder wake where the maximum val

ues were obtained. The sparser configurations s1 and

s2 show higher longitudinal variation than the denser

setups s3 and s4. Furthermore, the flexibility of the

cylinders has a damping effect and decreases the lon

gitudinal standard deviation (see for cases s2 and

s4). Away from the floodplain, the standard devia

tion remains almost constant in the main channel for

all setups. The transverse component is distributed

very uniformly along the channel and shows no peaks

respectively no significant influence of the wake zones

of the cylinders.

Generally, with increasing discharges the longitu

dinal peak values remained constant in the wake zone

whereas both components increased in magnitude in

the main channel (about 50% for Q= 20 l/s and 100%

for Q= 30 l/s). Figure 5. Depth-averaged standard deviations of longitudinal change of longitudinal <s(u¯)> [m/s] and transverse <s(v¯)> [m/s] time-averaged velocity components for all floodplain vegetation setups and a discharge of Q= 10 l/s. The gray line indicates the location of the floodplain boundary position and the first row of cylinders at y=-0.53 m. 3.4 Turbulent kinetic energy The longitudinally and time averaged turbulent kinetic energies in Figure 6 were calculated from the longitudinal and transverse turbulence intensities u rms [m/s] and v rms [m/s] using: k =½(u 2 rms + v 2 rms) 0.5 and afterwards averaged longitudinally to obtain <k¯> [m 2 /s 2]. Figure 6 shows for each setup four different zones of local energy peaks. First, a near-bed zone in the main channel generated by the bed shear stresses. Secondly, above the floodplains the generation of turbulent kinetic energy induced by the cylinders. The third zone marks the vertical boundary shear layer between the floodplain and the main channel in the interaction zone (-0.4 m< y<-0.3 m). The fourth local maximum is located within the main channel (at about y=-0.35 m) and close to the water surface. This again is related to the impact of secondary currents that shift energy from the floodplain boundary layer into the main channel interior. For the flexible 0 0.04 0.08 0 0.04 0.08 0.12 0 0.04 0.08 0.12 -1 -0.9 -0.8 -0.7 -0.6 -0.5 -0.4 -0.3 -0.2 -0.1 0 0 0.04 0.08 0.12 0 0.02 0.04 0.06 0.08 0.1 0.12 0.14 0.16 0.18 0.2 0.22 s1 (rigid, low density) s2 (flexible, low density) s3 (rigid, high density) s4 (flexible, high density) y [m] z [m]

Figure 6. Contour plots of longitudinally and temporally averaged dimensionless turbulent kinetic energy <k>/(<u¯> max) 2

[-] for a discharge of Q= 20 l/s.

cylinders (s2 and s4) the trace of the energy shift is more upward directed and close to the water surface, whereas for the rigid cylinders (s1 and s3) a stronger sideward shift around the vertical level of about half the water depth H occurred.

The magnitude of turbulent kinetic energy at the vegetation boundary layer increased with increas ing discharges and relative depth ratios. Compared with the bed shear generated energy, it was lower for the lowest discharge (Q= 10 l/s) and higher in case of the highest discharge (Q= 30 l/s). This points out that the relative depth ratio as well as vegetation properties are dominant parameter for the boundary shear layer between vegetation and open main chan nel flow.

4 CONCLUSIONS

The aim of the present study was to characterize the flow field and momentum exchange processes in a compound open channel with vegetated floodplain introducing pseudo-natural properties of vegetation and high relative depth ratios.

It was found that secondary currents are the pri

mary mechanism for momentum exchange. Near the junction a strong intrusion of high longitudinal main channel velocities into the floodplain was found at lower regions of the flow. Whereas slower mean velocities from the floodplain were dispersed far into the main channel at the upper regions of the flow. The analysis of longitudinal change of velocities proved that this effect is non-local and has a high longitudinal heterogeneity along the channel. The magnitude of the secondary currents increased with increasing water depth and caused significant deflections of the lateral and vertical velocity profiles. Furthermore, the maximum longitudinal velocities in the main channel were shifted away from the vegetation. This effect was amplified by the bending and lateral waving motion of the flexible cylinders. The distribution of turbulent kinetic energy within the channel confirmed the results. Energy generated at the shear layer between floodplain and main channel was shifted upwards and away from the vegetation corresponding to the measurements of the transverse currents. The magnitude of the boundary turbulent kinetic energy between the vegetation and the main channel was found to be a function of both the relative depth and the floodplain vegetation properties. The highest turbulent kinetic energy was measured for flexible vegetation arrangements compared to the rigid. This was observed at the two highest flow discharges. In fact the lower density flexible vegetation produces higher turbulent kinetic energy than the denser rigid setup. This suggests that the vegetation flexibility has a stronger influence on turbulent kinetic energy field than the vegetation density.

The experiments herein are a first step towards the physical understanding of interaction processes in compound channels of rigid and flexible vegeta tion properties. They show that plant properties like waving motions, deflection and compression have an important impact on velocities and exchange pro cesses and have to be taken into account in future

research.

Numerical evaluation of secondary flow effects on lateral momentum transfer in overbank flows

A. Tominaga

Nagoya Institute of Technology, Nagoya, Japan

D.W. Knight

The University of Birmingham, Birmingham, United Kingdom

ABSTRACT: In compound open channel flows, the momentum transfer from the main channel to the flood plain is a strong characteristic and the contribution of the secondary flow is known to be very large. In this study, numerical simulation is conducted to understand the secondary flow effect on the lateral momentum transfer with a standard k-ε model linked artificially with a given secondary flow. This simulation reproduces the typical linear distribution of the momentum transfer term. The simulated secondary flow can decrease the bed shear stress in the main channel. In cases of large relative depth, the secondary flow explains the bed shear stress increase on the flood plain reasonably well, but an unrealistically large secondary flow is required to reproduce the experimental apparent shear stress in cases of small relative depth. Hence another mechanism, like large-scale planform vortices, is needed to explain the characteristic increase of bed shear stress on the flood plain.

1 INTRODUCTION

When rivers flow overbank, significant momentum exchange occurs laterally, causing deceleration in the

main channel and acceleration on the flood plains.This noticeable feature of overbank flow was clearly shown by the SERC-FCF measurements (Knight & Sellin (1987)). It is postulated that large-scale planform vortices, rotating about a vertical axis, and streamwise secondary flows are the reason for the momentum transfer from the main channel to the flood plain. The lateral momentum transfer is represented as an apparent shear stress, which is calculated from the balance in a depth-averaged momentum equation. Shiono and Knight (1991) indicated lateral distributions of the apparent shear stress on the Flood Channel Facility (FCF) data. They also measured the Reynolds shear stress and extracted the secondary-flow dispersion term. As a result, the contribution of the secondary flow to the lateral momentum transfer is known to be very large. This secondary flow term plays an important role in the prediction of the bed shear stress and the depth-averaged velocity in compound open channel flows. However, the secondary flow structures that cause such a significant momentum transfer are still not fully understood. An accurate measurement of the secondary flow is very difficult, especially on shallow flood plains. In this study, 3-D numerical calculations were conducted with synthetically generated secondary flows. The patterns of secondary flows were generated according to the typical experimental results

ofTominaga & Nezu (1991) andTominaga et al. (1988). The strength of secondary flows was selected to reproduce the estimated distributions by Shiono & Knight and the effects of secondary flow structure and strength were investigated. 2 DEPTH-AVERAGED MOMENTUM ANALYSIS The depth-averaged momentum equation is obtained by integrating the streamwise component of the Reynolds averaged Navier-Stokes (RANS) equation over the flow depth (e.g. Shiono & Knight (1991)). The bed shear stress is expressed as follows: where y is the lateral direction, τ b is the bed shear stress, d is the water depth, S 0 is the bed slope, τ yx is the depth-averaged lateral Reynolds shear stress, − (ρUV) d is the shear stress due to the secondary flow, s is the lateral bed slope, ρ is the density of water and

g is the gravitational acceleration. From equation (1),

the shift of bed shear stress from the two-dimensional

value ρgdS 0 is produced by the second and third terms

on the right-hand side. The second term expresses

the turbulent diffusion of momentum. The third term

accounts for lateral momentum transfer due to the sec

ondary flow and has been measured for only a few

cases. This term is defined as '' by Shiono & Knight

(1991).

where the lateral Reynolds shear stress is expressed

by an eddy viscosity model, ε yx is the depth-averaged

eddy viscosity, and U d is the depth-averaged velocity.

The FCF data show that the actual bed shear stress

exceeds the two-dimensional value even in the region

of ∂U d /∂y= 0 on the flood plain (Knight & Shiono,

1996). In this region, the secondary flow term is the

only explicable reason for the increase of bed shear

stress, as follows:

Shiono & Knight back-calculated the value of '' from the experimental results of depth-averaged velocity, bed shear stress and the lateral Reynolds shear stress. They also indicated that the lateral distribution of - (ρUV) d is almost linear in the main channel and flood plains, respectively. Shiono & Knight (1991), Knight & Shiono (1996), Knight & Abril (1996) and Abril & Knight (2003) solved equation 1 analytically and numerically by adopting respective constant val ues of '' for the main channel and flood plain, and got good agreement with the experimental data. However, the secondary flow effects on lateral momentum trans fer were estimated indirectly and definite evidence has not been obtained because of the difficulty in mea suring the secondary flow sufficiently accurately. It is thus very important to clarify the inner structure of this secondary flow term, ''.

Many researchers calculated the secondary flow in compound open channels, trying to reproduce the experimental data of Tominaga & Nezu (1991). Naot et al. (1993) used an algebraic stress model and Thomas & Williams (1995) calculated by using Large Eddy Simulation (LES). Their calculations were suc cessful for reproducing secondary flows. However, their geometric conditions were limited to high rela

tive depth and a narrow open channel.The channel was

an asymmetric rectangular compound channel with a

relative depth Dr= (H – h)/H = 0.5 and a width ratio

B/b= 2.0, where H is the main channel depth, h is

the flood plain height, B is the channel width and

b is the main channel width. Thomas & Williams (1996) simulated FCF experimental data by using LES. This calculation was undertaken for a symmetric trapezoidal compound channel with Dr= 0.25 and B/b= 2.2. In this case, the calculated secondary flow pattern was very different from the rectangular case and Dr= 0.5. The characteristic inclined upflow from the junction between main channel and flood plain does not appear. But the experimental data used in the comparison was not accurately measured. Moreover, this case has smaller side slope of the main channel (s= 2) and a narrow flood plain. The calculated bed shear stress agrees well with the experimental one. The prediction of secondary flow by high order turbulence models is still an uncompleted task in such a shallow compound open channel flows. Therefore, a standard k-ε turbulence model is used herein for calculating the primary velocity; subject to given or pre-selected secondary flows. 3 NUMERICAL SIMULATION METHOD The streamwise component of the Reynolds equation and continuity equation were solved numerically by using the k-ε turbulence model.Transport equations of turbulent kinetic energy k and dissipation rate ε were solved with standard model constants. The equations are discretized by a finite volume method with hybrid scheme and solved by the SIMPLE algorithm. A block masking method for a rectangular coordinate system was used to express the cross-sectional shape of the channel. As to the boundary conditions, the near-wall velocity is assumed to comply with the log-law that covers the rough boundary, as follows: where k s is the equivalent roughness height, U ∗ is the friction velocity, ν is the viscosity and κ is the Karman constant (κ= 0.41). Equation 6 is the approximation for the Nikuradse’s experimental curve for roughness function B. In all FCF cases, k s = 0.0004 m is adopted. The free surface is treated as a rigid lid and all the gradients normal to the water surface are zero. A standard isotropic k-ε model is known not to reproduce the turbulence-induced secondary flow, and is inadequate in predicting separating or impinging flows. In this study, however, this simple turbulence model has sufficient

ability to predict the primary velocity field affected by secondary flows, because the secondary flows are artificially modelled and the channel is prismatic.

Secondary flows are given for each cell by using

stream functions in accordance with the experimental

results, as follows:

where i is the number of the secondary flow cell, y i1 ,

y i2 are the left and right limits of the secondary flow

cell, z i1 , z i2 are the bottom and top limits of the cell,

A i is a constant for the secondary flow strength, and

B i & C i are constants for eccentricity of the secondary

flow. The V and W equations are not solved but the

velocity correction by pressure gradient is applied to

satisfy the mass conservation. The values of constants

were adjusted to reproduce the bed shear stress due to

secondary flow obtained by the FCF measurements.

4 SIMULATION RESULTS

4.1 Secondary flow parameters

Typical secondary flow patterns that were used in the

simulations are shown in Fig.1. This structure of sec

ondary flow is based on the experimental results of

Tominaga & Nezu (1991), but it is somewhat modi

fied for simplicity. The flood plain cell is projected

into the main channel to achieve effective momentum

transfer from the main channel to the flood plain. The 0 0.02 0.04 0.06 0.08 0.1 0.12 0.14 0.16 0.18 0.2 0 0.25 0.5 0.75 1 1.25 1.5 1.75 2 2.25 2.5 2.75 3 3.25 z (m) y (m) 0 0.1 0.2 (m/s) 0 0.05 0.1 0.15 0.2 0.25 0.3 0 0.25 0.5 0.75

Figure 1. Modelled secondary flow vectors given into calculation (Upper: FCF 0205, Lower: FCF 0308). secondary flows near the sidewall on the flood plain were not considered in this study. The lower pattern of the case 0308 is almost similar to that measured by Tominaga & Nezu (1991), but the upper pattern has not verified because there is no detailed measurements. Shiono & Knight (1991) measured the secondary flow in the FCF cases of Dr< 0.24. Unfortunately, there are few measuring points on the flood plain because of experimental difficulties. Therefore, the secondary flow structures on the flood plain are not clarified yet. As to the main channel, the lower cell of the secondary flow is observed and the maximum velocity is about 0.02 m/s. The upper cell is not clear. On the other hand, from the calculation of Thomas & Williams (1996), the calculated maximum secondary velocity is 0.81U * and maximum value of -(UV) d is almost -2.0U 2 * , where U * is the friction velocity. The simulated secondary flow is rather large but its structure is similar to the observed one, except for the upper cell. The strength and shape parameters, A i , B i and C i of the given secondary flows were adjusted for each cell respectively, to reproduce the observed shear stress due to secondary flow. The calculated results of primary velocity, and the momentum transfer due to secondary flow, were then depth-averaged. Fig.2 shows the lateral distribution of -(ρUV) d with different values for the strength parameter A for the flood plain cell. The profiles of-(ρUV) d show the linearly descending feature that is quite similar to the experimental results calculated from equation 1 by Shiono & Knight (1991), but the magnitude is smaller. Since a much larger secondary flow is required to get the same magnitude as

stress (FCF 0205).

the experimental –(ρUV) d , only these three cases are

shown.

Fig.3 shows the lateral distributions of experimen

tal and calculated bed shear stress with secondary

flow of different strengths. The calculated bed shear stress with secondary flow is in fairly good agree ment with the experiment when A fp =-0.0012 and it clearly illustrates the effects of secondary flow in comparison with the ‘no secondary flow’ case. The increase of the bed shear stress on the flood plain cor responds well with the lateral gradient of -(ρUV) d . On the other hand, the depth-averaged velocity did not increase but somewhat decreased on the flood plain in low relative depth cases, in contrast with the result of the depth-averaged analysis. In high relative depth cases, the velocity on the flood plain also increased to agree with the experiments.

To establish the typical distribution of -(ρUV) d on the flood plain, the eccentricity coefficients, B and C, are known to be important. In this case, B= 0.35 and C = 0.6 were adopted. The coefficient B determines the gradient of -(ρUV) d , whereas C provides effi ciency in lateral momentum transport. Typical lateral

distributions of that on the flood plain are shown in -0.14 -0.12 -0.1 -0.08 -0.06 -0.04 -0.02 0 0.02 0.04 0.06 0.08 0.5 1.5 2.5 3.51 2 3 y (m) V (m / s) z = 0.19 z = 0.186 z = 0.176 z = 0.167 z = 0.161 z = 0.155 Figure 4. Vertical distributions of lateral velocity on the flood plain (at y= 1.025 m). Fig.4. Those distributions descending toward the sidewall can establish the linear distribution of -(ρUV) d . Fig.5 shows the typical vertical distributions of the lateral mean

velocity V adjusted for cases of FCF 02series at the nearly peak position on the flood plain.The values are normalized by the averaged friction velocity. These skewed distributions are similar to those in curved open channels (Tominaga & Nagao (2000)). It is verified that this type of secondary flow profile can most effectively transfer the momentum. However, the required secondary velocity is much larger than that observed in many previous experiments.The maximum secondary flow velocity is almost the order of U * in most measurements and calculations. With an increase of the flood-plain depth, the required velocity becomes smaller to approach a realistic value, but it is still large, especially near the bed. On the other hand, the maximum lateral velocities for the main-channel lower and upper cells are reasonably less than the order of U * in the main channel. The bed shear stress in the main channel is well decreased by the given secondary flow structures. due to secondary flow (FCF 02-series).

shown in Fig.6 for cases of FCF 02-series. The lat

eral distributions become fairly linear for the cases of

Dr> 0.24, where Dr is the relative depth defined as

Dr= (H – h)/H . However, it was difficult to realize

the linear distribution for the cases Dr≤ 0.2. Although

it may be possible to make those more similar to the

experimental results by adjusting the parameters, it

was not investigated further in this study. The sec
ondary flow structures in a shallow flood-plain depth
may be different from the adopted pattern that was
observed in cases of deep flood-plain depth. Fig.7
shows the calculated lateral distribution of the bed
shear stress in comparison with the experimental data
in the case of Dr= 0.16 and Dr= 0.5. In the case of
shallow depth (0203), the calculation agrees reason
ably with the experiment even though the momentum
transfer term is different from the experimental one.
The steep gradient of -(pUV) d near the interface
on the flood plain sustains the increase of the bed
shear stress. However, the turbulent momentum trans
fer should make a large contribution to the increase
of the bed shear stress in this interfacial region with
a large lateral velocity gradient. The increase of the
bed shear stress is under-estimated in the region of no
lateral velocity gradient. For the case of large relative
depth (0308), the bed shear stress is increased over
the whole flood plain, but is underestimated near the
sidewall. This is because the secondary flow pattern is
not properly considered near the sidewall of the flood
plain in this simulation.

The lateral momentum transfer due to the secondary
flow is also affected by the vertical distribution of

the primary velocity. Fig.8 shows the semi-logarithmic

plot of the primary velocity at y= 1.0 m on the flood

plain. The solid line indicates the log law distribution,

as follows:

The constant A s = 4.8 is taken from the figure. The

Figure 10. Calculated primary velocity contours (Upper: FCF 0205, Lower: FCF 0308). In this case, the secondary flow effects reasonably explain the flow characteristics. Fig.10 shows the calculated primary velocity contours with and without the given secondary flow in Fig.1. In the case of 0205, the velocity in the main channel is noticeably decreased by the secondary flow effect, whereas that on the flood plain is not changed so much, as seen in Fig.9. Fig.11 shows the measured contours of primary velocity. The

calculated result approaches the experimental one by incorporating the artificially generated secondary flow. The total discharge is decreased as a result of the additional energy loss due to the secondary flow. In the case of 0308, the effects of secondary flow work well and calculated contours are very similar to the experimental ones except very near the free surface and the sidewall of the flood plain. Particularly, the flow structure in the interfacial region is well reproduced. 4.3 Effects of secondary flow on turbulence The calculated turbulent kinetic energy k and vertical Reynolds stress -ρ uw are shown in Figs.12 and 13, respectively, with and without the secondary flow for the case of 0205. The turbulent kinetic energy is considerably increased around the interfacial region by the effects of secondary flow, whereas that near the bed of the main channel is decreased. The Reynolds stress with the secondary flow indicates minus value below the interface bisector because of the minus gradient of ∂U/∂z. More significantly, it becomes much larger just above the bisector. the primary velocity gradient and then this increases

the generation rate of the turbulent energy. Thus, the

secondary flow can cause the drastic increase of the

turbulent energy in the interfacial region. It is also con

sidered that the advective energy transfer contributes

to this phenomenon.

The lateral Reynolds stress-ρ uv is more important

because it is directly related to the lateral momen

tum transfer. Fig.14 shows the lateral distribution of

the Reynolds stress -ρ uv with the experimental data

shown by Shiono & Knight (1991) for the cases of

FCF 0205 and 0203. In the case of Dr= 0.24, the cal

culated value is almost similar to the experimental one,

though the peak position is shifted toward the main

channel side. With a decrease of the floodplain depth,

in the case of 0203, the calculated Reynolds stress increases slightly but the experimental one increases significantly. As a result, the present turbulence model cannot predict the Reynolds stress-p uv well for shal low compound open channels.This underestimation of the Reynolds stress in the interfacial region is caused by the fact that the present model cannot reproduce the large-scale vortices inherently.

It is well known that large-scale coherent planform vortices, rotating about vertical axes, are generated in compound open channel flows.These large-scale plan form vortices cause significant fluctuations in both the longitudinal and lateral velocities, as shown by Knight & Shiono (1990). A time-dependent numerical model is necessary for accounting for such large-scale planform vortices. Accounting for this difference, the given secondary flow is excessive in this interfa cial region in this shallow depth case. The turbulent momentum transfer concerns an increase of the eddy viscosity in the depth-averaged analysis using equa tion 1 but does not contribute to the increase of the bed shear stress in the region of no velocity gradient. In this region, the momentum transfer due to secondary flow is still important. 5 DISCUSSION In this study, it was shown that the synthetically given secondary flow could reproduce the presumed momentum transfer term in the

lateral momentum equation 1. However, it remains to explain why such a large secondary flow is required to simulate the experimentally determined momentum transfer. In the case of low relative depth, the maximum secondary velocity that gave the best fit was around 10–15% of the maximum primary velocity U max , whereas it is known that the measured secondary velocity is generally of the order of 4% (Tominaga & Nezu (1991)). This implies that the increase of the bed shear stress on the flood plain, that is, the value of '' in equation 2 cannot be explained by only secondary flow effects. As another mechanism, a uniform open channel flow with planform vortices is considered. Planform vortices are moving with certain celerity and they cause periodic perturbation of all the variables in Eulerian observation. Ikeda et al. (1995) shows the distinctive pictures of the planform vortices. Bousmar & Zech (2002) obtained the celerity and the wave period by experiment and stability analysis. To consider the periodic large-scale motion, a concept of the Unsteady Reynolds Averaged Navier-Stokes (URANS) model is useful. However, the mean velocity dispersion and the Reynolds stress based upon short-time averages are reduced to the usual long-time averaged expression. The planform vortices inevitably interact with the streamwise secondary flow. The secondary flow structure is then a result of time averaging of the complicated three-dimensional flow, including the effects of these planform vortices. The momentum transfer due to the large-scale perturbation should be captured as Reynolds stresses, and then, the secondary flow and the Reynolds stress only remain. In order to clarify this point, it is still necessary to perform careful experiments and time-dependent numerical calculations with a movable free-surface condition. 6 CONCLUSIONS Numerical simulation is conducted to understand the secondary flow effect on the lateral momentum transfer. The turbulence model used is a standard k-ε model linked with an artificially given secondary flow. This simulation revealed the inner structure of the secondary flow term of the depth-averaged lateral momentum equation. In cases of large relative depth and in the main channel, the secondary flow reasonably explains the bed shear stress increase or decrease. When the relative depth is small, however, an unrealistic strength of secondary flow is required to explain the increase of the flood-plain bed shear stress. This fact implies that another mechanism must be accounted for in the lateral momentum transfer.

Since the momentum transfer due to these vortices are

included in the Reynolds stress term in RANS model

through the long-time averaging process, the reason for the increase of the flood-plain bed shear stress in cases of small relative depth is still in question. Further experiments and 3-D unsteady numerical simulation are necessary to improve our understanding.

Effect of lateral variation of roughness on flow conveyance within a

trapezoidal channel cross-section

H.I. Mohamed

Lecturer, Civil Eng. Department, Assiut University, Assiut-Egypt

ABSTRACT: The hydraulic computations involved in design of open channel are (generally) based on the

uniform flow formula of Manning. The Manning roughness coefficient (n) in this approach is usually assumed

to be constant and not to vary with the flow depth or roughness. It has been known for many years, however,

that this assumption is erroneous. An important feature of most rivers and canals is the variation in roughness

between channel bed and side banks due to non-homogeneity in excavated soil, bank revetment, and/or vegetations

grow. In these channels, flow conditions lead to a complex flow situation with intensive mass and momentum

exchange between main channel and banks. Therefore the flow structures that occur in these channels are

extremely complex. A method for predicting the total conveyance of trapezoidal channel cross-section with

varying roughness in perimeter is developed. Where, a numerical hydraulic model is coupled with a physically

based flow-resistance equation. The resulting model is capable of simulating the total conveyance of trapezoidal

channels with varying roughness along bed and side banks. To make the model results more amenable to the

practicing engineer, design equations and plots were developed. These can be used as an alternative solution

for channel designs; relieving the practitioner of the need to run the numerical program. A comparison between

the present method and traditional divided channel approach proved that the model is superior on the other

methods.

1 INTRODUCTION

Situations where channels sections have roughness

varying laterally along the wetted perimeter are often

encountered in design problems and laboratory exper

iments. Canals and tunnels partly lined with different

construction materials in bottom and sides, highly

vegetated sides with smooth channel bed, and over

banks with varying land use and treatment under

high stages are the typical instances. Also, in allu

vial channels, a marked difference in roughness has been known to exist across the channel bed and sides, Ahmed and Bakry (1997), El-Attar (1980). Many of irrigation channels are excavated in non-homogenous soil (the roughness of the bed is varied than that of banks or banks itself have varying roughness with depth). If such types of channels are designed by the traditional methods (averaged cross-sectional para meters), this will expose these channels to expensive and environmentally damaging. In all such problems, computations of equivalent roughness for the whole section are sometimes necessary. Various formulas to compute this equivalent or composite roughness can be found in the literature, Chow (1959), French (1996), U.S. Army Corps of Engineers (1994), Armanini and Righetti (1998) and Garbrecht and Brown (1991). Recent researches have shown that the use of channel with varying roughness as a single unit will underestimate the values of discharge be obtained, Ali and Mohamed (1991), Myers et al. (1999), Dolgopolova (2001). This because the method used ignores the turbulent shear interaction and momentum transfer between the bed and side banks. The turbulent shear (forming vortices) that transfer momentum away from the bed to the banks has been thoroughly investigated by Rabkova and Garanina (2001). Where they measured the three-dimensional components of velocity in trapezoidal cross-section and confirmed kinetic energy exchange between adjacent layers.They concluded that this process controls the formation of longitudinal velocities in the water column. It is common knowledge that characteristic features of the turbulent flow are velocity fluctuations and the vortex motion, which results in the formation of three-dimensional vortices. The displacement of these vortices brings about redistribution of kinetic energy between elements of the liquid. This process is especially active in the zones, where local velocities vary

because of variations in the depth or bed roughness. Under the effect of transverse circulation, the accel erated liquid intrudes into the near bottom layers and vice versa. The result is the general levelling of three dimensional flow velocity both in the vertical and transverse direction.

To this date, however, very little has been done to evaluate unique model using numerical and mathe matical base. As shown from the mentioned above, there are clear needs for physically based methods of predicting the impacts of varying roughness on flow resistance and flow capacity. In the following, a numerical hydraulic model will be coupled with flow resistance equation for computing flow in channels with varying roughness.

2 THEORETICAL CONSIDERATION

As, it is showed above, the division lines used in divided channel method are not shear free bound aries in the case of variation in the roughness through the wetted perimeter due to the turbulent interaction between the fluid streams. Observation of depth aver age velocity distributions, such as those shown in Rabkova and Garanina (2001), illustrates that there is a transition between the main channel and banks velocities that can not be dealt with by applying an

apparent shear stress at a single interface. Rather, there

is a variation of the apparent lateral shear stress (τ xy)

across the channel. To better model this variation of

the apparent shear stress, Lambert and Sellin (1996);

Darby and Thorne (1996), (which is a representation

of the turbulent momentum exchange ρ.u.v) the chan

nel can be subdivided into a finite number of vertical

elements as shown in Fig. (1). The vertical element is

examined in more detail, using the control volume as

in Fig. (1-b). For uniform flow, it can be show that; 1.0
Sy (a) (b)

Figure 1. A schematic sketch of a channel division into a finite number of small vertical elements. where S is the longitudinal channel slope and τ b is the bed shear stress. The coefficient (B ∗) associated with the bed shear stress is used to account for the increased area of contact with the channel bed due to the lateral inclination of the channel bed at a crosssection (S y) and is equal to √ 1+ S 2 y .A factor similar to (B ∗) was first introduced by Rodi (1980) and by both Lambert and Sellin (1996); Darby and Thorne (1996). This approach to the derivation of Eq. (1) was chosen because of its ease and accessibility. The solution of Eq. (1) and in particular the evaluation of the apparent lateral shear stress (τ xy) and the bed shear stress (τ b) are detailed below. In Eq. (1), the downstream component of the weight of a unit value of water (term 1) is assumed to be balanced by frictional bed shear (term 2) and lateral shear (term 3) only. The value of bed shear stress (τ b) can be expressed by: where q= discharge per unit width, f=DarcyWeisbach friction factor, u=mean velocity through the element and ρ=water density. The value of the lateral shear stress (τ xy) (term 3) can be expressed by: where μ= absolute viscosity. Then (term 3) in equation (1) can be formulated as follow

where ε= eddy viscosity and the other parameters as

defined before.

Now by substituting Eqs. (2) and (4) into Eq. (1) the

following expression for describing the unit discharge distribution across the channel is obtained.

A solution of this equation is possible with the addi tion of non-slip boundary conditions (q= 0) at the outer boundaries of the channels. The numerical solu tion of Eq. (5) is obtained using a finite difference approximation and the solution of the resulting sys tem of non-linear equations is performed using the Newton-Raphson method. In Eq. (5) all the terms except the Darcy-Weisbach friction factor (f) and the eddy viscosity coefficient (ε) can be evaluated.

A simple but reliable eddy viscosity model is used in (5).

where $u_* = \sqrt{g.z.S}$= local shear velocity (m/s); and NEV= user-specified non-dimensional eddy viscos ity coefficient, usually taken as approximately 0.16, Darby and Thorne (1996) assumed uniform value across the channel.

To apply the flow model for predicting the distri bution of the unit discharge for a specified water surface elevation, it is necessary to estimate local Darcy-Weisbach friction factor at each computational node across the wetted perimeter, accounting for sed iment roughness elements. A procedure developed by Masterman and Thorne (1992) is used herein to do

this. Their method is based on the physically based

Colebrook-White equation.

where k= local roughness height (m); c= coefficient

assumed to take the value of von karman coefficient

(0.4); and a= coefficient that is a function of the cross

sectional shape of the channel.

For rough bed, Masterman and Thorne (1992) sug

gest that Hey's (1979) calibration of Eq. (7) offers

reasonable predictive ability, so that

where z= local flow depth; k= local roughness

height; and a s = shape-correction factor given by Hey

(1979), and

where R= hydraulic radius and D= the maximum

water depth. Eqs. (5)–(8) have been implemented in a computer program that provides estimates of unit discharge of a channel of a specified cross-section geometry and gradient, bed material size for the channel bed and side banks. The cross-section is divided into a number of computational nodes as a precursor to the numerical solution of (5). Two hundred computational nodes are used to ensure satisfactory numerical performance, Darby and Thorne (1996). 3 MODEL APPLICATIONS To study the effect of variation of wetted perimeter roughness, a number of numerical experiments were performed where the roughness of the bank was increased three times higher than the bed roughness, the side bank slope was changed three times, the ratio of channel bed width to water depth ratio was changed two times and the roughness of the bed also was increased three times than the roughness of banks. Table (1) shows the different variables used in Table 1. Variables used in the computations. this study where the longitudinal bed slope and water

depth were kept constants at 0.0001 and 2.0 m height

respectively.

Figure (2) shows the unit discharge for different

values of ds/db ratio larger than 1.0 at b/D value

equal to 5.0 for side bank slope equal to 1.0, where

d s = the mean particles size for side banks materials;

d b = the mean particles size for bed channel materi

als; b= the bed channel width and D= the maximum

water depth. From this Fig., it is noticeable that the

variation in bank roughness affects the distribution of

the unit discharge where the unit discharge decreases

by increasing the side bank roughness and this effect

is not only restricted to the bank but also extends along

the main channel. 0.00 0.20 0.40 0.60 0.80 1.00 1.20 1.40

Figure 3. Lateral variation in discharge for different ratio

of bank roughness to bed roughness at b/D= 5 and d b > d s

for side bank slope equal to 1.0. Also, Fig. (3) shows the unit discharge distribution for different values of d s /d b smaller than 1.0 where the bank roughness was kept constant and the bed roughness was increased. From this Fig., it is noticeable that the variation in the bed roughness affects the distribution of the unit discharge and this effect is high at mid of channel and decreases in the direction of channel banks. Figure (4) shows the ratio of flow capacity of nonuniform channel roughness to the flow capacity of uniform channel roughness versus the ratio of bank to bed roughness for different side bank slope at ratio of channel bed width to depth ratio equal to 5. It is apparent from that Figure, that the channel total flow capacity decreases by increasing of the bank roughness and this decreasing increases by increasing of the channel bank slope. In the same way, in Fig. (5) 0.93 0.94 0.95 0.96 0.97 0.98 0.99 1.00 1 d s /d b Q / Q o Sy=1 Sy=1.5 Sy=2 2 3 4 Figure 4. the same relation was drawn for ratio of channel bed

width to depth equal to 10. With comparison between

Fig. (4) and Fig. (5), it can be observed that the rate

of decrease in flow capacity reduces by increasing of

channel bed width to depth ratio.

To show the effect the ratio of increasing the chan

nel bed roughness, Fig. (6) shows the relation of

the dimensionless discharge versus the ratio of bank

roughness to bed roughness for different bank slope

values at ratio of channel bed width to depth equal to

5.0. From that Fig., it is noticeable that the reduction

may be arrive to about 0.88% in the flow capacity

at value of d s /d b equal to 0.25 and this reduction

decreases by increasing of the side bank slope but the

effect of side bank slope is not so high such as that the

result from the variation in roughness.

Boundary conditions between panels in depth-averaged flow models

revisited

D.W. Knight & M. Omran

The University of Birmingham, Birmingham, UK

J.B. Abril

Consultant in River Engineering & Honorary Research Fellow at the University of Birmingham, UK

ABSTRACT: This paper revisits the issue of the boundary conditions between panels or domains in depth

averaged flow models. The Shiono and Knight Method (SKM) is used to illustrate a potential problem in such

models, since sometimes the boundary conditions are misapplied, leading to invalid results in some cases, despite

giving reasonably good results in other cases under certain circumstances. Experimental results and numerical

studies are used to illustrate the problem and a suggestion is made as to how one of the most commonly used

boundary conditions should be applied. Algebraic expressions within the analytical solutions of SKM were

modified to illustrate the importance of using correct inter-panel boundary conditions.

1 INTRODUCTION

A two-stage, or compound channel, consists essen

tially of two major parts, the main river channel and

the flood plains. In natural rivers, the flow is confined

within the main channel for the majority of the time. However, during flood events the flow spills over onto the adjacent floodplains, which themselves form part of the ‘overall’river system. Since compound channels are frequently used in flood alleviation schemes, it is important to be able to predict the conveyance capac ity, velocity distribution, and boundary shear stress distribution for a given flood event. The velocity and boundary shear stress are also required when estab lishing the stage-discharge relationship, a relationship that is important in flood studies, since it is often extrapolated to estimate water levels for discharges higher than those that have actually been observed. The same parameters of depth-averaged velocity and boundary shear stress also feature in many engineering design studies concerning river morphology, sediment transport, bank protection, vegetation and habitats. The determination of these parameters is a difficult and challenging task for river engineers, due to the strong shear layers that develop at the main channel floodplain interface when the water level is above the bank full stage. Due to the difference in velocity between the faster moving water in the main chan nel and the slower moving water in the flood plain, a lateral transfer of momentum takes place, which significantly affects the conveyance capacity, the velocity

and boundary shear stress distributions in such channels (Knight & Shiono, 1996). Lateral distribution methods (LDM) have been shown to give promising results in modelling compound channels, and one such method, an analytical one, is known as the Shiono and Knight Method (SKM). 2 THEORETICAL BACKGROUND SKM is based on a depth-averaged form of the streamwise ReynoldsAveraged Navier-Stokes (RANS) equations, expressed for steady uniform flow by Shiono and Knight (1990 & 1991) as: in which S o = channel bed slope, s= channel side slope (1:s, vertical:horizontal), H = depth, U d = depth-averaged streamwise velocity, λ= dimensionless eddy viscosity f = local Darcy-Weisbach friction factor, U = velocity component in the x, streamwise, direction, V = velocity component in the y, lateral, direction and y= lateral co-ordinate.

Equation (1) depends on depth-averaged parame

ters of velocity, Reynolds stresses and secondary flow,

which in turn are governed by three calibration coef

ficients f , λ, '', concerned with local bed friction,

lateral shear, and secondary flow respectively. These

coefficients are defined by:

in which τ b = local bed shear stress, U * = shear veloc

ity and ε^{-}_{yx} = depth-averaged eddy viscosity.

Analytical solutions to equation (1) are given by

Shiono and Knight (1988) and Knight & Shiono

(1996), distinguishing between constant and variable

depth domains. Once the values of f , λ,'' are specified

for each domain or panel, and boundary conditions

applied, then analytical expressions for U d and τ b ,

may be obtained. Knowing U d and H across the chan

nel, lateral integration of the product will give the

discharge, and repeated use gives the stage-discharge

relationship.

Shiono and Knight (1988, 1990) originally pro

posed two boundary conditions at each domain junc

tion for the sloping wall case as follows:

• Continuity of the depth-averaged velocity

• Continuity of the lateral gradient of the depth

averaged velocity

These have continued to be used by themselves under

certain circumstances and by other authors, e.g. Ervine

et al. (2000), without their limitations always being

either fully explained or appreciated. The purpose of

this paper is therefore to highlight this issue, espe

cially where there are significant changes in depth or

parameters between panels.

3 BOUNDARY CONDITIONS BETWEEN PANELS

Many researchers have conducted experimental inves

tigations into the flow structures at the junction

between rivers and their floodplains. Data sets from

the large scale studies in the Flood Channel Facility

(FCF) (see Knight, 1992; Knight & Sellin, 1987), and

from studies in wind tunnels by Lai (1987) and Rhodes

(1991), are used herein to illustrate the lateral variation

in depth-averaged parameters.

Lai (1987) and Rhodes (1991) performed experi

ments in compound air ducts, to study the mean flow structure and in particular the boundary shear stress and velocity distributions.These data are used to check the variation of depth-averaged velocity, U d , lateral gradient of the depth-averaged velocity, dU d /dy, local water depth, H , unit discharge, q, lateral gradient of the unit discharge, dq/dy, and the apparent shear force (ASF) across the floodplain/main channel interface. Experiments have been selected from these data to illustrate the effects of main channel side slope, by distinguishing between channels with vertical walls and channels with sloping walls. It should be noted that the data of Lai and Rhodes were obtained with a very fine lateral spacing interval,y, in the vicinity of the main channel/floodplain interface, in some cases as small as 1 mm. Furthermore, the vertical interval z was such that the U d values were obtained from the average of between 6 and 17 local streamwise values, depending on the geometry of the cross section. These very high quality sets can therefore be used to illustrate the boundary conditions between panels in depth-averaged flow models. Figure 1 shows results from Experiment 14 (Rhodes, 1991), in which a large compound duct with a vertical side wall element was used, giving a step in the bed elevation of approximately 20 mm, as shown in Figures 1(a) & 1(b). The experimental results in Figures 1(c)-1(f) show that only the unit discharge q is continuous at the main channel/floodplain, interface, as would be expected from Samuels (1989), whereas U d , dU d /dy, H and dq/dy are not. Although q is continuous, there is a relatively large change at the interface position. Thus the boundary conditions between panels are: Equation (5) indicates that the boundary conditions suggested in equations (3) and (4) are invalid for cross sections with any vertical side wall elements, as might be expected. Figure 2 shows results from Experiment 20 (Rhodes, 1991) in which the same duct had one sloping side wall installed. Figures 2(c)-(f) show that U d , H and q are continuous at the main channel/ floodplain interface, whereas dU d /dy and dq/dy are not. Consequently, the boundary conditions can be summarised as follows: 831.1616400.37 20.24 20.18 CL 0.01 0.02 0.03 0.04 0.05 0.385 0.390 0.395 0.400 0.405 0.410 0.415 local depth, h (m) y (m) 4.00 6.00 8.00 10.00 0.385 0.390 0.395 0.400 0.405 0.410 0.415 y (m)

(a) (b)

(c) (d) (f)(e)

Figure 1. Results for Exp. 14 (Rhodes, 1991) (a) Geometry of duct cross section (mm), (b) Water depth variation, H versus

y, (c) Velocity distribution, U d versus y, (d) Velocity gradient distribution, (e) Unit discharge distribution, (f) Unit discharge

gradient distribution.

Equation (6) shows that for a channel with a sloping

side wall only the boundary condition in equation (3) is

valid. The second boundary condition, in equation (4),

is seen to be invalid for this particular experimental

case. For sloping side walls, because H is always con

tinuous the first two statements in (6) are equivalent

as an inter-panel boundary condition.

Figure 3 shows some bed shear and apparent shear

force data from Experiment 75 of Lai (1987), in which

a small compound rectangular duct was used.

Figures 3(b) & (c) show the lateral distributions

of bed shear stress on elements B1 and B2, although measurements were also made of wall shear stresses on elements W1 and W2 as well. The distribution of the apparent shear force (ASF), shown in Figure 3(d), is demonstrably discontinuous over the vertical interface. Figure 3(e) shows that the discontinuity is equal to the value of the shear force measured on the vertical wall, as

expected. The apparent shear force may be determined for any vertical slice in a depth-averaged model by considering the balance of forces acting on a particular element of the cross-section. For example, in a typical depth-averaged flow model for a river, the channel 799.92 411.74 20.02 19.95 CL 0.01 0.02 0.03 0.04 0.400 0.405 0.410 0.415 0.420 0.425 y (m) h (m) 8.4 8.6 8.8 9.0 9.2 9.4 0.400 0.405 0.410 0.415 0.420 0.425 y (m)

cross-section is divided into any number of verti

cal slices in the transverse direction, y, and the flow

assumed to be predominately in the streamwise direc

tion, x, given by equation (1). The apparent shear force

(ASF) acting on any vertical slice within the cross

section is then defined as the difference between the

weight force of those elements, resolved in the stream

wise direction up to that particular lateral position, y,

minus the integrated boundary shear forces around the

wetted perimeter up to the same lateral position. The

ASF thus accounts for any momentum transfer effects

across that vertical slice, arising from turbulent shear,

secondary flow and planform vorticity. Shiono & Knight (1991) have shown that the depthaveraged apparent shear stress (ASS) acting on any vertical interface within the cross-section, $\bar{\tau}_a$, may be calculated by integrating equation (1) to give The apparent shear force (ASF) per unit streamwise distance is then given by $\bar{\tau}_a H$. main channel side is denoted by ASF 2 , then one can

write:

where A FP = area of the floodplain, SF FP = shear

force on the floodplain and SF wall = shear force on

the vertical wall. From Figures 1 to 3, it is clear that the boundary conditions in equations (3) and (4) need to be applied with care. The first condition, given as equation (3), is clearly only valid for sloping side walls, as a step change in H introduces a corresponding step change in U d . The second condition, given as equation (4), is not generally true, regardless of whether or not there is a vertical or sloping side wall. However, as Fig. 2(c) shows, there are circumstances where it might appear to be valid, either where insufficient

care is taken over acquiring data or where the data

is ‘smoothed’ too much in any subsequent processing

stage. This is illustrated better in Figure 4, in which

depth-averaged velocity data from Experiment 17 of

Rhodes (1991) is used, obtained from the larger com
pound rectangular duct. If the velocity in the main
channel is depth-averaged at the vertical wall, then
measured at increments of 1 mm from the junction,
the ‘Not smoothed’ distribution is obtained.
However, if the first measurement of the velocity
distribution had started at a point just 3 mm away from
the main channel/floodplain junction, the ‘Smoothed’
curve would have been obtained. This indicates that
particular care needs to be taken over measurements
near the main channel/floodplain junction, as any
omission or subsequent smoothing of the data can lead
to inaccurate conclusions.

4 MATHEMATICAL ANALYSIS OF BOUNDARY CONDITIONS

In order to demonstrate these matters further, Abril
(2003) performed mathematical analysis of the bound
ary conditions between panels in compound channels
distinguishing between cases with continuous and dis
continuous parameters f , λ," and H using the SKM in
comparison with the RFMFEM finite element model
byAbril (1997).Two types of channel were considered,
a compound rectangular channel, i.e. one with a ver
tical side wall, and a compound trapezoidal channel,
i.e. one with a sloping side wall.

4.1 Compound trapezoidal channel

As a result of this analysis, for a compound trapezoidal

channel, from a physical point of view the continuity

between panels should satisfy equation (8): Equation (8a) states that U d should be continuous at the main channel/floodplain junction, and equation (8b) states that there is continuity of the unit force, (Hτ yx), where τ yx is the depth-averaged Reynolds shear stress, given by τ yx = ρλH √ f 8 U d ∂U d ∂y . From equation (8b) one can write: Provided that H is continuous and the velocity U d is continuous at the junction, as they would be in a compound trapezoidal channel, equation (9) may be simplified to give: Equation (10) can then be written as: where Equations (8a) and (11) explain the results obtained in graphs 2(c) and 2(d), in which the depthaveraged velocity is continuous over the main channel/ floodplain junction, while the lateral gradient of this velocity is not. However, as already pointed out, there are some circumstances where the boundary condition given in equation (4) might appear to be valid, firstly when local flow conditions might actually produce it and secondly when insufficient care is taken over acquiring and processing data. From the mathematical viewpoint equation (11) is equal to equation (4) only if f , λ and H are continuous across the compound section, thus the value of μ will be equal for adjacent panels, resulting in (∂U d /∂y) i = (∂U d /∂y) i+1 . The latter has already been illustrated in Figure 4, using smoothed data. 4.2 Compound rectangular channel A similar analysis was performed by Abril (2003) for a compound rectangular channel, where the boundary conditions between panels were assumed to be: xy Main Channel Floodplain main channel/floodplain B h H b τ (2) xy τ (1)

Figure 5. Compound trapezoidal channel. (1) (1) H yx τ (2) yx τ (2) H Main Channel main channel/floodplain junction h τ w h

Floodplain

Figure 6. Compound rectangular channel.

However, Equation (13a) could be replaced by:

Equation (13c) has been illustrated in Figure 1(e),

which shows that the unit discharge, q=H ×U d , is

continuous across a rectangular compound channel.

Equation (13b) has been illustrated in Figure 3(e),

which shows that the ASF is discontinuous over the

vertical wall and the discontinuity is equal to the

shear force on this wall. This is further illustrated in

Figures 5 & 6, where the force equilibrium at the main

channel/floodplain interface is shown for both types

of channel.

Equation (13b) can be rearranged as:

where

Equation (14) shows that the force on the verti

cal wall element has to be known, or supplied, before applying this particular boundary condition. This can be inconvenient from an analytical point of view, when determining the flow in a compound rectangular channel as an iterative procedure has to be employed to obtain the lateral distribution of U d , prior to calculating the total discharge. 4.3 Large scale vortex motions It should be noted that the use of the depth-averaged Reynolds stress in equations (8b) & (13b), rather than the apparent shear stress at any interface, appears to preclude any direct contribution from large scale vortex motions. However, these contributions are already simulated within the SKM by the " parameter (Shiono & Knight, 1991), and standard values were used herein, ensuring compatibility across groups of panels. Functional relationships for the ratio of " values between the main river channel and the floodplains, and its dependence upon depth, have been proposed (Knight & Abril, 1996; Abril & Knight, 2004b). Particular " values need therefore to be applied over several panels (positive in the river and negative on the floodplain) in order to mimic these large flow structures. The precise " values that should be used in all types of flow is as yet unknown, but experience in applying the SKM to both steep mountain rivers and mild slope valley rivers has proved to be reasonably successful (Abril & Knight, 2004b). The inclusion of the effects of planform vorticity into RANS based models is itself known to be problematic

(Tominaga & Knight, 2004). 5 IMPLICATIONS OF USING DIFFERENT BOUNDARY CONDITIONS The analytical solution of the SKM was used to investigate the impact of the boundary conditions in (11) and (14). Since no a priori analytical expression for the shear force on any vertical wall element in a compound channel has yet been obtained, the examples that follow will only cover the case of sloping side walls, using one FCF result from series 02 and one from a hypothetical channel. Figure 7 shows the effect of different boundary conditions on the lateral distribution of depthaveraged velocity, U d , for FCF experiment 020601 with H = 0.21355 m. The FCF series 02 relates to a symmetrical compound trapezoidal channel with b= 0.75 m, B= 3.15 m, h= 0.15 m and s= 1.0 for the geometrical parameters shown in Figure 5. Because of the symmetry, only 4 panels are needed in SKM for each half of the cross section (main channel bed, main channel side slope region, floodplain bed, floodplain side slope region). The parameter values that gave the best fit were found to be: f = 0.018,

0.015, 0.022, 0.070; λ= 0.07, 0.20, 0.10, 0.10; and

"= 0.15, 0.15, -0.20, -0.20 for the 4 panels respec

tively, with panels 1 & 2 being on the floodplain and

panels 3 & 4 in the main channel. The boundary con

dition given by equation (11) was then tested with the

same values of f , λ and " for two cases: μ (1) =μ (2)

and μ (1) ≠ μ (2) with μ being prescribed by equation

(12) for each panel. The latter condition gave values

of μ= 0.0093, 0.0245, 0.0148 & 0.0265 respectively

for the 4 panels. It should be noted that the values of

f , λ and "were calibrated to fit the FCF data since the

purpose of this paper is to show the effect of the new

boundary conditions on SKM and not to discuss the

calibration philosophy. It can be seen from Figure 8

that the introduction of the μ factor reduces the veloc

ity over the side slope regions, with local errors in U d

of as much as 7%.

However, because the side slope region is rela

tively small, the total discharge only changes from

0.4842 m 3 s −1 to 0.4908 m 3 s −1 , i.e. a change of

−1.35%. At larger depths, the differences are still less

than 2%. A comparison of the stage-discharge curves

for this example is shown in Figure 9, and the differ

ences are shown in Figure 10. These Figures indicate,

that using the correct boundary condition, based on 0.0 0.1 0.2 0.3 0.4 0.5 0.6 0.0 1.0 2.0 3.0 4.0 Discharge, Q (m 3 /s) S t a g e , H (m) SKM_mu SKM_no mu Figure 9. Differences in discharge (Example 1). equation (11) with appropriateμ factors, the discharge is reduced compared to setting μ (1) =μ (2) . Figure 11 shows the results for a hypothetical 9 node flood channel, divided into 8 panels each with a different side slope, roughness, eddy viscosity and secondary flow strength. Each panel was further divided into 10 sub-areas to improve computational accuracy. The panel (1-8) f values were varied from 0.02 by an increment of 0.01 per panel to 0.09, λ values were varied from 0.07 by an increment of 0.07 per panel to 0.56 and '' values were taken as 0.15 (panels 1 & 2), 0.30 (panels 3 & 4), 0.45 (panels 5 & 6) and 0.60 (panels 7 & 8). The geometrical parameters were chosen to represent a small river with floodplains rougher than the main river channel. The computed stage-discharge relationships in Figure 11 again indicate that the introduction of the μ factor reduces the discharge. Figure 12 shows that for a depth of 3.0 m the difference in discharge is as much as 15% (45.437 m 3 s −1 to 39.676 m 3 s −1), thus warranting the inclusion of the correct boundary condition. Further examples of how the SKM may be used to make stage-discharge predictions are shown in Knight, Shiono & Pirt (1989) and Abril & Knight (2003b). 6 CONCLUSIONS

The boundary conditions between panels in depth averaged models have been shown to be important when either analysing experimental data or formulating a numerical model. Using a simple velocity gradient law at each panel junction in channels is appropriate where f & λ are the same across panel

interfaces, regardless of differences in ". Where f & λ differ across panel interfaces, then it has been shown that the assumption of a simple gradient law is inap propriate, and can lead to possible overestimates of velocity and hence discharge. Although differences in total discharge may be small in certain cases, the differences in local values of depth-averaged veloc ity may be significant when the inter panel μ ratios are set equal to unity. Where f , λ and " vary signif icantly between panels, then physical and numerical studies have illustrated the need to introduce the cor rect boundary condition, based on equation (11) for channels with side slopes, and equation (14) for chan

Knight, D.W., Shiono, K. and Pirt, J., 1989. Prediction of depth mean velocity and discharge in natural rivers with overbank flow. Proc. Int. Effect of vegetation on boundary layer with turbulent free stream

P. Gualtieri, G. Pulci Doria & L. Taglialatela

Hydraulic and Environmental Engineering Department Girolamo Ippolito, University of Naples Federico II,

Napoli (Italy)

ABSTRACT: Effects of vegetation on flow hydraulic characteristics as flow resistance, conveyance capacity,

turbulence characteristics, represent a very studied research topic, mostly in relation to uniform flow condition. In

this paper effect of vegetation on velocity distributions in a boundary layer are experimentally investigated. Veg

etation is modelled through regular array of vertical brass cylinders of two different heights. Local mean velocity

distributions were detected through an LDA system. The presence of vegetation produces an evident change

in velocities profiles and a meaningful increase of boundary layer thickness. But in any case the equilibrium

boundary layer characteristics are preserved with vegetation too.

1 INTRODUCTION

1.1 Vegetated surfaces problems

In the past, vegetation on river beds has been con

sidered just as a source of flow resistance, and for

this reason it has been usually eliminated in order to

improve the water conveyance.

Now, vegetation is no longer regarded merely as an

obstruction to the movement of the water, but rather

as a mean for providing stabilization for banks and

channels, habitat and food for animals, and pleasing

landscapes for recreational use. Therefore the preser

vation of vegetation is of great relevance for the eco

logy of natural and artificial systems.

For this reason, the study of the effects of vegetation

on the hydrodynamic behaviour of the rivers represents

one of the most basic knowledge required by hydraulic

engineers.

Vegetation may be regarded as a kind of surface

roughness whose effects depend mainly on height,

density, distribution and type of vegetation.

Mean flow and turbulence characteristics of open

channel flows over a submerged vegetated boundary

has been studied by either laboratory measurements or

numerical computations through proper turbulence

models.

In particular, referring to the mean velocity pro

file above submerged vegetation, it is known that it

depends on several factors.

Numerous investigations have been made about the

velocity profile above either rigid or flexible sub

merged vegetation.

Rigid vegetation was modelled through wooden or

metallic cylinders, flexible vegetation was modelled through plastic strips or through grass or other vegetation types (Bettess 2003, Fisher-Antze et al. 2001, Kouwen et al. 1969, Kouwen et al. 1973, Kouwen et al. 1981, Lopez et al. 2001, Stone et al. 2002, Sung-Uk 2001, Tsuijimoto et al. 1990, Tsuijimoto 1999). 1.2 Boundary layer problems On another hand, the hydrodynamic behaviour of boundary layer is one of the most important topics of fluid mechanics. The classical boundary layer is born when a uniform potential current, without any turbulence, strikes against a flat plate parallel to the current direction. In this situation, an almost entirely turbulent flow is born near the plate, and its thickness grows in the direction of the flow itself. This turbulent flow is called a boundary layer one, whereas the yet potential current superimposed to it is called external layer flow. The hydrodynamic laws which rule the boundary layer are now reasonably well known, also if they need yet further research. In particular, in the aforementioned hydrodynamic condition, the value of the pressure gradient along the flat plate is the most important parameter which fixes the local mean velocity

distribution along the direction orthogonal to the plate. For instance, one of the first researchers who established for this distribution in case of smooth plate a law more advanced than the simpler logarithmic one was (Coles 1956): his law is called the “wake law”. This “wake law” supposes that the simple logarithmic law must be corrected with the addition of a further term formed through the product of a universal law and a parameter (called #) depending on

the non dimensional value of the pressure gradient

along the plate. This “wake law” is valid only if this

non dimensional value of pressure gradient is constant

along the plate itself: in this case the boundary layer

is called an “equilibrium boundary layer” and the non

dimensional velocity distribution is the same in all its

different sections.

A more sophisticated type of boundary layer flow

is that which is born when a turbulent current strikes

against the flat plate parallel to the current direction.

This is obviously an important type of boundary

layer, because the presence of turbulence in streams is a

very frequent condition.At the present time, the impact

of free stream turbulence on fully turbulent boundary

layer has been investigated in several experimental,

analytical and computational studies.

Many of these studies deal with the effects of

free stream turbulence on the main statistical turbu

lence quantities and in particular with the mean local

velocity distribution laws (Bandypadhyay 1992, Blair

1983a, b, Castro 1984, Charnay et al. 1971, 1976,

Evans 1985, Evans & Horlock 1974, Hancock & Bradshaw 1983, Hancock & Bradshaw 1989, Hoffmann & Mohammady 1991, Huffman et al. 1972, Kline 1960, Mc Donald & Kreskowsky 1974, Meier & Kreplin 1980, Robertson & Holt 1972).

Coming back to the previous example, Coles believed that his “wake law” could represent also this type of boundary layer, because he assumed that the presence of turbulence in free stream would have the same consequences on velocity distribution than an adverse pressure gradient.

Two of the writers too worked in previous years in the boundary layer with free stream turbulence research field (Gualtieri & Pulci Doria 1997, 1998a, b, 1999, 2001, 2003, Pulci Doria 1991), performing their experimental tests in a water boundary layer instead of air boundary layer as usual. The produced papers dealt with the influence of free stream turbulence on boundary layer thickness and the main statistical turbulent quantities, on the possibility of conceiving a particular boundary layer model, and some of them (Gualtieri & Pulci Doria 1998b, Pulci Doria 1991) dealt in particular with the inside mean velocities distribution problem. The investigated boundary layers were always equilibrium ones with zero value of piezo

metric head (condition that for water is equivalent to

the zero value of pressure gradient in air).

2 AIM OF PRESENT PAPER

In the growing literature about vegetated streams the

effects of vegetation on boundary layer characteris

tics has been not yet considered, at least in relation

to authors' knowledge. A new research line recently

opened by the authors therefore regards, in relation to boundary layers with free stream turbulence, the possibility of discovering how wall vegetation can affect their dynamic development, the values of their thickness at different distances from the leading edge, and the mean velocities distribution inside. This type of research has clearly a basic theoretical meaning, but also can aid to clear applied problems, as for instance to detect the rapidity of changes of a current behaviour after abrupt changes of the nature of the vegetated walls. The aim of the present paper is to give first contributions to this new research line through comparisons between the behaviour of a boundary layer with free stream turbulence on a flat plate and of a boundary layer with the same free stream turbulence but developing on differently vegetated plates. In particular our objective is to examine the interconnection between vegetation and mean velocity distribution in a turbulent boundary layer developing in a water channel.Towards this end, the vegetation has been modelled through regular array of vertical brass cylinders, having two different heights, whose values are comparable with the boundary layer thickness. 3 EXPERIMENTAL PLANT 3.1 Fundamental plant For the sake of carrying out suitable experimental surveys, the plant represented in Figures 1, 2 has been used. The main device of the experimental plant is a variable slope channel 4 m long and 15 cm large, with plexiglass walls and bottom, coming out from a feeding tank supplied by a circulation pump. This tank feeds the channel through an adjustable rectangular sluice gate. The inlet towards the sluice gate is modelled through a suitable plexiglass device so shaped to avoid any possible trouble to the incoming current. In this plant, it is possible to measure the water height in the tank, the height of the sluice gate, the slope of the channel, and the water heights in all cross sections of the channel itself. In the

first sections of this channel a boundary layer flow is generated on the bottom. This boundary layer grows in the following sections, until its thickness attains the same value of the circulating flow height at a distance from the inlet of the channel (boundary layer leading edge) depending on the dynamic characteristics of the flow itself, but which is in any case of the order of 1 m or something less. In a true boundary layer the external layer flow thickness should be very high (theoretically infinitely high) and the current should be very large (theoretically infinitely large): consequently the described channel flow could not be considered a true boundary layer flow. Nevertheless, in hydraulic literature this way of generating a

Figure 1. Photo of the experimental channel.

Figure 2. Layout of the experimental channel.

boundary layer is very common. The authors too used this type of plant other times, in their already remembered papers, and in these papers they stressed that the statistical quantities distributions (as mean velocities and velocities momentums, length scales and so on … .) were in accordance with the literature ones for boundary layers: in particular, for instance, mean velocities distributions were in accordance with Coles' wake law, except in the upper part of the boundary layer (till velocities attained the 97% values of the external layer velocities), where Coles law cannot fit perfectly experimental data, also if the # parameter is suitably varied. Moreover, very recently, the same authors of this paper prove definitively in a new paper (Gualtieri et al. 2004) through systematic experimental surveys conceived deliberately for this sake, that the aforemen

tioned current can be wholly considered a boundary

layer flow, at least until the thickness of the boundary

layer doesn’t attain almost the thickness of the cur

rent (that is to say practically till a little more than

50÷ 60 cm from the inlet).

The instantaneous velocity measurements have

been carried out through LDA technique. A new gen

eration compact LDA device has been used. The beam was of a frequency out of visible band (not visible ray). The optical system worked in backscatter, with Bragg cell and frequency shifter. The data sampling system consisted of a simple and classic frequency tracker, which performed also the mean of the data (with mean times that could be freely chosen) in order to obtain in real time the values of local mean velocities. Each value of local mean velocity was in fact obtained through a mean time of 200 s, that had been considered sufficient to eliminate at least the main part of turbulent velocity fluctuations. Finally an electromagnetic device, which is not shown in Figure 2, was disposable along the pipe which supplies the tank, in order to measure the flow-rate in condition of permanent motion. 3.2 Vegetation modelling The experimental surveys have been performed with the superimposition of a further removable plate on the bottom of the channel.This additional plate was 1,20 m long, 15 cm large, and 1 cm thick. The plate was as large as to be exactly introduced in the channel between the two lateral walls.The first 20 cm of the length of the plate were disposed before the sluice gate, laid on the plexiglass suitable shaped device. The first 10 cm of the length of the plate were blunted from 0 to the 1 cm plate thickness, so to let the water enter the channel without disturbances even in presence of this plate. The plate filled the channel till a section 1 m far from the sluice gate section. This length was sufficient to let the boundary layer fully develop till the section where its thickness attained the current height. After the plate the current came down a 1 cm step and consequently became irregular, but this circumstance did not matter as the current itself was a supercritical one. Three types of additional removable plate were prepared in order to represent different types of vegetated currents. The first plate was a simple flat plate, and it produced a comparison

classical boundary layer flow. The second and the third plate were vegetated ones. In particular, in order to represent vegetation on these plates, it has been chosen to drive into them many cylindrical little brass vertical sticks, whose diameter was of 4 mm. They have been arranged in an array like that of Figure 3. Eleven rows of six sticks everyone have been prepared, with sticks 2,5 cm far each another and 1,25 cm far from the lateral walls. Each row followed the previous one at a distance of 5,0 cm, and the first row was placed 2,5 cm from the inlet of the channel (sluice gate section). The meshes of the array were therefore rectangular ones 5,0*2,5 cm 2 wide.Two sticks arrays have been proved, the first one with 5 mm high sticks, and the second one with 10 mm high sticks. The second and third plates therefore one another in the sticks height. In this way, in each plate, the whole arrangement was symmetric, the centreline of the channel bottom

was free from sticks and it was possible carry out velocity distribution (from the bottom to the free surface) measurements on this centreline. In particular four test sections have been chosen 20 cm, 30 cm, 40 cm, 50 cm respectively far from the channel inlet. These test sections were all placed exactly between two following rows, so that the measurement verticals lied in any case exactly in the centre of a rectangular mesh.

4 EXPERIMENTAL SURVEYS CARRIED OUT AND RELATIVE RESULTS

Three different conditions of boundary layer flow have been experimentally considered. The first condition was a flow along the flat plate without sticks; the second one was a flow along the plate with 5 mm high sticks; the third one was a flow along the plate with 10 mm high sticks. Comparisons have been performed among these three conditions. In order to let the comparisons be meaningful, in all conditions, some fundamental hydraulic parameters have been kept constant.

The height of the sluice gate has been always of 7.49 cm. Consequently the height in the vena contracta was of 4.61 cm.

The head of the tank above the vena contracta was always of 10,34 cm. Consequently the velocity in the vena contracta was of 1,424 m/s. The flow-rate was of 9.85 l/s.

In each condition, attention was paid to maintain a substantially horizontal free surface (at least in the first 50 cm of the flow where measurements had to be carried out), in order to cause the boundary layer to be always an equilibrium one with zero piezometric head gradient (as a liquid flow was dealt with, it was nec essary to keep constant the piezometric head and no more the simple pressure as it happens in gas flows). In order to obtain this condition the slope of the channel had to be changed in each different condition because of the different bottom friction losses without sticks,

with 5 mm sticks and with 10 mm sticks. In particular, 0.00 10.00 20.00 30.00 40.00 50.00 60.00 0.60 0.70 0.80 0.90 1.00 1.10 1.20 1.30 1.40 1.50 u(m/s) y(mm) Smooth wall Rough wall (5 mm) Rough wall (10 mm) 99% u0 97% u0 Figure 4. Velocity profile in section 2. 0,25%, 1,13%, 1,45% slopes were established in the three conditions respectively. It is evident that with presence of sticks, and mostly with 10 mm sticks, the slope increases because of the increased bottom resistances. In such a manner, the hydraulic head was constant and equal to 10,34 cm also along the whole current in each flow condition; and the velocity in the external layer was 1,424 m/s always and everywhere. Finally, the flow condition without sticks and with smooth bottom are just alike to one of those experimented in (Gualtieri et al. 2004) on the same experimental plant. In that paper it was stressed that the feeding device of the channel couldn’t generate a

perfect potential flow in the external layer, and that on the contrary this external layer presented a turbulence level characterized by the ratio u’/u∗ (between the r.m.s. value of turbulence fluctuations u’ and the friction velocity on the bottom u∗) nearly equal to 1,5.Therefore the examined current was to be considered, in every flow condition, a current with not negligible free stream turbulence. In each of these three flow conditions, local mean velocity distributions have been measured in the four aforementioned test sections.The results of these measurements are referred in Figures 4, 5, 6, 7. Each Figure corresponds to one test section, and contains the experimental velocity distributions relative to without sticks, 5 mm sticks and 10 mm sticks flow conditions. Some first qualitative results are immediately evident. The vegetation presence affects widely velocity

distributions in boundary layers. In particular, with presence of vegetation, the boundary layer thickness grows and the velocities inside the boundary layer decrease. The total flow-rate of the current, which doesn't vary in the different conditions, is secured, also with smaller velocities, by the increase of the slope and consequent increase of the cross sections.The momen tum of the current, on the contrary, decreases with vegetation presence because of the increased bottom resistances. At last it is very meaningful to notice that, at least at first sight, no evidence appears of possible irregularities of the velocity distributions at the height of the sticks.

At a deeper insight, it would be possible to observe, in the section 20 cm far from the sluice gate, a lit tle irregularity in velocity distributions either in 5 mm sticks plate or and more in 10 mm sticks plate. In this paper this irregularity will be not considered.

In Table 1 the values of the different 99% thickness in the different test sections and the different flow con ditions are reported. These values have been evaluated through a special procedure. In fact it is difficult to read directly on the diagrams the 99% thickness. On the contrary it is much easier to read the 97% thickness.

Therefore the first step was to read on the diagrams the

97% thickness values. The second step was to read as

best as possible also the 99% values. For each diagram

and each condition the ratio between the 99% and the

97% thickness values was performed. If the boundary

layer is in each flow condition an equilibrium one, the
Table 1. Boundary layer thickness. Smooth Rough Rough (0 mm) (5 mm) (10 mm) δ S1 (mm) 3.8 15.0 19.6 δ S2 (mm) 7.1 26.4 30.8 δ S3 (mm) 10.9 33.0 41.4 δ S4 (mm) 13.5 43.5 50.4
aforementioned ratio must be equal in each condition for the four test sections, and the possible differences of measured values must be imputed to reading errors, mainly of 99% values, which are more difficult to be correctly read. In this hypothesis it was possible to compute the means among the four values of each flow condition in order to obtain the best estimate of the ratio for every flow condition. Consequently these means were computed in relation to each condition (three mean values of the ratio were obtained, and in particular, the values 1,65, 1,50, 1,40 respectively with smooth, or 5 cm sticks, or 10 cm sticks bottom). Finally the 99% boundary layer thickness was computed, in each test section and each flow condition, as the product of the 97% thickness of the considered velocity distribution among the twelve experimentally obtained, and the aforementioned mean relative to the suitable flow condition. Later in this paper we shall come back on the hypothesis of equilibrium boundary layer. The final values of Table 1 corroborate the previous qualitative remarks. Moreover this table can be read in alternative ways, making some simple interpolation of data. Let’s consider the sections where the boundary layer thickness in condition of smooth bottom equals the heights of the sticks (23,6 cm from the leading edge for 5 mm sticks, and 37,6 cm from the leading edge for 10 mm sticks); in these sections the thickness of boundary layer was the following ones: in the section at 23,6 cm from the leading edge the thickness of boundary layer flow with 5 mm sticks was of 19,1 mm; in the section at 37,6 cm from the leading edge the thickness of boundary layer flow with 10 mm sticks was of 38,9 mm. The increase of boundary layer thickness has been of 3,82 in the first case and of 3,89 in the second case. Yet alternatively, the same boundary layer thickness is attained in 6,67 cm in the first case and in 10,20 cm in the second case; that is to say that the

distance from the leading edge necessary to attain the boundary layer thickness equal to the sticks height is 3,54 times less in the first case and 3,68 times less in the second case. It is possible to say that, taking into account a thickness of boundary layer of the same value as the sticks height, the presence of stick-modelled vegetation on the bottom of the channel makes adaptation processes in river flow behaviours in any case about 3,7 times faster.

5 NON DIMENSIONAL VELOCITY DISTRIBUTIONS

All the twelve velocity distributions reported in Figures 4, 5, 6, 7 can be transformed in non dimensional ones through the V 0 velocity in the external layer and the 95% δ thickness of the boundary layer.

In Figures 8, 9, 10 the non dimensional velocity distributions respectively in condition of smooth bottom, 5 mm sticks and 10 mm sticks are reported: the ordinates of the diagrams have been cut at the 2 value.

It is evident in each figure that the four velocity distributions relative to the four test sections are clearly superimposed one another: that is to say that non

(10 mm). dimensional velocity distributions are alike in each flow condition. This behaviour of velocity distribution, on the ground of a reasoning that will be immediately performed, is the clear marker of the equilibrium state of the three considered flows, not only in case of smooth bottom (obviously), but also in case of vegetated surfaces: and this circumstance represents a completely new phenomenon. On this matter, it is suitable to remember that, according to the rule, a boundary layer on a flat plate is called an equilibrium one when in external layer pressures (or piezometric heads for liquids) have a streamwise zero gradient, and consequently velocity distributions, once they have been made non dimensional in

the shape of velocity defect laws, appear to superimpose one another. In the case we are dealing with, it is very hard also only to try to represent velocity distributions in the shape of velocity defect laws, because, in order to obtain such a representation, it is necessary to refer to friction velocity. Now, in the considered vegetated flows, the friction velocities are variable from a point to another one also in the same section (as it happens to velocity distributions too) because of the presence of the sticks. Therefore, in this paper and unless further information should be given in future work, the possibility to refer to friction velocity has been discarded. Furthermore the distances of test sections from the inlet (from 20 cm to 50 cm), are of the same order, and in this condition in the classic boundary layer the friction velocities differ very little one another. Consequently the superposition of velocities distributions in the shape of velocity defect laws implies with good approximation also superposition of simply made non dimensional diagrams and vice-versa. This conclusion is fully confirmed by the diagrams of Figure 8. They certainly should be superimposed in the shape of velocity defect law, as they refer to a surely equilibrium boundary layer, and they appear to be superimposed also in diagrams simply made non dimensional. As a result of this reasoning, the condition of equilibrium flow can be assessed, also in the flows over vegetated bottom considered in this paper, directly through the superposition of simply non dimensional velocity distributions, as it has been done at the beginning of this paragraph. The circumstance that the flows over vegetated surfaces appear to be equilibrium flows, is a very important and intriguing result. In fact, in each of the two sticks conditions, the sticks height is a constant value in all the four test sections. Consequently, this height, if made non dimensional with respect to the local boundary layer thickness, assumes a different value in the four test sections. This notwithstanding, the velocity distributions

y/δ i

Figure 11. Dimensionless velocity profiles for all section in any roughness conditions (0, 5, 10 mm).

is not affected by this circumstance. That is to say that the sticks presence affects the whole behaviour of the boundary layer, not affecting, at least at the accuracy level we can attain, the velocity distribution at the exact height of sticks (as it had been already qualitatively noticed).

It is important here to stress that the equilibrium state implies equality of non dimensional velocity dis tribution along the whole boundary layer thickness (as it clearly happens), so that equilibrium state is truly existing and it would not be possible to attribute this equality to the methodology employed for the evalu ation of the boundary layer thickness, which involved only two values of velocity.

In Figure 11 the three non dimensional velocity distributions of previous diagrams are reported all together. It is sufficiently clear in this new diagram that the three considered distributions don’t superim pose one another. That is to say that the presence of vegetation affects the velocity distributions not only in dimensional shape but also in non dimensional shape referred to external layer velocity and 99% boundary

layer thickness. The equilibrium states relative to the three flow conditions are not the same.

6 CONCLUSIONS

In last years much attention has been paid to the problem of the behaviour of free stream currents with vegetated surfaces in relation to atmospheric or river flow problems. Most of these researches, or perhaps all these researches, deal respectively with wind problems or uniform river flow problems. The study of the influence of vegetated walls on the growth of turbulent boundary layer can let us understand some further behaviours of the currents.

The analysis of boundary layer data in flows with smooth walls and vegetated walls shows that in the former case the behaviour of fluid mechanics processes in relation to boundary layer thickness

Response of velocity to a sudden change of bed roughness in sub critical open channel flow

A. Carravetta & R. Della Morte

Department of Hydraulic and Environmental Engineering, University of Naples Federico II

ABSTRACT: Large variations in the flow field and bottom stress may be determined by an abrupt change of the channel bed from smooth to rough. The variation in the mean local velocities propagates in the current by a gradual increase in thickness of an internal boundary layer. Instead, the presence of a sudden peak in shear velocity downstream the bed change may be observed, the so-called overshooting.The entity of the peak is related to several factors, including the entity of the roughness change, the size of the bed elements and emergence of the rough part of the bed with respect to the smooth one, the reduction in the current cross section due to water level depression and bed elevation and the entity of the pressure gradient. A large number of experiments appears necessary in order to investigate all these interactions: the writers are currently carrying out such experimental work.

The results of a part of these experiments are discussed in this paper. An abrupt change in bed roughness from smooth to rough was brought about by positioning a single layer of stones on the smooth bed of a flume.

Emersion of the rough part of the bed with respect to the smooth one, flow rate, water levels were systematically varied. Experiments confirmed that the spatial distribution of bottom shear stresses down the roughness change

is related both to flow characteristics and bottom geometry.

1 INTRODUCTION

The effect on open channel flows of sudden changes in bed roughness is an interesting problem of river hydraulics. The main goal of many Authors dealing with such a topic has been to find out the spatial distribution of shear stresses across the change. In many cases the presence of a sudden increase in shear velocity immediately downstream the roughness change was observed, and indicated as the overshooting property of shear velocities. The presence of this property was stated by some authors (Nezu & Tominaga, 1994). On the other side, Chen & Chiew (2003) observed the absence of overshooting. The real presence of overshooting could cause local scours in rivers with problems regarding the stability of waterworks.

Starting from the channel section where bed configuration changes from smooth to rough, an internal boundary layer of increasing thickness develops near the bottom. Within the boundary layer the velocity profile is deformed by the change in bed resistance and by an increment in velocity which verify in the upper part of the current.

The problem of the response of an internal boundary layer to a step change in the boundary conditions was

largely studied in the past, but mainly concerning aero

nautical and environmental science (Smits & Wood, 1985). In river hydraulics the problem can assume a higher complexity because a change in channel geometry necessarily occurs together with a pressure gradient induced by the free surface variation. The writers have recently carried out experiments where a smooth to rough change was investigated (Carravetta & Della Morte, 2002, 2004). The dimensions of the rough bed grains were 1.9 and 6.0 mm. The velocity profiles along channel axis were well interpreted by using a defect log-law along the whole vertical, in absence of any velocity dip. Shear velocity distribution along the bed was determined and overshooting was observed. The maximum value of shear velocity, representing the overshooting peak, was found to be related to the parameter: with u *1 the shear velocity of the approaching current and d a the difference between the levels of the bottom before and after the roughness change. This dimensionless parameter will be called in the following emersion Reynolds number. Overshooting was of a higher entity for larger K d* values, i.e. for bed roughness increasingly emerging over the upstream bed and/or for increasing shear velocity of the approaching

Figure 1. View of the experimental channel.

current. In order to confirm this interpretation a new

set of experiments has been performed with a larger

size of bed particles.

2 LABORATORY SET-UP

A perspex channel 8.0 m long, 0.76 m wide and 0.76 m

deep, having a fixed slope i= 0.001, was used for the

experiments. Large scale disturbances at the channel

inlet were avoided by inserting a metallic sieve. Dif

ferent water levels were obtained along the channel by

inserting a step in the downstream section. Two differ

ent steps were used: the first (step I) 0.025 m height

and 0.15 m length, the second (step II) 0.15 m height and 0.15 m length.

At x o = 5.0 m from the inlet of the channel a sin gle layer of stones was positioned on the bottom, for a longitudinal length of 9.5 m, Figure 1. Average dia meter of the stones was k rou = 30.0 mm (Fig. 2). The roughness change is represented in Figure 3. Two val ues of emersion d a of the rough bed were obtained by elevating the smooth up-stream floor with mobile elements: d a = k rou (bed configuration C); d a = 0.5k rou (bed configuration D).

On each configuration of the channel bed, sev eral steady state tests were performed with different flow rates or upstream water levels, h 1 , measured at

A summary of the experimental conditions is reported in Table 1. Experiments were performed in the intermediate and small scale roughness range (Bathurst, 1985), with h 1 /k rou variable between 8.06 and 3.07.

An acoustic profiler, Signal Processing DOP2000, was used to acquire the vertical distribution of local velocities along channel axis at the distances x- x 0 = -0.40;-0.30;-0.20;-0, 10;-0.05; 0.00; 0.05; 0.10;

0.40; 0.80; 1.20; 1.60; 2.0; 2.4 m. The origin of the vertical axis y on the rough part of the bed was fixed at 0.5k rou below the particle crest. Water levels along channel axis were measured by using a point gauge with a vernier scale.

3 RESULTS

As an example of test results, the vertical profiles of local velocity are represented in Figure 4, for test CI-2, and Figure 5 for test DI-2. In the same figures the pro files of computed turbulence intensity are also plotted, along with the corresponding water levels.

The results of a previous test, performed with the same flow rate, but with a different choice of bed geometry – k rou = 6.0 mm and d a = k rou – are plotted in Figure 6 (Carravetta & Della Morte, 2002; 2004 test B3). Two regions in the velocity profile can be observed: a bed region, where an internal boundary layer of increasing thickness develops, and a core region in the upper part of the current. In each of the two regions a different response to bed roughness 0

sity, water level for case DI-2 (stone in figure is undistorted). change is evident. In the core region, the velocity profile exhibits a rigid translation, due to flow acceleration induced both by the water depth depression and by the velocity reduction in the bed region. In the bed region, the velocity profile is deformed by the change in bed resistance and the increment in velocity in the core region.Also the vertical distribution of turbulence intensities undergoes a modification in the bed region. Within the internal boundary layer, larger values of turbulent intensity were observed when compared to the ones at equal y on the smooth part of the channel. The same kind of modification was present on Chen & Chiew's and Nezu & Tominaga's measured Reynolds stresses. The evolution of the velocity profiles in the present tests with larger roughness size was slightly different, as observed in Figure 4. In particular, the velocity profiles undergo a larger deformation that can be better observed in the plot of Figure 7, where the velocity profiles, measured at different abscissa, are superimposed. Immediately downstream the bed change, the profile deformation is similar to the one observed in the case of small bed elements, but larger because of the stronger variation of the current cross section. An acceleration in the upper part of the current and high velocity gradients at the bottom are present. 0,0 0,1 0,2 -0,4 -0,2 0,0 0,2 0,4 0,6 x-x o y (m) u=0,2 m/s u'=0,05 m/s Figure 6. Figure 10. Turbulence intensities for case DI-2.

For large x- x 0 values, the change in the local veloc ity profile is characterized mainly by the presence of a progressive transition to the S-shaped form that is peculiar to gravel bed streams (Baiamonte et al., 1995; Nikora & Smart, 1997). In this phase a water level recovery is present.

In test DI-2 (Figs. 5, 8), where the contraction of the cross section was lower, for the presence of a smaller emersion of the rough bed with respect to the smooth part, the velocity profiles undergo a smaller deformation.

The vertical distribution of turbulence intensity exhibits a more gradual modification (Figs. 9, 10).

Turbulence intensity increases in the internal boundary layer. The increase in thickness of this layer with the distance from the roughness change is evident. In conclusion, experimental evidence shows that, for given flow rate, upstream water level h 1 and emersion d a of the rough bed are relevant quantities for the entity of the current cross section and, then, of the deformation of the velocity profile immediately downstream the roughness change. The value of k rou seems relevant in the spatial variation of the boundary layer at larger distances from the roughness change. 4 DISCUSSION The writers in previous studies, referring to k rou = 1.9÷ 6.0 mm (Fig. 6), argued the validity along the whole vertical of a double-log law written in the form: with s thickness of the internal boundary layer and u s velocity value at the distance s from the bed. On the rough bed two different values of shear velocities, u ∗ , were used in equation (1). For the core region, u ∗ was assumed as constant and equal to the upstream value u ∗1 at x- x o =-0.40. For the bed region u ∗ was found by optimization. Least square method was applied to all measured data along the vertical. With reference to the present data, the velocity distributions (Figs. 7, 8) cannot be interpreted by a law as simple as equation (1), because of the large size of the roughness elements. Nevertheless, eq. (1) was still used but with reference to the only part (yu ∗ /ν)≥ 30 and (y/s)< 0.2 of each vertical. Equation (1) is consistent with the final velocity distribution: in fact, log-law was found to be valid for (y/h)< 0.2 even in the intermediate roughness scale (Baiamonte et al., 1995). Therefore, equation (1) was written in the form: The thickness s of the boundary layer was assumed as the height of the part of the current where larger values of turbulent intensity were observed when compared to the ones at equal y on the smooth part of the channel. The value of velocity at y= 0.2s was taken from measures. The least square method on the measured data was used to obtain u ∗ values. Schofield (1976) suggested a trial and error procedure for the assessment of the origin of the velocity profile and of the shear stress value. As in the case of Islam & Logan (1976), the recommended procedure has not been attempted because of the fewness of data near the wall. y direction was fixed at % of the equivalent rough

ness height below the particle crest, corresponding to

0.5 k rou (Robertson, 1971; Bayazit, 1983).

In Figure 11 (cases DI-2 and DII-1) and Figure 12

(cases DI-3 and DII-2) the space distributions of shear

velocities u ∗ are plotted. Tests refer to k rou = 30.0 mm

and d a = 0.5k rou with the same flow rate, but different water levels, as observed in Figure 13. Overshooting is present only in the tests with smaller water levels (DI-2 and DI-3). The peak in shear velocity is limited to a short portion of the channel bed.

In Figures 14, 15 the space distribution of u * values is plotted for test having the same flow rate -0.02 and 0.04 m 3 /s respectively, but different dimension of roughness elements and emersion d a of the rough bed. Shear velocity exhibits a different behaviour depending on the geometry of the bed: the level of overshooting increases for increasing emersion d a of the roughness elements, but the higher is the level of overshooting the faster the shear velocity after the peak reaches its downstream values. In these experiments rough bed values of shear velocity were already observed at x- x o = 0.05 m, where just the queue values of an eventual peak in shear velocity were probably evaluated from velocity data. In Figure 16, u *max /u *1 values for each test are plotted versus the corresponding emersion Reynolds number K d* . Data confirm the influence of K d* on the overshooting property. Two trends appear in the

figure: the first is related to tests where overshooting was observed, the second to tests where u * reaches directly the rough bed values without overshooting. In the range of writers' experiments the product h 1 · d a was

effective to assess the presence of overshooting. Over

shooting was present only in experiments with h 1 · d a

smaller than 0.0032. This finding is in agreement with

the results of Nezu & Nakagawa (1991).

5 CONCLUSIONS

The results of several tests on the transition from

smooth to rough bed in open channel flow have been

presented. Each steady state experiment was different

for bed geometry and approaching flow conditions.

Velocity and turbulence intensity profiles revealed

strong modifications along the rough bed downstream

the bed change. The space evolution of an internal

boundary layer was observed.

Streamwise velocities in the boundary layer were

interpreted with the defect log-law and shear velocity

were calculated by least square method.

Tests show that the real presence and the entity of

the overshooting property, namely the presence of a

peak in the shear velocity distribution along the rough

part of the bed, were related both to bed geometry

and flow conditions. In particular, the product between

upstream water level, h 1 , and rough bed emersion, d a ,

seems to be relevant for assessing the real presence of

overshooting.

The entity of overshooting was related to the value

of shear velocity on the smooth bed, and to the emer

sion of the rough bed with respect to the smooth one.

Velocity distribution in a V-shaped channel

M. Mohammadi

Dept. of Civil Eng., Faculty of Eng., Urmia University &
Faculty of Eng., Khoy Azad University, Khoy, Iran

ABSTRACT: To explore the hydraulic characteristics of a
V-shaped channel, several series of experiments

were conducted for measuring point velocity and boundary
shear stress. Low & high-speed velocity propellers

were used for measuring point velocities. In order to show the effect of cross sectional shape on the distribution

of depth-averaged velocity in the experimental channel, some measurements of point velocities were undertaken

for different flow cases. The contour plots of 2D isovels were drawn interpolating among averaged depths

and velocities at a given position, obtained from superposing the various profile sections. It can be seen that

the isovels are parallel to the channel boundary in a region close to the bed, and almost symmetric about the

centerline, but not completely. A strong surface phenomenon is observable throughout the isovels plots. The

variation of point velocities in each slice considered along spanwise direction in order to study the depthwise

velocity profile distributions are plotted. Integrating the local velocities, u, over the flow depth, h, gives the

depth-averaged velocity, U d . The lateral variations of depth-averaged velocities are plotted. The results illustrate

that the distributions are almost symmetrical about the cross sectional centerline, but they deviate for some flow

cases; despite the flow condition was uniform for all cases. It may be found that the widely used log-law for

vertical profile of velocity is not accurate and it is not applicable for any channel shape. At large flow depths the

maximum velocity occurs at the centerline and reduces continuously towards the sidewalls indicating that the

sidewalls exert a large influence on flow behavior. This leads to the view that the secondary current cells affect

the flow behavior.

1 INTRODUCTION

When a fluid passes over a solid boundary, the bound

ary exerts a force on the fluid which is magnified by a reduction in the fluid viscosity. The reduction in velocity becomes less apparent as the distance from surface increases. The region varying flow velocity next to the solid boundary is referred to as a boundary layer. For a smooth surface the boundary layer can be divided into three regions, namely laminar, transitional and turbulent. Figure 1 illustrates these regions and logarithmic velocity profile for a rough boundary together with the turbulent mixing-length, by considering a hypothetical flat plate, immersed in flowing fluid. A full details on this subject may be found in some hydraulics textbooks and Mohammadi (1998).

Herein, for every set of flows both point velocities in cross section and dynamic pressures in contact with channel boundary were measured for the same flow condition. For both velocity and boundary shear stress, the data are analyzed from a variety of different perspectives, and the results from each analysis are used to interpret the mechanics occurring in the flow.

The findings from each perspective complement each Figure 1. Regions of boundary layer Inner and Outer laws, and logarithmic velocity profile for a rough boundary with turbulent mixing-length (after Mohammadi, 1998). other and highlight the consistency of the experimental data. This paper also deals with the presentation of all experimental data, together with the analysis of results obtained so far. 2 BACKGROUND THEORY Nezu & Rodi (1985) found, based on accurate laser Doppler anemometer measurements of secondary currents in open-channel flows, that the flow is strongly

dependent on the aspect ratio α≡ b/h where b is the channel width and h is the flow depth). Depending on this ratio, a channel can be classified as narrow or wide, as indicated below.

(a) Narrow channel (α≤α c ≈ 5). Secondary currents due to sidewall effects result in a “dip” in the velocity distribution near the surface such that the maximum velocity is below the water surface.

(b) Wide channel (α>α c). The strength of the sec ondary currents due to sidewall effects is reduced in the central zone of the channel within a band of width equal to b−α c h. As a result, two dimensional (2D) flow properties are present in this region in the long-term structures averaged over turbulence, as long as the wide span variation of the bed-shear stress is a periodic.

The vertical distribution of stream wise velocity in turbulent open-channel flows is very complex. Three regions (see Fig. 1) have been identified in the vertical flow field for steady uniform flow in smooth, wide, open channels: (a) the wall region [y/h≤ 0.15 to 0.2, y is the distance above the boundary], referred to as the inner layer in boundary-layer theory, where the length and velocity scales are ν/u ∗ , and u ∗ , respectively, where ν is the kinematic viscosity of the fluid, u ∗ is the

boundary shear velocity defined as u ∗ = (τ b /ρ) 1/2 , τ b is the boundary shear stress, and ρ is the fluid density; (b) the free-surface region [0.6≤ y/h≤ 1], where the length and velocity scales are the flow depth h and the maximum velocity u max ; and (c) the intermediate region 0.15 to 0.2< y/h< 6, that is not strongly affected by either the wall properties or the free surface properties and where turbulent energy production and dissipation are approximately equal. Within the wall region in wide channels with a smooth bed, the velocity distribution in the viscous sublayer, i.e., yu ∗ /ν<<B is described as

where u + = u/u ∗ , y + = y u ∗ /ν and B≈ 26 (Nezu and Rodi, 1986), whereas in the region B<≤ y + h 0.2u ∗ /ν the velocity distribution can be described by the logarithmic law

where κ is the von Karman constant (equal to 0.41), and A is a constant. In the case of rough channels, the length scale is represented by Nikuradse's equivalent sand roughness k s , which accounts for the effect of the roughness elements. In general, k s is a function of the shape, height, and width of the roughness elements, as well as their spatial distribution on the channel surface. Experimental observations suggest that the more uniform and evenly distributed the roughness elements on the channel bed are, the closer is k s to the actual height

of the protrusions (Schlichting, 1979). Depending on the ratio of roughness and viscous length scales (often referred to as non dimensional roughness parameter or roughness Reynolds number), ks + = u ∗ k s /v, the turbulent flow regime in wide open channels can be classified as hydraulically smooth, transitionally rough, or fully rough. The flow regime is considered hydraulically smooth for k + s < 5, fully rough for k + s > 70, and transitionally rough for the range in between. In general, for the range between hydraulically smooth and completely rough flows, the logarithmic-law distribution is applicable whenever k s is used as the length scaling factor; that is where Ar= f (k + s). According to Nikuradse's measurements, for a turbulent flow in completely rough regime Ar= 8.5 (Schlichting, 1979) and, thus, Equation (3) can be reduced to Nezu and Nakagawa (1993, pp. 16–17) discuss that the logarithmic law is inherently valid only in the wall region and that deviations of the velocity distribution from this law should be accounted for by considering a wake function such as that proposed by Coles (1956). However, in practical applications it is still commonly assumed that the logarithmic law describes the velocity distribution over the entire depth of uniform, steady open-channel flows. The power law is an alternative model to represent the vertical distribution of the streamwise velocity in open-channel flows. Chen (1991) presented a generalized power-law model for velocity distribution in open channels and analyzed the ranges of applicability of different powers. In general, the power-law model is expressed as where y ′ is defined as the physical location in the boundary layer at which u= 0, and a and m are a coefficient and an exponent, respectively. Based on theoretical considerations, Chen (1991) shows that for perfect agreement between the power law and the logarithmic law, the product of κ, m, a, and e, (where e is the base of natural logarithms) should be equal to 1. From this condition, upon substitution of the values of e and κ, the expression m.a= 0.92 is obtained.

This indicates that the exponent m is inversely pro

portional to the coefficient a. However, this is only

a particular case that corresponds to a unique point

in the domain of the logarithmic law. For fully rough

flows, a relation between y ′ and k s can be obtained from

the logarithmic law as y ′ = k s /e κA r g or approximately

k s /30 (Chen, 1991). For this case, best-estimate values for a and m in the power law that for a certain range of u/u ∗ or (y/y ′) satisfy the logarithmic law within a given tolerance in a least-squares sense can be obtained based on nonlinear regression analysis.This part of the Chen analysis demonstrates that both parameters in the power law m and a vary with global relative roughness for fully rough flows due to incomplete similarity. Several methods are available to estimate u ∗ (see e.g. Nezu and Nakagawa, 1993, pp. 48–49). The sim plest one, derived for steady uniform flow in wide channels, estimates u ∗ = √ ghS 0 , in which g is the gravitational acceleration, and S 0 is the slope of the channel bed (for uniform flow the slope of the chan nel bed, the friction slope, and the water surface slope are all equal). In the case of steady non uniform flow, the energy slope S replaces S 0 . Accurate assessment of the representative bed slope in the vicinity of the measured section is difficult; therefore, u ∗ must be estimated with other methods. These methods, how ever, are only applicable when accurate measurements of either velocity fluctuations or wall shear stress are available, such as in the case of carefully performed laboratory experiments. An alternative method fre quently applied to determine u ∗ is based on the best

fit of the measured mean velocity distribution to the logarithmic law.

3 EXPERIMENTAL APPARATUS AND PROCEDURE

To investigate the hydraulic characteristics of a V-shaped bottom channel (see Fig. 2 for cross-section and notation), several series of experiments were con ducted for measuring point velocity and boundary shear stress. The described experimental channel, was built inside the existing 15 m long tilting flume. Low and high speeds velocity propellers were used for mea suring point velocities, and a Preston tube was used for measuring dynamic pressures to evaluate boundary shear stress.

For a certain channel bed slope, a discharge was introduced and uniform flow was established using stage-discharge results and discharge-tailgate relation ships. To avoid the effects of upstream entrance and drawdown at the downstream end a section of 2 m from the tailgate was chosen as a measuring section. This section was the same as that chosen for normal depth and boundary shear stress measurements.

Several series of experiments were conducted for measuring primary point velocity in aV-shaped bottom channel. Low & high speeds velocity propellers were used for measuring point velocities. For a certain channel bed slope, a discharge was introduced and uniform flow was established

Figure 2. V-shaped bottom channel cross-section.

using stage-discharge results and discharge-tailgate relationships. The flume was supported by two hydraulic jacks and rotated about a hinge joint beneath the middle of the channel.The flume also had a motorized slope control system with a mechanical visual read out on a ruler at the upstream end of the flume used for determining the precise channel bed slope. The maximum slope obtainable was S 0 = 2%. The experimental channels, with a V-shaped bottom cross section built by using PVC panels to make a 14.5 m long channel having 50 mm crossfall, were built along the inside centerline of the existing flume. Water was supplied to the channel by an overhead tank through a 101.6 mm pipeline for discharges up to 30 ls −1 and a 355.6 mm pipeline for discharges higher than 30 ls −1 . To reduce large-scale disturbances, and in order to ensure that the flow was uniformly distributed, a system of honeycombing was placed at the upstream end of the channel where the entrance tank and bell-mouth shaped inlet transition section were located. However for the case of supercritical flow i.e. Fr> 1 the honeycomb was not very useful. Individual bell-mouth shaped transition sections were designed and made for each channel types and served to reduce separation and improve the development of the mean flow into the channels. Discharge measurements (up to 30 ls −1) were made by means of a Venturi meter connected to mercury and air/water manometers at the head of the flume. An electromagnetic flow meter was also installed in the supply line after the Venturi and was used to check discharges. For the case of higher discharges a dall-tube connected to an air/water manometer was used in the 355.6 mm diameter supply line. The flume had a very rigid bottom designed for high loads, and therefore it was not necessary to do any deflection tests. A slatted tailgate weir was installed in the downstream end of the channel in order to minimize upstream disturbance of the flow, and hence allowed a greater reach of the channel to be employed for experimental measurement in subcritical flows.

Figure 3. The averaged point velocities measured in V-shaped channel: Q= 125.89 ls −1 & S 0 = 0.2%.

The test section consisted 12 m long zone, commenc

ing at a distance of 1.25 m from the channel entrance

and 1.85 m from the flume entrance. However, for

supercritical flows, because of the S2 profiles, the

test length was reduced to about 7 m. A trolley was

mounted on rails running along the flume with a depth probe, having an electrical contact to the water sur face level (accurate to 0.1 mm) and hence the channel bed slope was obtained. It has also been possible to do lateral measurements using the same trolley. The depth was measured at one meter and sometimes half a meter intervals in the test length by means of a cen terline pointer probe moved down from the instrument carriage.

The present research work deals with the veloci ties measured different positions inside of the channel cross-section and velocity distributions. Local velocity measurements were carried out by using the propeller technique with two Nixon 14 mm low and high speed propellers, namely type 403 serial No 1976 Low Speed, and type 404 serial No 1981 High Speed. The related calibration equations are

(for low speed probe type 403/1976)

(for high speed probe type 404/1981)

The probe was mounted on a carriage and aligned vertically inside water flow and normal to the bed. It was placed on the channel every 10 mm intervals on the vertical lines and every 20 mm intervals in spanwise direction. The velocity numbers (N) were recorded by connecting the propeller to a simple indicator. The reading numbers were applied to assess the primary velocities using equations 6 & 7. 4 VELOCITY MEASUREMENTS RESULTS, ANALYSIS

AND DISCUSSION 4.1 Primary velocities In order to explore the distribution of depth-averaged velocity in a V-shaped channel, some measurements of point velocities were undertaken for different flow discharges. As an example, the positions of velocity measurements within the channel cross-section is shown plotted in Figure 3, for the condition of Q= 125.89 ls −1 & S 0 = 0.2%. A propeller indicator was set on 10 seconds and at least five numbers were recorded. Those five numbers were then averaged to obtain for evaluating the primary point velocities. Applying a corresponding calibration equation for any propeller, the point velocities were obtained. Point velocities were measured at a number of vertical sections normal to the bed along the spanwise direction to cover as much of the cross section as possible at 20 mm and sometimes 10 mm intervals. For flow discharges up to 30 ls −1 an em flow meter was used, and for flows higher than 30 ls −1 a Dall tube was used for discharge measurement. The local point velocities were multiplied by the surrounding subareas, and integrated slice by slice, from which the integrated discharge, Q int. , was obtained. The electro-magnetic flow meter discharge, Q em. , and

Dall tube discharge, Q dall. , were then compared with

the integrated discharges obtained from velocity mea

surements. The percentage error values of discharges

were expressed as

Depth-averaged velocities were then adjusted to the

em/Dall mean values, so that when integrated they

gave Q int. =Q em/dall . The discharge errors calculated

via eq. 6. were very small in the case of large flow

depths, typically less than 2% but increased for low

flow depths slightly. Overall, the percentage error

values are reasonably satisfactory.

4.2 2D Isovels diagrams

In order to transform the point velocities to 2D isovel

diagrams, a commercial software package known as

“SURFER-6.04” was used. The contour plots were drawn interpolating among averaged depths and velocities at a given position, obtained from superposing the various profile sections. The errors due to the averaging velocities and depths at a given point or section were not significantly different from any extreme value for that point or section. However one of the drawbacks with this software is that the calculations and diagrams are undertaken assuming a computational square mesh i.e. a rectangular channel cross section. This can provoke problems when the geometry of channel is not easily represented by this approach. Nevertheless, this does not affect the overall accuracy of the interpolation, but it produces a non smooth boundary when the results are viewed graphically. It also implies that the isovels near the channel boundary only represent the actual distributions approximately. However from a quantitative point of view, the software is adequate. To solve this problem, a series of data was produced representing the channel boundary at small intervals along the wetted perimeter, and they were replaced as a channel boundary having zero velocities. The channel boundary is therefore viewed reasonably well. One of the representative 2D isovel patterns for different flow conditions is shown in Figure 4.

The primary point velocities were normalized by the section mean velocity, U , and plotted in a similar manner. A complete set of the results is presented by Mohammadi (1998). All the isovel plots illustrate the presence of steep velocity gradients close to the channel boundary, a feature that is characteristic of turbulent boundary layer flow. As can be seen from these Figures, the isovels are parallel to the channel boundary in a region close to the bed, and almost symmetric about the centerline, but not completely. The plotted Figures likewise Figure 4, however indicate

that as the flow depth increases, and the channel gets
Figure 4. Isovel plot for V-shaped channel: Q= 125.89 ls -1 & S 0 = 0.2%. steeper, the isovel patterns become more distorted and the position at which maximum isovel value occurs is depressed below the water surface. From the sediment transport point of view, this phenomenon causes more lift and erosion on the bed particles, and hence more sediment movement. The distortion of the isovels and the location of maximum velocity are strong evidence of secondary currents being present in this V-shaped bottom channel. The discontinuity between the V-shaped bottom part of the channel and the vertical walls is responsible for those distortions producing anisotropic turbulence. In some cases related to the steeper channels, the isovels are compressed towards the corner regions. This may suggest that momentum is being transported towards the corners. This phenomenon can be seen in the data and isovel contours given by Powell & Posey (1959 and 1961) for triangular 90 ∘ channels, and in Wasley (1961) for the vertical walled shallow triangular channels. No explanation was attempted by them. It has also been noted by Tominaga et al (1989) for trapezoidal channels. They however proposed that this may be related to the bed generated vortex, and the free surface flow. A strong surface phenomenon is also observable throughout the isovel plots. It can be seen that the distortions increase as the flow depth increases and the slope gets steeper. This effect likely to be linked to

the number of secondary flow cells. If the secondary flow patterns could be drawn accurately from direct measurements of V & W precise conditions could be drawn. 4.3 Vertical distribution of local velocities and prediction of friction velocities The variation of point velocities in each slice considered along span wise direction in order to study the depth wise velocity profile distributions is

Figure 5. Velocity profiles over the depth, z, at different spanwise positions, y, in a V-shaped channel: Q= 125.89 ls -1 &

S 0 = 0.2%.

shown plotted in Figure 5. Figure 5 is in fact the sec

tional drawings for the 2D isovel contours explained

in the previous section. The profiles are plotted from

the wall towards the channel centerline. As can be

seen from Figures likewise Figure 5, when profiles are

going close to the flow surface, they tend towards the

centerline part of the channel cross section. This again

indicates the strong presence of secondary currents.

It is customary to compare velocity profiles with

the universal logarithmic velocity law. In order to

do this, the local velocity, u i , must be normalized

by the subsection friction velocity, u *i , i.e. by u *w ,

for the velocities normal to the walls and by u *b

for velocities normal to the bed, to give value of

u + , where u + = u/u *i . The depth levels, z, at which

velocities were measured must also be normalized,

as u *i z/v for velocities over smooth surfaces, and as

z + = z/k s for velocities over rough boundaries. The

local shear velocity, u ∗l , can be calculated by using a

semi-logarithmic relationship between the local veloc

ities and related depths. For this purpose the following

equation may be applied

where M s is the regression coefficient, and κ is the

Karman constant taken in this study as κ= 0.41 sug

gested by Nezu & Rodi (1986). Then the local shear

stress is estimated by However it was not possible to apply this approach, because the above mentioned relationship in equation (9) did not give a reasonable value for M s with which to evaluate the local friction velocities. Instead the boundary shear stress results were used to estimate the local friction velocities, where the flow conditions for boundary shear stress were the same as for the velocity measurements used were also measured. For the V-shaped bottom channel, this process was carried out and the results were used for log-law examination. Using the local boundary shear stress measurements the adjusted values of shear velocity u ∗l = √ τ l /ρ were tabulated and used to compare the experimental relating data with the universal velocity law. The variation of normalized point velocities, u + = u/u ∗l at y= 75, 155, 235, 315, & 395 mm along spanwise direction are shown plotted versus ln (z +) in Figure 6. The universal logarithmic velocity law, used by Nezu & Rodi (1986) coefficients are: A= 2.427 & B= 5.29. It is clear that experimental results are not consistent with the universal logarithmic velocity law, as might be expected. As can be seen from the Figures likewise Figure 6, the universal log-law only matches some parts of velocity profiles in some flow conditions. For example, it lies on centerline profile at Q= 25.03 ls −1 & S 0 = 0.9%, and for the case of Q= 50.931 ls −1 & S 0 = 0.4% it matches a little with profiles at y= 155 & 355 mm positions. However in some cases of flows, the universal law is far from 0 5 10 15 20 25 30 5 8 9 10 ln(u ∗ z/ν)

u

/ u

u

/ u ∗ y=75 y=155 y=235 y=315 y=395 Nezu & Rodi (1986) 76

Figure 6. u/u ∗ versus ln(u ∗ z/v) at different span wise positions, y: Q= 125.89 l/s & S 0 = 0.2%.

agreement with the experimental data (see Moham madi, 1998). As expected, the strong effects of cross sectional shape and secondary currents on the flow behavior in this particular channel shape cause the relating distributions to deviate from their simple 2D distribution law.

4.4 Lateral distribution of depth-averaged velocities

Integrating the local velocities, u, over the flow depth, h, gives the depth-averaged velocity, U d . As an example, Figure 7a shows the lateral variations of depth-averaged velocities and also their normalized distributions for different flow discharge and slope settings. The section mean velocities are also shown as solid lines related to every flow test on the same Figures. It can be seen from these Figures that the distributions are almost symmetrical about the cross sectional centerline, but they deviate for some flow cases, despite the flow condition was uniform for all cases. At large flow depths the maximum veloc ity occurs at the centerline and reduces continuously towards the sidewalls indicating that the sidewalls exert a large influence on flow behavior. These data would be useful for validating various computational

models, such as the 2D depth-averaged model given by

Shiono & Knight (1991). The measured depth-mean

velocities were also normalized by section mean veloc

ity, U d /U and plotted versus spanwise direction, y, for

some selected flow tests, as shown in Figures likewise

Figure 7b. It can be seen from this Figure that some

deviations are observable. This leads to the view that

the secondary current cells affect the flow behavior.

4.5 Location of maximum point velocity and its relation with section mean velocity, U

In open channel flows, the maximum velocity, u max ,

and its location in a channel cross section as well as the

mean velocity, U (=Q/A), is a valuable parameter. In Figure 7a. Lateral distribution of depth-averaged velocity in a V-shaped channel: Q= 125 ls −1 . Figure 7b. Dimensionless lateral distribution of depth-averaged velocity in aV-shaped channel: Q= 125 ls −1 . contrast with U , it is mentioned very little.The location of the maximum velocity in a channel cross section depends upon the shape of the channel cross section, and consequently it depends upon the resultant effects of the secondary currents. The relation between U and u max for pipe flows in most textbooks is referred to as where c is a constant and is equal to 0.8167 (Streeter & Wylie, 1979). This relationship can be achieved by using the Prandtl (1/7th) velocity distribution law in a circular pipe as: in which u is the point velocity at a depthwise distance, z, from the pipe wall, and r 0 is the pipe radius. Chiu (1988 & 1989), Chiu & Murray (1992), Chiu et al (1993), and Chiu & Said (1994 & 1995) have studied the velocity distribution in either pipe flows or open channel flows, and by applying the entropy concept

Figure 8. Variation of maximum velocity values in a

V-shaped channel at different flows.

they have given the following equation to describe the

ratio c:

where M is the dimensionless entropy parameter

(M = 1/c= 1.2244 for pipe flows and does not sat

isfy the approximate equality very well). According

to Chiu & Said (1994 & 1995) the measurable max

imum velocity can be considered as a ‘single’ value,

from which one can know the range of the velocity in

a channel cross section and furthermore obtain useful

information about the type of open channel flow. The

above relationships between U and u max was examined

by Xia (1997) for a natural river i.e. Mississippi river

and by Sterling (1997) for a part-full pipe channel.

They found that there is a linear relationship between

u max and U . It may be concluded that for natural rivers

and man-made channels, the maximum velocity might

play a useful role, but not as important as U . For open

channel flows of different cross sectional shapes, not

only does the constant number c or M vary, but also

the location of the maximum velocity does alter. This

makes the use of u max somewhat problematic.

In order to determine the location of the maximum

velocity and its relationship with section mean veloc

ity, U , for different flow conditions, Figure 8 was

constructed. Figure 8 illustrates that there is a good

linear relationship between u max and U , given by

Employing a least square analysis on the data and

imposing the condition that the trend line set to zero

i.e. when U = 0, then u max = 0, and one gives

A comparison of equations (13) and (15) gives constant

parameter values as: c= 0.8379 and M = 1.1934. This

result confirms that for a V-shaped bottom channel the value of dimensionless entropy parameter, M, is lower than that of the standard value for circular pipe flows. The position of maximum velocity in the spanwise direction, was produced. It was seen from this Figure that the majority of the data lie on the central slice of the cross section at y= 230 mm, with only a few data positioned in two neighbouring slices. 5 SUMMARY AND CONCLUSIONS The primary velocity and boundary shear stress measurements have been undertaken in the uniform flow condition for five target flow discharges of 10, 25, 50, 85 & 125 ls -1 at four different channel bed slopes of 0.1%, 0.2%, 0.4% & 0.9% (see Mohammadi, 1998). In addition 16 different flow conditions were examined for velocity and the same 16 for boundary shear stress, in a V-shaped bottom channel. Therefore a considerable amount of data has been collected and the associated parameters have been analyzed. On the basis of results already presented in previous sections, the main findings are: 1. Experimental velocity isovels and transverse velocity distributions have been presented for uniform flow conditions. 2. The isovel plots (see Fig. 4) are generally symmetric, except in the central region where a local maximum occurs. However, it seems that the generally symmetrical distributions of primary flow are sometimes unstable, so that an alternative pattern of asymmetry may form. Such an alternating pattern is random for different flow conditions, being affected by secondary flow cells which make the flow 3D. 3. The depth wise velocity profiles tend towards the centerline of the channel near the water surface (see Fig. 5). This finding is one of the strong evidence for the presence of secondary currents. It is more apparent for the higher Froude numbers. 4. The logarithmic velocity law developed for wide open channel flows, has been shown to be largely ineffective for the current channel shape (see Fig. 6). 5. The distributions of depth-averaged velocity show that they are fairly flat for low Froude numbers (see Figs. 7a & b). This is not the case for higher Froude numbers. 6. There is a good linear relationship between the maximum velocity, u max , and section mean velocity, U , and is given by

equations 11 & 12 (see Fig. 8). 7. The depth wise position of maximum velocity is shown to be at near the surface for low Froude numbers. The filament of maximum velocity is depressed below the free surface as the Froude number increases. 8. For theV-shaped bottom channel, the dimensionless entropy parameter, M, introduced by Chiu is greater than that of given for the full pipe flows.

9. The random or stochastic nature of a fundamental instability of the flow field, was also seen in the data of Powell & Posey (1959 & 1961) and Wasley (1961). No explanation for the observed asymmetry was attempted. However,Tominaga et al (1989) pro posed that this may be related to the bed generated vortex, and the free surface vortex.

10. There is a strong evidence of cross sectional shape effects on the distribution of velocity.

11. The effect of multiple pairs of secondary flow cells was evident in the perturbations of the depth averaged velocities for both subcritical and super critical flows. Although at low flow depths where the Froude number is not so high i.e. greater aspect ratios the presence of secondary currents was not immediately apparent in the primary velocity distributions as measured by the propellers.

12. The number of perturbations, and hence the num ber of secondary flow cells, has been shown to be dependent on the flow depth and discharge i.e. the aspect ratio. Up to three pairs of flow cells can be

detected at a large discharge in a steep channel with

a V-shaped bottom.

13. The information in this chapter may prove useful to

any computational modelers dealing with channels

with a similar shape. The work may also be valu

able to river engineers trying to solve stable channel

problems as well as sediment transport in channels

with side slopes, similar to channels with aV-shaped

bottom.

River roughness – the integration of diverse knowledge

C. McGahey & P.G. Samuels

Water Management Department, HR Wallingford, Howbery Park, Benson Lane, Wallingford, Oxon, UK

ABSTRACT: In 2000, the Environment Agency of England and Wales identified the need to reduce the

uncertainty associated with flood level prediction through using recent research advances on river and flood

plain conveyance (Samuels et al, 2002). This has led to the

development of the Conveyance Estimation System

(CES), involving a partnership between researchers and experts in hydraulics, aquatic vegetation and software

development and with close consultation with typical users. A key component of this development was taking

knowledge on river resistance from a diverse set of sources, covering different types of vegetation in the river

and on the flood plain and, different channel dimensions and bed material type. The calculation methods are

documented elsewhere (McGahey & Samuels, 2003) and are based on the Darcy friction factor to represent local

river bed stresses coupled with other fluid dynamic processes. Most data sets on flow resistance provide average

values of Manning's n for whole river sections and include the influence of bed material, vegetation and larger

scale topographic variation. A key requirement of the CES project was to produce a roughness advisor to allow

the user to access this information in a structured manner and construct information for the CES conveyance

calculation. The field data also needed further interpretation to assess the local resistance properties to include in

the calculations. This paper describes the integration of this information on flow resistance into the conveyance

calculations in the CES software including an approach for the estimation of friction factors when the flow depth

is comparable to the effective roughness length scale.

1 INTRODUCTION

Over the past two decades there has been an improve

ment in knowledge and understanding related to esti

mating the conveyance capacity of natural channels.

Research into the exact nature of the flow processes such as local friction, turbulence due to lateral shearing and the presence of secondary flows, together with an ever increasing database of observed flow parameters such as the managed programme of research on the Flood Channel Facility (FCF) at HR Wallingford, provides the facility for testing and validating these new approaches. Significant contributions include those of Chang (1983), Ervine & Ellis (1987), Shiono & Knight (1989), Ackers (1993), Bousmar & Zech (1999) and Ervine et al (2000). Historically, most one-dimensional hydrodynamic software packages are based on the Manning equation, first published in 1891 (Manning, 1891). This empirically derived equation is not based in rigorous physics and provides meaningless results for sudden changes in area or wetted perimeter with depth, where shape effects are ignored.

In 2000, the Environment Agency commissioned a Scoping Study into reducing the uncertainty related to flood level predictions. The key outcome was a Targeted Programme of research to be undertaken by a multidisciplinary team of experts and led by HR Wallingford, which would deliver a Conveyance Estimation System (CES). This stand-alone software would comprise three core components: the Roughness Advisor for assistance in the estimation of local roughness, the Conveyance Generator for the improved calculation of conveyance and the Uncertainty Estimator which provides some measure of uncertainty for the predicted water level. The CES would be available as open code for inclusion in any one-dimensional hydrodynamic modelling software. The conveyance methodology

to be incorporated in the CES (McGahey & Samuels, 2003) is based on the depth integration of the ReynoldsAveraged NavierStokes Equations (HR Wallingford, 2003).

where:

g = gravitational acceleration (m/s 2)

q = streamwise unit flow rate (m 2 /s)

H = local depth normal to the channel bed (m)

S o = reach-averaged longitudinal bedslope

y = lateral distance across the channel (m)

β = coefficient to account for influence of local bedslope on the bed shear stress

α = function of the reach-averaged sinuosity

The total flow rate Q (m 3 /s) is calculated from integrat

ing this lateral unit flow distribution across the channel

section, and hence the total cross-section conveyance

K (m 3 /s) is determined from,

where the reach-averaged longitudinal friction slope

S f is approximated by the reach-averaged longitudinal

bedslope S o .

Equation (1) has four calibration coefficients: the

local friction factor f , the dimensionless eddy vis

cosity λ, the secondary flow parameter '' and the

coefficient of meandering C uv . The intention of this

paper is to describe the approach adopted for determin

ing the lateral variation of f for a given depth of flow.

The conversion of a unit roughness ‘n’ to an equiva

lent resistance f is described, with particular consider

ation given to the evaluation of f where the roughness height is large relative to the local water depth.

2 LATERAL DISTRIBUTION OF f FOR A GIVEN DEPTH

Previous approaches for determining the lateral distribution of f for a given depth include:

1. Diagrams for pipe resistance such as the Moody Diagram, where the pipe diameter can be replaced by four times the hydraulic radius R (m) for open channel flow.
2. The Blasius equation which is applicable for smooth turbulent flows where the flow conditions are dominated by the viscous forces, typically used for experimental flumes (4000<Re< 10 5). This formula is based on pipe flow.
3. The Kármán-Prandtl equation which is used at higher Reynolds Numbers, where the Blasius equation under-predicts f .
4. The Hazen-Williams equation, which is derived for pipe flow.
5. The ‘Power Law’ approach, which relates the ratio of the Darcy-Weisbach resistance coefficient on the floodplain f fp and main channel f mc respectively, to the relative depth by a power of 3/7 (Shiono & Knight, 1991; Rhodes & Knight, 1994). 6. Calibrated

relationships that relate the main channel resistance f mc to the floodplain resistance f fp by an empirically derived factor R f (Knight & Abril, 1996; Abril, 1997). 7. The Chezy (1768) equation with an additional conversion to relate the Chezy coefficient C (m 0.5 .s −1) to f as a function of the hydraulic radius. The Chezy equation is based on balancing the resistive force due to the wetted perimeter and the square of the average velocity with the driving force due to the longitudinal bedslope and the cross-sectional area. It is therefore applicable where rough turbulent flow dominates as a result of the boundary friction represented by C. 8. The Manning equation with an additional conversion to relate Manning's n to f as a ratio of the local depth to the power 1/3. This equation is independent of the Reynolds number and the friction factor depends only on the hydraulic radius. Manning's equation is therefore only recommended for fully rough turbulent flow conditions. The units of n are s.m −1/3 , although some authors believe that the roughness is not related to time and that it includes a gravitational term g 0.5 , giving the actual units of n as m 1/6 and thus relating n to the hydraulic radius R 1/6 . Based on the approximations in deriving the Manning equation and the uncertainty in the value of n, it seems unjustifiable to carry the numerical constant to more than three significant figures (Chow, 1959). 9. The full Colebrook-White (1937) equation i.e. inclusive of the smooth and rough turbulent laws. White identified two types of surface: those that give a constant f at sufficiently high Reynolds Numbers i.e. where f is dependent on the relative roughness only (rough law) and those for which f continues to decrease as the Reynolds Number increases (smooth law). In general, the values of f appear to be larger for pipes at the same Reynolds Number and relative roughness. Kirshmer (1949) attributed the differences to the secondary flows that are not present in pipe flow. The transition from smooth to fully rough flow is further dependent on the form and spacing of the roughness elements (Henderson, 1966; US Task Force, 1963). These approaches are not applicable to channels whose beds are in motion. It is assumed throughout that the bed topography is fixed. The lateral distribution of f in the Conveyance Generator is based on a form of the Colebrook-White equation, with coefficients suitably adapted for open channels. This equation was selected over the Chezy and Manning equations, as (i) it covers smooth turbulent,

transitional and rough turbulent flows; (ii) it has a

strong physical basis as it is derived from the log

arithmic velocity profile together with the channel geometry; and (iii) it incorporates the variation of roughness with depth. Data measurements from the Mississippi, Tennessee and Irrawaddy Rivers (Chow, 1959) clearly illustrate this variation of the cross section roughness n with depth, and in particular, the rapid increase of n at low flows. Ackers (1958) pub lished a thorough study of channel flow and concluded that the Colebrook-White formula is the best available. He noted that k s should be increased by 20% over the value for the same material in pipes, to correct for the different cross-sectional shape.

In equation (3), the coefficient ‘2.03’ is from taking von Kármán’s universal constant as 0.4 (assumes clear water). The coefficients ‘12.27’ and ‘3.09’ are based on this coefficient together with the channel cross section shape and the nature of the roughness ele ments. Previous research (Henderson, 1966; Keulegan, 1938; Rouse, 1938; Zegzhda, 1938) has provided advice on the coefficients for a variety of channel types, ranging from smooth rectangular shapes to fully rough, wide, natural channels. The coefficients in equation (3) are based in part on this advice. However, since the application of the Colebrook-White is to local element ‘slices’ rather than the entire cross-section for

which the equation was derived, these predictions of f are further compared to the f -values back-calculated from bed shear stress measurements. The EPSRC FCF managed programme of research provided high qual ity flow, velocity and shear stress data for straight, skewed and meandering trapezoidal compound chan nels, situated in a 56 m long, 10 m wide and 0.4 m deep laboratory flume. Velocity measurements were taken with a vane attached to a rotary potentiometer at regu lar spacing across the sections, for a number of depths within each vertical column. This enables calculation of the local depth averaged velocity profile U d (m/s), and together with the measured (using a Preston tube) bed shear stresses τ b (N/m 2), the local resistance f can be determined,

where ρ (kg/m 3) is the fluid density. Comparison of the Conveyance Generator predicted f -values to the FCF PhaseA data (Figure 1) confirms the applicability of the selected coefficients in equation (3) for smooth channels over a range of depths, including both inbank and out-of-bank flow.

natural vegetation includes 12 morphotypes (Table 1)

based in part on the RHS data as well as categories due

to human intervention such as grass, hedges, trees,

shrubs and crops e.g. wheat, sorghum, corn, cotton,

soybeans and sunflower. Irregularites include urban

trash, groynes, exposed boulders, pools and riffles,

ridges on ploughed fields, undulations on the flood

plain and obstructions such as debris deposits, exposed

roots, stumps, logs, piers and isolated boulders.

For solution of equation (1), the lateral variation of

f is required, and hence the lateral distribution of this

local boundary roughness n l . Since the local rough

ness at a point in the section can comprise up to three roughness components, these can be combined to get the total unit roughness at a point through, where n veg , n sur and n irr are the local roughness values due to vegetation, surface material and irregularity respectively. These are associated with a depth of 1m, selected as a representative depth of flow for UK rivers. The reason for adopting the “root sum of the squares” approach is twofold: it highlights the contribution of the largest roughness component; and the roughness is squared before being

combined since the energy loss is related to the square of the local velocity. The assumption is that the roughness mechanisms are mutually independent and hence the total resistance can be expressed as the sum of the individual resistances. Previous work (Einstein & Banks, 1950) employed a similar approach whereby the measured bed shear stress relative to the square of the velocity (τ/v 2) was compared to the addition of this term for the independent resistance components.This is similar to equation (5) with both sides squared. The local roughness contributions from flow over (i) flat blocks, (ii) an offset and (iii) pegs were measured. These were combined and compared to the total measured roughness due to all three components, and the measured total resistance values were found to correlate well with the combined data. It was concluded that the separate resistances should be expected to have an additive property provided the roughness types do not exhibit excessive mutual interference. 4 CONVERSION OF LOCAL MANNING n l TO AN EQUIVALENT ROUGHNESS k s Solution of equation (3) requires the conversion of the local roughness ‘n l ’ to an equivalent length scale ‘k s ’. Although the roughness height k s is traditionally defined in terms of the sand grain dimension (Nikuradse, 1933), the vegetation k s can be interpreted as an equivalent turbulence length scale i.e. a measure of the turbulent eddy size. This length scale may be greater than the water depth, e.g. willow trees, boulders etc., as it represents the horizontal mixing action, whereby eddies may be larger in plan than the local water depth.The equivalent k s value can be determined from (variation of Strickler, 1923; Ackers, 1958), This equation is only applicable where the depth H is in the range of 7–140 times the roughness size. For the flow conditions under which the equation was derived,

this was found to be suitable, as it was applied to

the whole cross-section or three regions: i.e. the main

channel and two floodplains. For application within

the Conveyance Generator, two issues arise:

1. In equation (1), the solution is required for each

lateral division across the section and hence for a

given section the local roughness height may be

equivalent to a large fraction of the depth or in some

cases, exceed it e.g. tall grass on the floodplain.This typically occurs at low inbank and low overbank flows.

2. Large typically-used Manning n-values result in highly inflated k s values. E.g. should the bed mate rial be characterised by large boulders, with an equivalent Manning n-value of 0.5, this would pro duce a k s value over 5,000 km, which is meaning less in terms of the channel depth anywhere in the cross-section or entire river reach (Table 2).

An alternative approach is to use the rough turbulent law, i.e. the first term in equation (3),

where f is given by,

Hence at a depth of 1 m, k s is given by, 0 2 4 6 8 10 12 14 0 E q u i v a l e n t r o u g h n e s s h e i g h t k s Colebrook-White Acker’s 0.2 0.4 0.6 0.8 1 1.2 1.4 1.6 Local Manning n l 0.050 0.045 0.040 0.035 0.030 0.025 0.020 0.015 0.010 0.005 0.000 0.01 0.015 0.02 0.025

Figure 2. Conversion or n l to k s for a typical range of n l values. This relationship and equation (6) can be viewed in Figure 2 and Table 2 for a typical range of n l values. As n l approaches infinity, the bracketed term approaches zero, and k s asymptotes to 12.27, the coefficient in the Colebrook-White law. In the Acker’s approach, k s approaches infinity, and hence equation (9) is preferable. For the region 0.01< n l < 0.025, both laws predict a similar relationship. These approaches are not suitable for experimental flumes where the smooth turbulent law dominates e.g. in Table 2 the values of k s for n l ≤ 0.01 decrease rapidly.The assumption is that the unit roughness k s is constant with depth, although this has been shown otherwise for whole cross-section k s -values in tidal reaches. Knight (1981) considered the variation of n, f and k s with stage in the 1.2 km long tidal reach of the Conwy Estuary and found that all three parameters varied

significantly with depth. In particular, the Nikuradse roughness Table 2. Comparison of k s predictions based on the calculation approach of Ackers and the simplified Colebrook-White Law. Equivalent k s (Colebrook-White Equivalent k s n l (s.m -1/3) Rough Law) (m) (Ackers, 1958) (m) 0.0010 3.0373E- 55 3.3212E- 10 0.0050 9.2805E- 11 5.1894E- 06 0.0100 3.3745E- 05 3.3212E- 04 0.0500 9.4780E- 01 5.1894E+ 00 0.1000 3.4102E+ 00 3.3212E+ 02 0.5000 9.4980E+ 00 5.1894E+ 06 0.8000 1.0455E+ 01 8.7064E+ 07 1.0000 1.0795E+ 01 3.3212E+ 08 100000 1.2270E+ 01 3.3212E+ 38

height k s was found to vary significantly with stage,

increasing from 0.2 m at high water to a value (2.5 m)

comparable with the water depth at low water.

5 CONVERSION OF EQUIVALENT ROUGHNESS k s TO LOCAL FRICTION FACTOR f

Once k s has been determined, the full Colebrook

White equation (3) can be used for the solution of

f at a given depth. This approach is not universally

applicable, and it can provide unrealistically large val

ues of f . Consider the term in brackets in equation (3).

Should the flow be characteristic of a natural river, with

a large k s /H ratio, the viscous forces and hence the

smooth law contribution become negligible. As k s /H

approaches 12.27, the bracketed term approaches one,

and the logarithm tends to zero. The result is that,

and the inverse of this small number squared provides

an unrealistically large f -value (Table 3). This f is

meaningless and thus at high k s /H ratios, a Power Law

is introduced.

The mathematical formulation of the velocity distri

bution in the overlap region of the boundary layer (i.e. between regions dominated by either viscous or inertia forces) must be either of the logarithmic or the Power Law form. The logarithmic form (i.e. basis for the Colebrook-White Law) is generally favoured as it cov ers a wider range of Reynolds Numbers, whereas the Power Law must change with Reynolds Number and also with roughness. In the literature, the Power Law generally relates f to R 1/3 . For simplicity, it is assumed in equation (11) that a 3 = 1 (Samuels, 1985). The

Table 3. Calculated resistance f values for an increasing absolute roughness over depth relationship.

Roughness ratio k s /H	Equivalent resistance f
0.5	0.13
1	0.20
1.66	0.32
2	0.39
8	7.03
10	30.74

12.26	1935416.14
12.27	∞

coefficients a 2 and a 4 can hence be derived through ensuring equations (6) and (10) are continuous in f and that the derivative of f with respect to depth, df/dH, is continuos at the cross-over point between these two laws i.e. at H = a 4 k s . Expressing equation (11) at the upper limit of its range of applicability, and taking the derivative with respect to depth gives, Rearranging

equation (7) in terms of f and setting a 1 = 8× 2.03 2 [log 10 e] 2 = 6.218 yields, and df/dH is given by, Equating the expressions for f and df/dH from equations (12) to (15) gives a 2 = 41.3015 and a 4 = 1/1.6606. Thus for a k s /H ratio greater than 1.66, the Power Law is used to solve for f , where To prevent unrealistically large predictions of f , the upper limit is set at a ratio of k s /H = 10, which corresponds to an f -value of 1.937. This restricts f from approaching infinity as H approaches zero for shallow flows. The maximum measured resistance in Nikuradse's (1933) experiments is approximately 0.125 in the laminar region, and the entire turbulent region falls well below an f -value of 0.1. Essentially this large f -value would occur in regions with extremely shallow water relative to the roughness elements that are expected to have a virtually negligible contribution to the overall cross-section conveyance. Thus the exact value of f is of little significance. For k s /H < 1.66, equation (7) is employed, and the smooth law component is only introduced for experimental channels. Figure 3 illustrates how, for a given n l value (n l = 0.05), these friction laws are selected depending on the k s /H ratio. For this case, the Colebrook-White equation increases rapidly below a stage of 0.5 m, 0 0 1 2 3 1 2 S t a g e (m) C-W Power Law Law 1.8 1.6 1.4 1.2 0.8 0.6 0.4 0.5 1.5 2.5 0.2 Resistance f Colebrook-White Power Law Limit at k s /H = 10 Combination of above k s /H = 1.66

Figure 3. Graphical representation of the combined Friction Laws.

i.e. the region where the k s /H ratio approaches 12.27.

The Power Law replaces the Colebrook-White Law in

this region and is restricted at k s /H = 10.

For smooth turbulent flow e.g. experimental flow

conditions, a lower limit on k s is set i.e. k s = 0.1 mm.

This corresponds to an n l value of 0.0109.The distribu

tion for f is determined from the full Colebrook-White

equation (3). Since the rough term will have a vir

tually insignificant contribution, the distribution of

f will be based on the viscous effects and can be

solved iteratively. The Blasius Law would be a suitable alternative.

The complete approach for estimating the lateral distribution of f for a given depth of flow, from the local n l values provided by the RA, is illustrated in Figure 4.

6 CONCLUSIONS

An extensive literature review of roughness methods and data has provided a source of interdisciplinary knowledge and advice on river roughness. This rough ness information is presented within the Roughness Advisor (RA), a core component of the Conveyance Estimation System. The RA provides unit roughness values for the three component roughnesses: surface material, vegetation and irregularities. This roughness is based on skin friction only, and does not incorpo rate form losses or shape effects, the latter of which is considered in the conveyance calculation. The unit roughness values are combined to form the total unit roughness at a point within the channel section, and hence converted to an equivalent k s value that is constant with depth. The resistance f for a given depth of flow is determined from this k s value. Consideration has been given to the extrapolation of the existing friction laws for flow conditions that they were not specifically derived for. 7 RECOMMENDATIONS The RA may be extended to provide more advice on representation of urban floodplains, changes in roughness with velocity and/or relative depth [e.g. grass bending at high flows] and form losses between consecutive cross-sections. The roughness calculation

within the Conveyance Generator may be updated to include a function that accounts for the additional resistance due to bedforms. ACKNOWLEDGEMENTS This paper draws upon the Targeted Programme of research commissioned by the Environment Agency as project W5A-057 under the joint DEFRA/Agency Flood and Coastal Defence R&D Programme. We wish to thank Dr Mervyn Bramley, the Agency Project Manager for his encouragement and support. Martín-Moreta, P.

Civil Engineer, IAHR member, San Gerardo, Madrid, Spain

ABSTRACT: The paper is intended to discuss how well or badly the common 1-D numerical models of open

channel flow are behaving in terms of flow distribution across any section in a compound channel. Comparison

is made with new experiments in a physical model of a reach of the Besõs river Restoration Project close to

Barcelona.The case in focus involves thick vegetated floodplains (wetlands in prototype), a low-flow meandering

channel and high water depths over the main channel and floodplains. 1-D models fail to predict the velocities

in the main channel (which are exaggerated) and floodplains (which are underestimated). The paper describes

an improvement of the 1-D computation based on the consideration of the shear stress at the main channel

floodplain interface on the one hand, and the influence of upstream velocity distribution with the help of 2-D

numerical models on the other hand.

1 INTRODUCTION

Water-profile computation in open channel flow is

customarily done by means of 1-D numerical models

based on the energy equation. In the case of compound

channels (those made of a main channel and a pair of floodplains) a great effort has been made in the last decades to take into account the complex mechanisms in the main channel-floodplain interfaces. Bousmar & Zech (1999) presented a summary of the single chan nel method, the divided channel method corrected empirically by Ackers (1992), and the lateral dis tribution method. They also proposed an exchange discharge model aimed at improving the 1-D practi cal computation, consisting of a term standing for the turbulent momentum flux through the interfaces plus a term for the change of geometry in floodplains, either increasing or decreasing in width.

Similarly, the research in this paper aims to dis cuss some very simple refinements in the 1-D models that can cope with such complexities in a straightfor ward way. The research focuses on the prediction of the flow distribution across the channel. While the free surface profile seems to be more easily simulated by 1-D numerical models, the same does not hold for the velocities unless the appropriate term at the interface is used. The correction preferred here is the use of lateral momentum transfer as well as a force on the interfaces, as was done before by Wormleaton & Merrett (1990). Moreover, attention is paid to the results given by widely used 2-D models which give some hints on how to improve 1-D numerical modelling.The numerical models are compared with new experiments, which involve two rough vegetated

floodplains. 2 EXPERIMENTS Several physical models were built in the context of a restoration program for the River Besòs in the urban area of Barcelona (Martín-Vide, 2001).The model of a river consisting of a low-flow meandering channel and two floodplains was used in the experiments. Figure 1a is a photograph of the model. The bed in the main channel and floodplains was filled with gravel 20 mm in size. Flexible plastic strips were selected so as to simulate the roughness characteristics of Phragmites australis (a spontaneous weed in the area, which was the main specimen in the restoration plan). These plastic plants completely covered both floodplains with a density of 1 plant every 10× 10 cm. The flow rate was measured by a V-notch weir. Two tests were run with each discharge: one without plants

Figure 1a. River Besòs model. See the meandering low flow

channel and the plastic strips on the floodplains. In the tests,

the simulated vegetation completely covered the floodplains.

Figure 1b. Test on the roughness of plastic plants in the

straight flume.

(i.e. with gravel everywhere) and the other with plants.

Only the latter are dealt with here. Discharges amount

ing 96.3 and 171.3 l/s were chosen, so that the plants

were always completely submerged. Figure 2 shows

in plan view the central part of the domain, which

is the part to be used in the 1-D and 2-D numerical

modelling. It includes one complete low-flow chan

nel wavelength. Measurements in the physical model

were made on 11 cross sections, a sub-set of the sec

tions drawn in Figure 2. Water surface profiles were

measured with point gauges at three points across each

section, one over the centre of the main channel and the

other two close to the walls. Extensive velocity mea

surements were performed with a 2D electromagnetic Figure 2. Plan view in the experimental set-up (sections named like prototype distances). left fl. mean v. main ch. mean v. right fl. mean v. 0 0.1 0.2 0.3 0.4 0.5 0.6 0.7 0.8 0 10 v e l o c i t y (m / s) distance (m) 2 4 6 8 Figure 3. Mean velocities measured in the prototype, on the left floodplain, main channel and right floodplain, for the discharge of 171.3 l/s. probe. The probe was placed at any vertical in such a way that the measurement point was always at a distance from the bed equal to the 40% of the local water depth (an approximation for the mean velocity). Three measurement verticals were located in the main channel, one at its centre and the other two 15 cm to the centre's right and left; two more verticals were located in both floodplains 5 cm from the main channel verges. Finally, verticals 5, 20, 35 and 65 cm from each wall were used if they fitted. The main flow velocity components (v x) are the only ones dealt with here. As an example, Figure 3 shows the main channel and floodplain velocities along the model. As the main channel wanders from side to side, so the floodplain velocities increase or decrease. Tests on the roughness characteristics of the gravel and plants were run on a 0.97 m wide, 10 m long flume in uniform flow on the same slope and with the same unit discharges as in the main experiments (Fig. 1b). The Manning coefficient of the gravel was n = 0.025. The one for the plastic plants implanted on the same gravel was dependant on the flow rate, as expected, varying from n = 0.062 (minimum flow rate) to n = 0.049 (maximum flow rate in the experiments). 3 1-D MODELLING PERFORMANCE 1D models based on the energy equation or Bernoulli equation will be compared here with the experimental W.S. results in terms of water surface profile and velocity

distributions. The well-known Hec-Ras model is used,

as well as a second 1D model that “duplicated” Hec

Ras but allowed some refinements to be introduced.

One refinement is the use of the momentum equation

for the whole calculation. In a step by step procedure,

the equation to be solved states that:

where the subscripts 1 and 2 stand for the downstream

and upstream sections respectively, m and tot stand

for mean and total, β is the Boussinesq coefficient,

A is flow area, v is flow velocity, g is gravitational

acceleration, d is the distance between two consecutive

sections, z is the depth of centroid, I is friction slope

and s is the angle of the bed slope. Only one friction

slope (I) is used for the whole section. As usual in 1-D

models, the conveyance in each zone (main channel

and floodplains) is given by:

where k stands for the zone, n is the Manning coeffi

cient and Rh is the hydraulic radius.

The friction slope is given by:

Figure 4 shows how well both Hec-Ras and the sec

ond model (using momentum equation) compare with 0 0.05 0.1 0.15 0.2 0.25 0.3 0.35 0.4 0 0.1 0.2 0.3 0.4 β-1 (experimental) β 1 (c o m p u t e d) Q = 171.3 l/s Q = 96.3 l/s Figure 5. Experimental and computed velocities (momentum equation) in floodplains and main channel for the discharge of 171.3 l/s. the experimental water surface profiles for the two discharges. However, the computed flow distribution in a case like this, with thick vegetated floodplains, departs considerably from the experimental one. The computed velocities on the main channel are considerably higher than the experimental ones but they are considerably lower on the floodplains.This is shown by the comparison between experimental and numerical β coefficients in Figure 5 (in terms of β- 1). The velocities are much more uniformly distributed in reality than in 1-D modelling, since their experimentalβ coefficients are much lower.The same is shown in Figure 6, in which computed and experimental velocities are

compared for 171.3 l/s. The fact that arises from this

comparison is that 1-D models based on either energy

or momentum equation fail to simulate flow distri

bution even though they simulate water levels well. It

should be kept in mind that the case in the experiments

is characterized by very different roughnesses in main

channel and floodplains and by high water depths.

4 WHAT CAN BE LEARNED FROM

2-D MODELLING

The FESWMS 2-D model has been applied to the com

putational domain in Figure 2. The model solves the

depth-averaged Navier-Stokes equations. Two bound

ary conditions apply: a known water depth down

stream and a known velocity distribution upstream (both known from the experiments). The computational mesh is made of rectangular elements with one node at its centre, one node at each corner and one node at the centre of each side (so that there is a total of 9 nodes in each element).

The way the total energy losses are shared by bed friction (through a roughness coefficient) and the turbulence (through a dissipation coefficient) was analysed against the experiments. The experimental results are best simulated if the roughness coefficient measured in the laboratory (Fig. 1b) is reduced to 60% of its initial value in the main channel (gravel) and to 80% of its initial value in the floodplains (vegetation). These percentages are close to the ones obtained by Vionnet et al. (in press) in a previous work with the same data but with the Telemac-2D model and the Lateral Distribution Model.

Figure 7 shows an example of the comparison between experiments and 2-D computation with FESWMS regarding water surface elevation and flow energy at one particular section. The section is located at an inflection point (section 6+500 in Fig. 2). The agreement is not bad, but more importantly, notice that the maximum flow velocities (i.e. the maximum $v^2/2g$

terms, which go from the surface line to the energy line) are not occurring inside the main channel, but on its right bank. The same feature is observed in the velocity plot in plan view (Fig. 8). The line of maximum velocity does not follow the main channel axis but goes straighter. This is due to the obstruction caused by the vegetation upstream. Upstream of the inflection point there is a mass of plants obstructing the flow through the left floodplain, whereas the flow through the right floodplain is eased by the presence of the main channel itself.

5 IMPROVEMENT IN 1-D MODELS

One alternative to the usual 1-D modelling in order to improve the prediction of mean velocities is discussed W.S. (computed) W.S. (experimental) Energy (computed) Bottom Energy (experimental) Section 6+500 0.6 0.7 0.8 0.9 -1.2-0.9-0.6-0.300.30.60.91.2 e l e v a t i o n (m) distance (m) Figure 7. Experimental and computed water surface (W.S.) and energy elevations in one cross section (named as in prototype), for a discharge of 171.3 l/s. Figure 8. Plan view of velocity results between sections 6+600 and 7+000 (named like in prototype), for the discharge of 171.3 l/s. (the darker the faster). in this paragraph. The shear stress at the main channelfloodplain interface by using the Boussinesq hypothesis is τ xy ~ (∂v x /∂y + ∂v y /∂x). This shows the need to take into account in 1-D modelling a term standing for the turbulent friction (the first partial derivative in τ xy) plus a term standing for the lateral momentum transfer (the second partial derivative in τ xy). Since the floodway walls are parallel, it is assumed that the v y components are negligible everywhere. However, since the main channel wanders across the left and right floodplains, there is a large lateral momentum transfer due to the change in floodplain size. This term plus one standing for the turbulent friction are included in the model, closely following the lines of Bousmar & Zech (1999). The

obstruction due to the mass of vegetation upstream of a section, which is the main lesson learned from 2-D modelling, is also taken into account, as will be shown. The first step in this improved 1-D model is the assumption that the water profile is already known with enough accuracy through the solution of Eq. (1) (with one boundary condition downstream in subcritical flow) and that it will not change significantly despite the adjustments in flow distribution across vl1, Al1 vc1, Ac1 vr1, Ar1 vl1, Al1

vlT1, AlT sen(l) 1 2 l vl2, Al2 r l vc2, Ac2 vl2, Al2 vr2, Ar2 h l l c r h r

development of Eqs (4)-(6).

the section. Therefore, every geometrical parameter

is known; at any section j the flow areas A lj , A cj , A rj

and the conveyances K lj , K cj , K rj for the three zones

(main channel and floodplains) are known. Thus, the

mean friction slope I j and the mean velocity v mj are

known. Equation (1) can be applied to each zone as

follows (see Fig. 9a):

The new terms with respect to Eq. (1) are the momen

tum transfer through the meandering interface (Fig. 9a)

and the turbulent friction force per unit weight F (F1

for the left floodplain, F3 for the right floodplain and

F2 for the main channel). v lT , y, v rT are the veloci

ties going in or out between the main channel and the

floodplains. These velocities are assumed to have only

v x components. They are determined by the continuity

equation (see Fig. 9a).A lT , y,A rT are the interface flow

areas, computed by averaging water depths between two

consecutive cross sections, a distance d apart (Fig. 9b): The sign of the angles α l and α τ of the interface (left and right) with respect to the floodway walls is positive if flow goes out of one zone and negative if flow goes into one zone. For example, in Figure 9a, α l is positive and α τ is negative. This sign convention is consistent with Eqs (4), (5) and (6), where sin(α) keeps the sign of α and conveys its sign to the lateral momentum transfer term. Note that the sum of Eqs (4), (5) and (6) is just Eq. (1) because: (definition of coefficient β) (idem) (definition of centroid) (idem) • The lateral momentum transfer terms are cancelled. • F2=-F1-F3 (Newton's third law) (Fig. 10). Prior to the numerical solution of Eqs (4)-(6), they have been used to test the magnitude of the new terms. This is done by substituting any variable in Eq. (5) by its experimental value (depths, areas, velocities …). Fig. 11 is a graph of the magnitude of the lateral momentum transfer term on the one hand, and the magnitude of it plus the turbulent friction force per Section 2 Section 1 Channel F3 - F3 Left - F1 F1 h r h l A I1 , v I1 A I2 , v I2 A r2 , v r2 A c2 , v c2 A r1 , v r1 A c1 , v c1 d Right

unit weight F on the other. Both magnitudes are plot

ted along the channel coordinate. The main point in

Figure 11 is that the friction force is much less (almost

negligible) than the lateral momentum transfer.

Coming back to the numerical computation,

Eqs (4)-(6) are applied from upstream to downstream.

An upstream boundary condition is given in terms of

measured flow velocities.The calculation between two

consecutive cross sections gives the flow velocities in

the 3 zones at the downstream section. The unknowns

are v l1 , v c1 , v r1 , v lT and v rT . As shown above,
Eqs (1),

(4), (5) and (6) are not independent: only 3 of them are

actually independent since (1) = (4)+(5)+(6). More

over, Eq. (1) has already been used to get the water

profile, so only 2 equations are left. The 3 equations

still needed to solve the 5 unknowns are:

• Continuity at the section:

where Q is known,

• Continuity at each control volume between two con

secutive cross sections and the interface, with the
assumptions stated above (Fig. 7a): Furthermore, the forces
F1 and F3 are assumed to be proportional to the velocity
difference between main channel and floodplain, by
averaging between two consecutive cross sections, as well:
where C is a coefficient. Calibration of C with the
experimental tests, by getting the best agreement in
velocity distribution, has given C= 0.0012 for 171.3 l/s
and C= 0.0030 for 96.3 l/s. By substituting v lT , v rT ,
F1 and F3 in Eqs (4) and (5), which are quadratic
equations, two solutions for v l1 and v r1 are obtained.
The criterion for selection of one of them is based on the

upstream. The derivative of the floodplain conveyance

along the coordinate ∂K/∂x is taken as a surrogate

of the degree of obstruction (because the floodplains

are fully covered with vegetation). If a length of one

quarter of the meandering low flow channel wave

length upstream is used to compute this derivative,

the agreement between computation and experiments

is the best. Then, if ∂K/∂x > 0 the solution selected is

the maximum of the two possible ones; otherwise the

minimum is selected. This criterion is related to the

relative importance of the momentum output through

cross-section 1 and the momentum transfer through the

interface (see Fig. 9a). There are also some computa

tions in which no real solution of quadratic Eqs (4)–(5)

exists. This is thought to be related to having neglected

a v y component, especially in the velocities v lT and v rT . It should be pointed out, finally, that this method is successful because it involves what happens (in terms of obstruction to the flow) in the next 1/4 of the wavelength upstream in the computation of the flow distribution at a section. Figures 12 and 13 summarize the results of this improved 1-D model. They must be compared with Figures 5 and 6 respectively, which are their counterparts, by using the common 1-D model (like Hec-Ras). Figures 12 and 5 in terms of (β − 1) show a great improvement for both flow rates. The same can be said of Figures 13 and 6 in terms of velocities themselves. While the experimental β coefficients are not higher than about 1.16, the computed β coefficients with the use of common 1-D model in case of vegetated floodplains are extremely high, which is corrected in the improved 1-D model. Notice also how the main channel velocity was exaggerated with common 1-D model but comes to be close to the experimental velocities with this improved 1-D model. 6 CONCLUSIONS This paper tries to draw attention to the fact that 1-D conventional numerical modelling of free-surface flow (like the model Hec-Ras) fails to reproduce the flow distribution across the section in compound channels, i.e. it fails to predict the main or low-flow channel velocity and the floodplain velocities (left and right). This is proven at least in the case of thick vegetated floodplains, high water depths and meandering lowflow channels, as in the experiments. Secondly, it shows two main reasons for this failure, which are also the ways for improvement: 1. The lack of any shear stress at the interface between main channel and the floodplain (a very well-known fact), in which one must distinguish two different sources of shear stress: lateral momentum transfer and turbulent friction, 2. The lack of any influence of the flow distribution upstream.This has

been proven to be important with the help of a 2-D numerical model. The paper shows a simple improvement of the 1-D equations, which include two new terms to take into account the first drawback and a procedure to take into account the second one. Coherent flow structures in a converging compound channel

D. Bousmar

Fond National de la Recherche Scientifique and Civil and Environmental Engineering,

Université catholique de Louvain, Belgium

B. Denis & Y. Zech

Civil and Environmental Engineering, Université catholique de Louvain, Belgium

ABSTRACT: This paper investigates the possible coexistence of the two kinds of momentum transfer observed

in compound channels, that cause significant conveyance decrease, namely: (1) the turbulent interaction that

develops in the shear layer between main channel and floodplains in a prismatic channel; and (2) the geometrical

transfer due to cross-sectional changes in a non-prismatic channel. Experiments are performed in a symmetrically

narrowing compound channel and focus on the behaviour of the shear layer along the transition between the

prismatic and the non-prismatic reaches. A digital imaging technique enables to clearly identify horizontal

turbulent structures in the upstream prismatic reach and to follow those structures when entering the converging

reach. It is observed that the horizontal vortices are stretched as they are translated in the main channel and then

quickly split into smaller scale structures that do not affect any more the conveyance.

1 INTRODUCTION

The flow in a compound channel is characterised

by significant momentum transfers between the main

channel and the floodplain. In a prismatic compound channel, a shear layer develops at the interface between both subsections due to flow velocity difference. Large-scale horizontal vortices grow in this shear layer and govern the observed momentum transfer. In a non-prismatic compound channel, a mass transfer and a corresponding momentum transfer between subsections are due to geometrical non-uniformity. These effects result in an overall channel conveyance decrease that has to be modelled when simulating flood propagation or mapping flooded areas.

Several one-dimensional methods were proposed to face these compound-channel modelling requirements. Most of them are dedicated either to prismatic (e.g. Shiono & Knight 1991, Ackers 1992) or to non prismatic geometries (e.g. Greenhill & Sellin 1993, Ervine et al. 2000) and address only one specific momentum transfer source. Only few methods, like the Exchange Discharge Model – EDM (Bousmar & Zech 1999, Bousmar 2002) attempt to encompass both situations.

Experimental data is also lacking on the transition between prismatic and non-prismatic reaches, in order to investigate the possible coexistence of both momentum transfer processes. Available data sets are usually focused either on prismatic compound channels (e.g. Knight

1992) or on non-prismatic ones (e.g. Sellin et al. 1993, Bousmar et al. 2004). This paper therefore investigates experimentally the behaviour of the shear layer along the transition between a prismatic and a non-prismatic reach. Additional measurements are performed in the symmetrically narrowing compound channel used by Bousmar et al. (2004). The possible stretching, splitting or vanishing of the horizontal vortices in the narrowing reach is explored using digital imaging, to determine whether some turbulent momentum transfer remains in the non-prismatic reach, in addition to the geometrical transfer. 2 EXPERIMENTAL SETUP Experiments are performed in a 10 m long and 1.20 m wide compound-channel flume at the Université catholique de Louvain, Belgium. The upstream part of the flume is shaped with a symmetrical cross-section made of coated plywood that presents one mainchannel 400 mm wide and 50 mm deep, flanked by two floodplains 400 mm wide. The floodplains width then reduces symmetrically, resulting in a single mainchannel cross section at the downstream end of the flume (Fig. 1). For the Cv6 series, the new measurements are performed with only a part of the converging Upstream prismatic reach (a) (b) X y 400 mm 6 m 6 m 2 m 2 m 4 m Converging reach 400 mm 400 mm

reach modelled, to keep a prismatic reach long enough

to enable the full development of the shear layer. Each subsection is supplied independently, enabling adjustment of upstream discharge distribution, and tailwater is controlled with an adjustable weir. Total discharge is measured by an electromagnetic flow meter, and water levels and velocities are recorded by an automatic point gauge and a Pitot tube, respectively (Bousmar et al. 2004). Table 1 summarises the geome tries and flow conditions investigated in the present paper.

In addition to classical flow-depth and velocity distribution measurements, the flow structures are investigated by surface velocimetry using a Particle Tracking Velocimetry (PTV) system (Capart et al. 2002). The flow free-surface is seeded with expanded polystyrene pearls of 4–6 mm diameter.The successive positions of these floating tracers are recorded using a digital camera, at a frame rate of 10 Hz during 60 s, and with an image size equal to 1024× 380 pixels, cover ing a 2.40 m length of the flume. Area of interest along the flume length are covered with two or three suc cessive stations of the camera. Post-processing of the recorded images enabled the identification of the trac ers, the reconstruction of their trajectories, the filtering of these trajectories, and the estimation of the tracer

velocities. More than 20,000 distinct tracers are usu

ally detected in each image sequence. In addition to the

velocities calculated at the tracer positions, instanta

neous velocity fields are also interpolated on a regular

grid for further analysis purpose. Station x (m) 0 10 0 108642 20 50 (a) F l o o d p l a n d i s c h a r g e (I n % o f t o t a l d i s c h a r g e) S u r f a c e l e v e l z (m m) (b) 70 60 80 30 Figure 2. Cv2/02/10 case: (a) free-surface profile; and (b) ratio between floodplain and total discharge. Figure 3. Schematic view of the flow structure in a compound channel with narrowing floodplains. 3 GENERAL FLOW DESCRIPTION A description of the main flow features was previously obtained using classical measurements (Bousmar 2002, Bousmar et al. 2004). Only some conclusions are presented here. A typical free-surface profile is given in Figure 2a for the run Cv2/02/10. Due to the channel constriction, the flow is accelerated and the flow depth decreases accordingly. As the floodplain width reduces, the floodplain discharge is also forced in the main channel (Fig. 2b), resulting in a significant mass transfer. The observations on the flow structure are synthesised in Figure 3: (1) a transverse current is generated from floodplains to main channel due to the channel constriction; (2) these currents enter the main channel, then plunge towards the channel bottom, due to symmetry; and (3) helical flow results in the inbank part of the main channel, with two counter-rotating cells.

These secondary currents can be found somewhat sim

ilar to those of meandering channels as described e.g.

by Sellin et al. (1993): both are located in the inbank

area and are generated by floodplain flow crossing or

entering the main-channel. However, the present flow

structure is less complex: it is symmetrical and no flow

is ejected from the main channel to the floodplains.

The total head loss were estimated for several cases

and compared with the friction losses, estimated from

experiments in a prismatic channel with the same cross section. A significant additional loss was highlighted in the non-prismatic geometries due to the momentum transfer associated with the observed mass transfer. The momentum transfer and additional loss increase with converging angle, flow depth, and total discharge.

4 COHERENT STRUCTURES IN THE UPSTREAM PRISMATIC REACH

4.1 Time-averaged analysis

The coherent turbulent structures that develop in the shear layer at the interface between main channel and floodplain are first characterised in the upstream prismatic reach, before investigating their behaviour in the converging reach. Similar analysis previously performed in an asymmetric compound channel indi cated that a minimum flume length of 5 m is neces sary to obtain a full development of the shear layer (Bousmar & Zech 2003). The upstream part of the converging reach was therefore located at x= 6 m, resulting in a partial setting for the Cv6 geome tries (Fig. 1) compared to the initial experiments by Bousmar et al. (2004).

In a first stage, the time-averaged surface veloc ity distribution is computed from the instantaneous surface velocity field in the upstream prismatic reach (3.6< x< 6.0 m) for case Cv2/02/10 (Fig. 4). The dis

tribution of the longitudinal velocity component U

confirms previous measurements: higher velocities

are found in the main channel and a smooth transition

is observed through the interface with the floodplain

due to the shear-layer development. The transverse

velocity V distribution presents two particular fea

tures: (1) there is a surface flow towards the main chan

nel axis in the area −0.35< y< 0.35 m and towards

the outer banks in the outer areas; and (2) the standard

deviation of V reaches a peak values near the interfaces

(at y ≈ −0.25 and 0.25 m).

The transverse surface flow towards the channel

axis can be first supposed to correspond to geome

trical transfers already taking place upstream of the

converging reach. The pattern of surface streamlines,

plotted from the time-averaged velocity field, indi

cates however that another phenomena occur (Fig. 5):

the floodplain streamlines do not converge towards

main channel as would be observed in the case of a Position y (m) 0.60.40.20.0-0.2-0.4-0.6 -0.10 V (m / s) U (m / s) 0.05 0.10 0.00 0.10 0.20 0.30 0.40 0.50 0.00 -0.05 Figure 4. Surface streamlines, computed from timeaveraged velocity field, Cv2/02/10 case, upstream prismatic reach. converging reach, but tend to diverge from the interface area.This surface divergence is due the secondary helical currents observed in the main-channel. These currents indeed exist in the

converging reach as quoted above, but also in a prismatic reach as highlighted by Tominaga & Nezu (1991). They generate upward flows in the interface area and downward flows near the channel axis.

Figure 6. Instantaneous tracers distribution and transverse velocity field, Cv2/02/10 case, image 110, upstream prismatic reach.

Additionally, Nezu & Nakayama (1997) showed that these upward flows are intermittent and closely related to the development of the large horizontal vortices observed in the shear layer. This effect is not visible on the time-averaged plot in Figure 5, but can easily be identified when plotting instantaneous tracers distribution together with the transverse velocity field (Fig. 6). The transverse velocity presents alternate positive and negative values, indicating the existence of large horizontal structures. The tracer density is uneven: higher concentrations are found in areas were surface water flows towards main channel, corresponding to vortex edges; while lower concentrations correspond to vortex centres and intermittent upwards-flow areas.

4.2 Periodical structures analysis

The observed peaks of the standard-deviation of V in the interface area (Fig. 4) can now be explained by the presence of the horizontal vortices that developed in the shear layer. The periodicity of these turbulent

structures is highlighted by the analysis of a time series of V values at a given interface point, or more accurately by the analysis of the time series along the whole interface, as plotted on Figure 7, following Bousmar & Zech (2002, 2003).The periodical alterna tion of positive and negative velocities is again clearly depicted.The variation frequencies are extracted using a Fourier analysis of these series (Fig. 8). A clear peak is obtained at the period T = 2.75 s for x< 5 m, and at T = 3.75 s for x> 5 m, indicating that the structures are possibly still growing in this area.

The transverse velocities vary with time at a given station, but also with space at a given time (Fig. 6). This indicates the presence of a row of vortices in the shear layer. The displacement of these structures is depicted by the pattern of diagonals shown by positive and negative velocities on Figure 7.The vortex celerity

Figure 7. Transverse velocity V , Cv2/02/10 case, upstream prismatic reach: variation with time along interface (y= 0.25 m). Figure 8. Transverse velocity V , Cv2/02/10 case, upstream prismatic reach: spectral analysis (y= 0.25 m). Dark areas correspond to high energy density. c is estimated from the slope of such a diagonal: This celerity is lower than the longitudinal velocity U at the interface y= 0.20 m (Fig. 4), indicating that (1) the vortices move at the floodplain velocity; and (2) their centres are located on the floodplain and not on the interface. From vortex celerity c and vortex period T , the vortex wave length obtains The Lagrangian single particle trajectories are then plotted in a frame moving at celerity c, clearly depicting the vortex structures (Fig. 9). As inferred from

0.6 0 -0.6 -4 -3 -2 -1 -0 1 2 3 4 x - ct (m) y (m)

Figure 9. Particle trajectories in a frame moving at vortex celerity (c= 0.194 m/s), Cv2/02/10 case, upstream prismatic reach.

ticles in the actual instantaneous velocity field, Cv2/02/10

case, upstream prismatic reach. Separate plots correspond to

t= 1 s intervals.

celerity values, the vortex centres are located on the

floodplains. The vortex wave length $\lambda \approx 0.72$ m is

also assessed from the trajectories plot. It can be

noted that some merging structures are still observed,

e.g. at $(x - ct) \approx 1.5$ m. No clear synchronisation is

found between the periodical structures in the two

shear layers. This indicates that they present indepen

dent instability behaviour, due to the lateral distance

between both interfaces (Bousmar & Zech 2001).

Lastly, the behaviour of a single vortex can be inves

tigated by computing the displacement of selected

virtual tracers in the instantaneous velocity field. Such

tracers are seeded on an idealised circular streamline

located around a vortex centre (Fig. 10). The tracers

are found to rotate around the circle centre. Secondary

structures then grow and deform the initial circular

streamline, due to smaller scale turbulence. The area

enclosed by the streamline also increases when mov

ing downstream: upwards flow in the vortex-centre

zone leads to streamline divergence at the free surface,

where the tracers are observed.

5 COHERENT STRUCTURES IN THE CONVERGING REACH

5.1 Cv2/02/10 case analysis

Similar analysis are performed in the non-prismatic

part of the flume for case Cv2/02/10. Surface 0.6 0.4 0.2 0.0 -0.2 -0.4 -0.6 6.0 6.5 7.0 7.5 8.0 Station x (m) P o s i t i o n y (m) Figure 11. Surface streamlines, computed from timeaveraged velocity field, Cv2/02/10 case, converging reach. streamlines and time-averaged velocity distributions at selected stations are given on Figures 11-12. Transverse velocities V are found to increase along channel length, due to the mass transfer occurring in the convergence. A maximum value is observed near x= 7 m, where an inflexion point was found in the free-surface profile (Fig. 2). The longitudinal surface velocity U has also a local maximum near this station x= 7 m, while the depthaveraged value was continuously increasing along the converging reach (Bousmar et al. 2004). The decrease of the surface velocity is probably due to the transverse currents generated by the convergence that mainly affect the upper layer of the main channel (Fig. 3). This confirms the

significance of the momentum transfer effects due to geometrical changes of the channel. The analysis of the transverse velocity V variation with space and time is now performed along a streamline originating near the interface, and no more along the interface itself, in an attempt to follow the vortices displacement with the averaged flow. Transverse velocities and spectral analysis are plotted on Figures 13-14. Variations of the transverse velocities V are still observed but flow from main channel towards floodplain almost disappears after x= 7 m. Also the

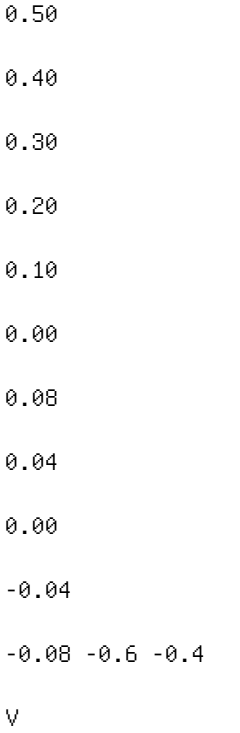

Figure 12. Time-averaged surface velocity distribution,

Cv2/02/10 case, converging reach. Positive transverse veloc

ity V flows towards increasing y.

Figure 13. Transverse velocity V , Cv2/02/10 case, converg

ing reach: variation with time along a streamline (originating

at y= 0.25 m).

celerity of the coherent structures tends to increase

from c= 0.205 m/s at x= 6.00 m to c= 0.421 m/s at

x= 8.00 m, due to the flow acceleration.

A clear frequency peak is again found in the

upstream part of the convergence (x< 7 m) at

T = 3.75 s (Fig. 14), corresponding to a wave length

λ= 0.77 m. In the downstream part, no defined period

can be identified.The spectral density seems located in

lower period values than upstream, indicating the split

ting of the horizontal vortices in smaller structures.
Figure 14. Transverse velocity V , Cv2/02/10 case, converging reach: spectral analysis (y= 0.25 m). Dark areas correspond to higher energy density. The tracers trajectories are again plotted in a moving frame. Now the transverse positions y are distorted by stretching the streamlines shown on Figure 11 to a regular grid, again in an attempt to follow the vortices displacement. Figure 15 shows that some horizontal structures can still be found in the first part of the convergence (6.00< x< 7.00 m), but then no more coherent structures appear. This confirms that the horizontal vortices have split into smaller scale, probably tri-dimensional, structures. This vanishing of large horizontal vortices is further evidenced by computing the displacement of virtual tracers in the instantaneous velocity fields (Fig. 16). The initial structure is stretched when entering the main channel, due to the velocity gradient. After x= 7 m, the whole structure is located in the main channel. Its width to length ratio is such that it can no more subsist as a single vortex. It will breaks into smaller vortices whose wave lengths are in the range of the flow depth, resulting thus in 3D structures. 5.2 Other cases analysis The analysis of case

Cv2/03/10 almost leads to similar results. Vortices are weaker in the upstream prismatic reach, due to a lower velocity gradient between subsections. They tend therefore to disappear faster when entering the convergence. As a conclusion for the two cases investigated in the Cv2 series, it seems that the horizontal coherent structures vanish rapidly in the non-prismatic reach. The structures still observed in the upstream part of the convergence in Cv2/02/10 case are probably vestiges of the structures developed in the prismatic reach and the shear layer plays a weaker role in the non-prismatic reach in terms of momentum transfer. In Cv6/02/10 case, periodical structures are observed along the whole converging reach modelled (6.00< x< 10.00 m).This is probably due to the lower 0.6 0 -0.6 y (m) -2 -1 0 1 2 3 4 5 6 x - ct (m)

converging angle, that generates less mass transfer. Nevertheless, as the end of the convergence is not reproduced in the experimental setup, the floodplains do not completely vanish downstream, resulting also in a different flow behaviour. No definitive conclusion could therefore be obtained for this case.

6 CONCLUSIONS

The coherent turbulent structures have been investi gated in a symmetrically narrowing compound chan nel, using digital imaging techniques, in addition of previous measurement campaigns.

In the upstream prismatic reach, large-scale hor izontal vortices were observed in the shear layer that develops at the interface between subsections. Interactions have been evidenced between the helical secondary currents existing in the main channel and those horizontal vortices, in the form of intermittent upwards flows in the interface area, that led to a diver gence of surface streamlines. The shear layer and the associated vortices were the main source of momen tum transfer between main channel and floodplains in this reach.

Variations and correlation of roughness indices of non-vertical

non-rigid fully submerged vegetation in open channels

A.M. Negm

Professor of Hydraulics, Civil Engg. Dept., College of Engg., Garyouns University, Benghazi, Libya

ABSTRACT: This study presents the results of an

experimental investigation on the effect of fully submerged non-vertical non-rigid cylindrical vegetation on the roughness indices in open channels.The considered roughness indices are the friction factor f, the Chezy's roughness coefficient C, and the Manning's roughness coefficient n. Six model were tested using three different channel bottom slopes. The vegetation elements were distributed in staggered way in four of them and in parallel way in the other two. It was found that the trend of variation of the roughness indices with the Froude number are similar regardless of the distribution pattern. The values of the roughness indices were found to be a function of Froude number F n , the channel bottom slope S, and the roughness density I. Statistical prediction models were developed to estimate the roughness indices in terms F n , S and I using the multiple linear regression analysis. Good agreement were obtained between predictions of the developed models and the measured values.

1 INTRODUCTION

Management of rivers and canals flows necessitates sufficient information on the type of vegetation, its density, degree of submergence and degree of resis tance to the flow. Such information may be obtained through different kinds of studies either by various methods of simulation and modeling techniques like those done by Shimizu et al. (1992a, b), Shimizu & Tsujimoto (1994), Kutija & Hong (1996), Nezu & Onitsuka (1999), Choi & Kang (2000) and Fischer Antze et al. (2001), or through field measurements

carried out by Bakry et al. (1992) and Dolgopolova (1998), or achieved by experimental tests of rough ness elements simulating the vegetation either in rigid state, such as those accomplished by Shimizu et al. (1991) and Tsujimoto et al. (1992), or for flexible case, such as that done by Kouwen and Unny (1973), Christensen (1985), EL-Hakim & Salama (1992) and El-Samman & Attia (1999) or for non-flexible no-rigid state which was covered by Fahti-Maghadam and Kouwen (1997) and Wu et al. (1999).

The resistance of vegetation to the flow may be measured by one of the roughness indices as the fric tion factor (f), the Chezy's roughness coefficient (C), Manning's roughness coefficient (n) or the so-called retardance coefficient (N).

Recently, Negm (2003) investigated the effect of partially submerged vegetation on the variation of the roughness indices in rectangular open channel. The vegetation elements were non-vertical rigid cylinders of diameter 0.735 cm with a height of 5 cm. Three vegetation densities were used (I= 0.6%, 1.2% and 2.1%) and three slopes (S= 0.377%, 0.754% and 1.1307%) with a range of Fr = 0.25 to 0.72. He obtained the following prediction equation for the roughness indices f, C and n. hence, or alternatively, Also, and

The coefficients of determination of the equations 1, 2b, 3 and 4 are 0.997, 0.994, 0.994 and 0.996 respec tively while the standard error of estimate for the same equations are 0.017, 0.02, 0.01 and 0.009 respectively.

This paper presents the results of an experimen
tal study on the effect of using non-rigid cylindrical
roughness simulating vegetation under the effect of
fully submerged flow conditions using various bot
tom slopes and various densities arranged in staggered
manners. The results were presented in terms of
the roughness indices f, C and n. Statistical predic
tion models were developed to predict the values of
roughness indices for this type of vegetation.

2 THEORETICAL BACKGROUND

Using the dimensional analysis, the roughness indices
could be proved to be function of the relative roughness
height K/R (K is the height of roughness and R is the
hydraulic radius), the Froude number, F n , the bottom
slope, S, the roughness intensity, I, and the method of
distribution of vegetation, φ (staggered or parallel) as
follows:

in which F n (F n =V/(gy) 0.5 , V is the average velocity,
y is the average depth of flow, g as the gravitational
acceleration. Normally it is difficult to obtain precise
values of K/R in open channels and hence it will be
dropped from Eq.(5). Thus Eq.(5) becomes:

Also, φ is neglected because one distribution type is
used.

The function φ 2 is an arbitrary function to be deter

mined by using the multiple regression analysis based on the experimental data.

3 EXPERIMENTAL WORK

The experiments of the present study were conducted on a glass sided tilting flume of 9 m long working section. The flume is 30.5 cm wide and 30 cm deep. The water depths were measured by means of point gauges (of ±0.1 mm accuracy) mounted on instrument carriages.The discharge was measured by a pre-calibrated V-notch installed in a measuring tank. The measuring tank is located below the outlet of the flume at its down stream end and is connected directly to underground sump tank. The flume is equipped with a tailgate to control the tailwater depth.A centrifugal pump lifts the water from the underground sump to the flume inlet. The water runs through the flume working section then returns back to the sump tank via the measuring tank. Plastic cylinders tubes of diameter equals 7.35 mm and height of 50 mm was used to simulate the vegetation in the channel bed. The plastic tube is normally flexible when its length and the affecting force are sufficient. However, a length of 50 mm from such tubes is being non-vertical but the flow forces are not capable to move any portion of the fixed cylinders and therefore they are termed non-vertical rigid vegetation. The elements were fixed in the flume bed through holes of equal diameters in a wooden plate 354.735 cm long. The model was fixed at 300.05 cm from the flume entry. Each tested model consisted of many elements arranged either in staggered or parallel to form one of the tested models. A total of six models were tested under submerged flow conditions. Out of the six tested models, the elements in 4 models were arranged in staggered way with intensities of 0.6%, 2.1%, 2.327% and 8.8%. The elements of the other two models were arranged in parallel way with intensities of 1.2% and 4.654%. The roughness

intensity was calculated by multiplying the cross section of one element by the number of element in the model divided by the product of the roughened length and the width of the flume. A typical staggered model with intensity of 0.6% consisted of 148 cylinders with 59 rows having transverse spacing of 6 cm and longitudinal spacing between roughness elements of 10 cm. The tests were conducted under uniform flow conditions when no roughness elements were used but with roughness elements the flow through the test section varies due to the increasing head loss from upstream to downstream side of the model. The bottom slope was varied three times for each tested model as 0.3765%, 0.7538% and 1.1307%. The depths of flow were measured at four locations. The first depth measurement was taken at 5 cm upstream the model. The other three depth measurements were taken at equal spacing from the first one, each one is 100 cm apart from the other one, such that the fourth reading is at 65 cm away from the end of the model. 4 RESULTS AND DISCUSSIONS The friction factor was computed from the measured quantities using the equation f= (8gRS)/V 2 in which V is the average values of the velocity at the three locations over the length covered by vegetation, R is the average hydraulic radius, S is the bottom slope and g is the acceleration due to gravity.The computed values of f were used in Coolebroke resistance equation, to compute the relative roughness height K/R by trials and error procedure. The values of friction factors for nonvegetated channel, f s , was calculated using Blasius equation, f s = 0.223R -0.25 n in which R n is the Reynolds 0.00 0.20 0.40 0.60 0.80 Froude number, Fn 0.0 2.0 4.0 6.0 8.0

number. The friction factor for the vegetated bed was obtained by subtracting f s from f.The Chezy roughness coefficient was computed using C= (8g/f) 0.5 while Manning n was computed using n=R 1/6 /C.

The variations of total friction factor f with F n for different tested vegetation intensities, I, differ ent patterns, and channel bottom slope, S are given in Figure (1). It is observed that the friction factor is very small for non-vegetated channel compared to vegetated one. The trend of variation of f with F n is nonlinear with higher values at lower Froude number and vice versa. Steeper bottom slopes produces higher values of the friction factor which match with the fact that the friction increases with the increase of the energy slope as more energy is dissipated when the resistance to the flow is large. The friction fac tors for larger vegetation density is greater than for those having smaller vegetation density. Larger vegeta tion densities produce higher friction factors at smaller Froude number because the velocity is reduced when the flow suffers from high vegetation or roughness resistance. It should be mentioned that the friction fac tor due to vegetation only, f r , (Fig. 2) follows the same trend of variation because the total friction factor is

the sum of the friction factor due to non-vegetated and

vegetated channel beds.

The variation of Manning Roughness n with F n

shown in Figure (3) shows similar trend as f with F n

because n is inversely proportional with the velocity

and directly proportional with the slope. Also, at low

values of F n and larger values of I, the friction factor is

higher. Manning's n decreases with the increase of F n

at constant slope since small values of n means little

resistance to the flow and hence high velocity values

that yield larger F n . Low density of vegetation offer

relatively smaller resistance to the flow and hence it

produces smaller values of n. 0.00 0.20 0.40 0.60 0.80 Froude number, Fn 0.0 2.0 4.0 6.0 8.0 F r i c t i o n f a c t o r , f r Figure 2. Relationship between n and F n for different vegetation intensities and slopes. Inversely to f and n, the variations of C with F n as shown in Figure (4) follows a linear increasing trend assuming constant slope with smaller values of C at low F n and high I. The values of C is higher for larger slopes. The values of C for non-vegetated bed is very high compared to those of vegetated channels. Vegetation with higher densities offers more resistance to the flow and hence the coefficient C will be smaller yielding smaller velocity value at constant slope. It is interestingly to observe that the plot of the equivalent roughness height, K/R with F n indicated in Figure (5) follow similar trend to those of f with F n and n with F n because larger values of K/R normally produce higher roughness indices f and n at lower values of F n . 0.00 0.20 0.40 0.60 0.80 Froude number, Fn

5 PREDICTION OF ROUGHNESS INDICES

OF VEGETATED BED

Using the collected data for the three roughness pat

terns and the three bottom slopes, the multiple linear

and non-linear regression were used to test numerous

proposed model to correlate the parameters of Eq.(6).

The following set of equations were found to be well

representative for the data with both coefficient of

determination and standard error of estimate as given

below.

hence or alternatively, Also, and The coefficients of determination of the equations 7, 8b, 9 and 10 are 0.997, 0.997, 0.994 and 0.999 respectively while the standard error of estimate for the same equations are 0.025, 0.031, 0.013 and 0.004 respectively. Figures 6a, b, c, d show the comparison of the measured values of the roughness indices and the predicted values using Eqs.(7), (8b), (9) and (10). It is observed that good agreement was achieved between measured values and predicted ones using the developed equations. Combining the data of the previously developed models for partially submerged vegetations with the present data for fully submerged vegetations, the following equations were obtained. hence, or alternatively, Also, and, The coefficients of determination of the equations 11, 12b, 13 and 14 are 0.992, 0.993, 0.992 and 0.999 respectively while the standard error of estimate for the same equations are 0.042, 0.044, 0.021 and 0.007 respectively. Figures 7a, b, c, d show the comparison of the measured values of the roughness indices and the predicted values using Eqs.(11), (12b), (13), (14). Measured values for roughness indices versus predicted ones (a) f using eq.(12b), (b) f r using eq.(11), (c) n using eq.(13), and (d) C using eq. (14). vegetation were presented. The total friction factor, f, the friction factor due to vegetation only, f r , the Manning roughness coefficient, n, and the Chezy roughness coefficient, C, were all used in the analysis. The trend of variation of f, f r and n with F n were all similar and having decreasing trend with the increase of F n while C is increasing with the increase of F n .

The values of the roughness indices are higher for

steeper slopes and for larger vegetation intensity. Pre

diction models (Eqs. 7, 8, 9 and 10) were developed

using the statistical methods to predict the roughness

indices. Comparison of predicted values with those

obtained from measurements indicated good agree

ment. Also, general models (Eqs. 11, 12, 13 and 14)

for both partially and fully submerged vegetations

were developed by combining the present data with

the previously published ones for partially submerged vegetation.

Recirculating flow behind groynes for compound-channel geometries

N. Rivière

S. Proust & A. Paquier

CEMAGREF Lyon, Lyon, France

ABSTRACT: Overbanks flows in a straight geometry are quite uncommon in the field. They usually cross

transition reaches where the flow width can significantly varies. The extreme case is met when important

obstacles, such as bridge-abutments, are present on the floodplain. They locally promote a rapid variation of

the hydraulic parameters of the flow. Indeed, they first act like a groyne in a single-bed channel and so create

downstream a slack-flow where silting can occur, while they promote local scour near their corner. Then, in

the particular case of compound channels, they also partially block off the flow in the flood plain and promote

a huge discharge transfer to the main channel. Available results on abrupt expansions in single-bed channel

show that the flow in the vicinity of the obstacle obeys to two asymptotic regimes: deep or shallow water flows

(Babarutsi et al., 1989) defined by a bed friction number. First, they have to be extended to the case of groynes

and secondly to the case of compound channel geometries where the overspeed in the main channel affects the

recirculation zone. Experiments are conducted both in single and compound channels. They confirm the validity

of the expansion observations in the case of groynes, but under some corrections. They also put in evidence the

crucial influence of another parameter in compound channels: the relative water depth in the floodplain.

1 INTRODUCTION

Flood flows are classically divided in two parts: a deep and rapid flow in the main channel and a more shallow and slower flow in the flood plain. The flood plain is usually occupied by vegetation, by small relieves or by small buildings that act on the uniform discharge distribution through an increase of its roughness. More important obstacles, such as bridge-abutments, can locally promote a rapid variation of the hydraulic parameters. First, they act like a groyne in a single-bed channel. They thus create a recirculation flow where silting can occur, but a more dangerous effect exists as they also induce local scour near their corner. Sec ond, in compound channels geometries, they partially block-off the flow in the flood plain and give birth to a huge discharge and momentum transfer towards the main channel, generating secondary-current cells (Proust et al., 2002). Such behaviour is similar to the one observed in the main channel of skewed compound channels (Elliot & Sellin, 1990) so as in meandering compound channels (Shiono & Muto, 1998). From an engineering point of view, it seems necessary to char acterise the mutual influence of the groyne and of the compound channel. Sturm and Janjua (1994) point out that the overspeed in the low bed must be taken into account to correct the correlations giving the scouring at the abutment corner. Conversely, the nature of the recirculation area downward obstacles seems to affect the

ability to redistribute the discharge towards the flood plain and to recover the uniform flow discharge distribution (Proust et al., 2002). Studies concerning the flow around an obstacle are available mainly in single, prismatic, channels, where the length of the recirculation zone varies with flow conditions. Babarutsi et al. (1989) work on sudden enlargements that can be assimilated to groynes of infinite thickness. They put in evidence two asymptotic regimes: shallow and deep water flows. The distinction is related to a bed friction number S = f.d/(8h) where d is the enlargement width and where f, the Darcy-Weisbach friction coefficient, and h, the water depth, are defined in the expansion cross-section. In the shallow regime (S > 0.1), the recirculation length does not depend on the enlargement width: In the deep flow regime (S < 0.05), it depends only on the enlargement width:

Babarutsi et al. (1996) explain the difference

between the two regimes by two distinct turbulence

productions. The bed friction produces small eddies –

with a horizontal axisand is dominant in the shallow

regime; the transverse velocity shear produces larger

eddies – with a vertical axisand is dominant in the

deep flow regime.

The case of groynes attached to one bank is more

complex. First, the flow has to skirt the obstacle.

A strong contraction is then created, resulting in an

important flow acceleration, notably close to the bed

(Molinas et al., 1998). In the groyne section, the flow

is no more homogeneous, as it was in the case of

enlargements. Both the water depth and the veloc

ity intensity increase from the obstacle corner to the

opposite wall; the velocity is also deviated towards

this wall.This influences the recirculation zone length:

values reported in the literature vary from 12.5d (Tingsanchali and Maehswaran, 1990) to 11d (Ouillon and Dartus, 1998). They concern, to the authors' knowledge, exclusively the deep flow regime, but are clearly higher than the 8d observed with enlargements. As the shallow regime is most common in the flood plains, it is necessary to improve the knowledge of the groyne working in this regime.

Francis et al. (1968) show that in a rectangular duct, the influence of a inclined obstacle is the same as its projection perpendicularly to the main stream direc tion, seeing that its inclination from the bank is in the range 60 ∘ −150 ∘ . Thus, in the sequel, only obsta cles perpendicular to the flood plain bank and to the flow are considered. Molinas and Hafez (2000) indi cate that the abutment thickness has a straightening effect past the upstream corner: the recirculation zone is more pronounced downward the groynes that are thicker. Hence, the study is focused on infinite thick ness obstacles (enlargements) and, on the other hand, on negligible thickness obstacles (metal plates). Other wise, several obstacle widths are considered, as Francis et al. (1968) underline the influence of the distance to the wall opposite to the groyne corner.

First, the experimental set-up and the measur

ing techniques are described. Then, the experimental

results are exposed, for enlargements and after for

groynes, both in single and in compound channels.

The observed behaviours and the possibility to model

the different regimes are finally discussed.

2 EXPERIMENTAL SET-UP AND MEASURING TECHNIQUES

Experiments are performed in a compound chan

nel flume of useful length L= 8 m, of total width

B= 1.2 m (Fig. 1), with a bed slope S 0 = 1.8× 10 −3 .

The main-channel bank is vertical and 5 cm high, while

its width is B mc = 0.4 m. The flood plain width is Figure 1. Experimental set-up. B fp = 0.8 m. The bed is made of PVC. The upstream stilling basin is separated in two chambers that allow to adjust independently the partial discharges: Q mc in the main channel and Q fp in the flood plain. When a single-bed channel is needed, only the flood plain is used; it is separated from the main-channel by plywood plates. They are covered by plastic rubber on their submerged part, ensuring a roughness equivalent to the one of PVC. A centrifugal pump provides water to the flume, distributed between the two channels, from an underground sump. For each channel, the water enters the stilling basin through a perforated cylinder, and then crosses honeycombs and grillage buffers. Q mc and Q fp are measured by two electromagnetic flow meters installed on each supply pipe. Indeed, during experiments in compound channels, the ratio Q mc /Q fp is adjust to match the one of a uniform flow defined by the relative water-depth H r = h fp /h mc , where h fp is the water depth in the floodplain and h mc in the main channel. This avoids flow-development problems due to the relatively small length to width ratio B/L≈ 6.7 (Bousmar et al., 2003). Last, two independent adjustable gates, one at the downstream end of each bed, allow a constant water depth in the whole channel. The water levels are measured thanks to a moveable point gauge, with a reading accuracy of±0.1 mm. Velocities are acquired by a miniature propeller (1.5 cm of diameter). Their alignment

with the x-direction is checked using a homemade miniature vane, with an accuracy of about ±2 ∘ . Depth-averaged velocities are obtained from 4 measurements on each vertical in the main channel, and then integrated to give Q mc . In the high bed, the mean velocity is deduced from the evaluation of the cross section of the flowing part and the substraction of Q mc from the whole discharge. The bed friction has to be characterised in the flood plain. Due to the range of Reynolds numbers encountered, the friction coefficient varies with the local velocity. Considering the Darcy-Weisbach coefficient f , and a small h/B ratio, it writes (Graf, 2000):

This relation is valid for a hydrodynamically

smooth bed. First, this requires a Reynolds number

Re= 4R h U/ν> 2000, where R h is the hydraulic radius

and U the average velocity. Considering a section

of width B and depth h, the two latter write respec

tively R h = 4hB/(2h+B) and U =Q/(hB). Secondly,

the smooth assumption was checked for every flow

thanks to a Moody diagram, considering k s < 0.05 mm

(PVC sheets).The two conditions were always fulfilled

in the flood plain in the experiments.

Two techniques of flow visualisation are used to

locate the stagnation point and thus the reattachment

length L. First, milk is injected into the flow, approx

imately at middepth. Second, photographs give the

trajectories of sawdust particles spread on the free sur

face, with 8s time of exposure. The stagnation point is

adopted from an average of 6 to 10 photographs. The

first technique is far less accurate as vertical vortices

are produced at the enlargement (or obstacle) angle;

they grow as they are advected towards the recircula

tion end. Depending on the flow depth, their typical

size can reach there the order of the reattachment

length. Thus, the random passage of vortices – fre

quency O(0.1 Hz)strongly affects the motion of the

injected milk, and so the location of the stagnation

points (Figs 2-a and 2-b).

Figure 2-a. Lateral expansion configuration.

Figure 2-b. Groyne configuration. 3 EXPERIMENTAL RESULTS 3.1 Lateral expansion A wooden case, 2 m long, partly blocks off the flow entering the channel (Fig. 2-a) and forms a lateral expansion of width d = 0.3 m (d/B fp = 0.375). The flow velocity and depth are almost uniform just upstream the expansion. First, Figure 3 shows the overestimation of L/d measured by milk injection due to the presence of the advected vertical vortices mentioned above. In the isolated flood plain, the results are in agreement with the experiments of Babarutsi et al.(1989), and obey to two asymptotic regimes corresponding to high (>0.06 rather than 0.1) or small (<0.05) values of the bed friction number S. As the main objective was the groyne, only two measurements are performed in a compound channel: they seem to put in evidence another parameter, the relative water-depth H r . It must be notice that the H r value refers to the one of uniform flow corresponding to the inlet ratio Q mc /Q f . For H r = 0.2, the expansion acts like in a single bed. For H r = 0.4, the behaviour is really different. However, too few points were acquired to propose a definite conclusion on the role of H r , as the main purpose was groynes, which are studied in next section. First, it must be shown if obstacles of negligible thickness follow the same behaviour as obstacles of infinite thickness, i.e. expansions. Second, more numerous measurements have to be performed to examine the role of H r . 3.2 Groynes Four obstacles (brass plates of negligible relative thickness e/d) of width d = 10, 15.6, 30 and 40 cm are used (Fig. 2-b). The corresponding rati d/B fp are respectively 0.125, 0.2, 0.375 and 0.5. The velocity shear is stronger at the groyne corner than in the case of the expansion. Consequently, bigger vertical vortices are produced and advected towards the stagnation point, causing

a higher dispersion in the length L measurements. 3.2.1 Single bed geometry The first results concern the single bed flows. Again, S is derived with the flow parameters of the obstacle section. Figure 4 clearly shows the existence of two asymptotic regimes: deep and shallow, also in the case of obstacles, but with somewhat different features. A first one is the underestimation of L/d by relations (1-a) and (1-b). This is mainly due to the flow contraction that does not exist in the case of abrupt expansions. This is valid for both regimes. In the deep flow limit, the values are conform to the one reported in the literature, about L/d = 10-12 instead of 8. When the flow is dominated by friction, the slope of L/d as a function of S is similar to the one observed with

enlargements, but with an upward shift for d< 0.3 m.

For higher d, another parameter must be accounted for:

the ratio d/B fp , as proposed in the literature (Francis

et al., 1968), but only for a deep flow regime. Indeed,

the more the wall opposite to the groyne is close to

the corner (strong d/B fp), the more the reattachment

length is reduced. The upward shift between the data

obtained for d/B fp = 0.12 and 0.375 illustrates this effect in the deep limit, so as the downward shift for d/B fp = 0.5 in the shallow limit. 3.2.2 Compound channel A clear feature that confirms the experiments performed on an expansion is observed. With H r = 0.2, the water depth in the flood plain is small and S is high for d = 0.154 and 0.3 m: the behaviour is like

Figure 5-a. Water depth profiles H r = 0.2; d = 0.375 B fp ;

L= 6d.

Figure 5-b. Water depth profiles H r = 0.4; d = 0.5 B fp ;

L= 4.2d.

a shallow water flow in a single bed. With H r = 0.3

and d = 0.1 m, the regime becomes “deep-water”, and

again the behaviour is similar to the one observed

in single beds. On the other hand, the H r = 0.4 con

figurations correspond again to values of L/d really

smaller than the theory prediction, and this both for

small or high d/B fp values. Additional experimental

values, obtained previously in a concrete compound

channel flume (total length= 13 m, total width= 3 m,

B fp = 2.2 m), at the Compagnie Nationale du Rhone,

are given in Figure 4 (CNR compound channel). The

obstacle was either 143 cm or 77 cm large, and the rel

ative water depth H r for uniform flows was either 0.2

or 0.33.

They confirm the preceding results but with

a rougher bed as the Manning roughness was

n= 0.013 m −1/3 ·s -resp. 0.011 m −1/3 ·s - in the flood

plain -resp. in the main channel-. Experimental details

can be found elsewhere (Proust et al., 2002).

The evolution of the water depth h downstream the

obstacle is sketched on Figure 5-a and Figure 5-b. In

this figures, measuring the depth from the bottom of

each bed causes a huge discontinuity for y= 80 cm but

allows gauging the relative evolution of the flow depth

in each bed. Four transverse profiles are acquired: a

first one in the obstacle section, the second in the max

imum contraction section, a third one at the end of the recirculation area and a fourth one between the two latter. For the configuration (H r = 0.2, d = 0.375B fp), the water depth variation on the flood plain are about 30%. On the opposite, for (H r = 0.4, d = 0.5B fp), the water depth sharply decreases downstream the obstacle: the reduction reaches a factor 5. This should result in strong longitudinal variations of h, U, f and finally of S. To check this point, velocity profiles are acquired simultaneously with the water depths. Then, f and S are calculated from the averaged depth and axial velocity in a section. The results are sketched on Figure 6, where the evolution of S is plotted as a function of x/L, both for groynes and expansions. For H r = 0.2 or 0.3, the variations of S are small on the whole recirculation length, and S reaches a constant value. Conversely, S varies steadily on the whole reattachment length for H r = 0.4, both for the expansion and the d/B fp = 0.5 groyne. For the latter, S is multiplied by 4, that should cause an

evolution from deep regime to the transition zone described by Babarutsi. Regarding CNR data, by sake of clarity, the S evolution for Hr= 0.2 and d= 143 cm, which varies between too high values, namely 0.2 and 0.8 is not plotted on Figure 6. Nevertheless, from x/L= 0.3, the S value is almost constant around 0.8. For the other configuration, the good position of experimental point in Figure 4, is in agreement with the absence of regime modification on Figure 6. In Figures 3 and 4, the odd position of the H r = 0.4 measurements is thus due the fact that the value of S, computed in the obstacle section, cannot be representative of the different S values until the reattachment. The upstream value of S is so unable to account for the competition between the different turbulence production sources that finally condition the size of the recirculation zone. 4 DISCUSSION Experiments were performed to examine if the asymptotic regimes identified by Babarutsi et al. (1989), observed for abrupt expansions in single bed flow, can be extended to other flow cases. First, sharp obstacles were used instead of an enlargement. Very similar trends are observed, but another parameter has to be taken into account: the relative distance between the groyne corner and the opposite wall. It is interesting to notice that the local increase of the friction coefficient f due to modifications of the vertical velocity profiles, as suggested by Molinas et al. (1998), does not prevent from using the S criteria that is estimated through a global friction coefficient f . Second, experiments were conducted in a compound channel instead of a single bed. In this case, as long as H r is small enough, the reattachment length behaves like in single channel. When H r reaches higher values (0.4 in the

Figure 6. Longitudinal variations of S downstream the expansion and the groynes.

present experiments), the reattachment length can con

siderably decrease both for abrupt expansions and

obstacles. The longitudinal gradient of the water depth

from the main channel to the flood plain are able to

cause important variations of the bed friction number.

The possibility to define a mean value of S is still to

develop.

Thus, future work has to be devoted to complete the data set with a measuring technique giving access to a more precise location of the reattachment point so as to turbulent variables. The experimental set-up is well adapted to this scope, through its transparent section allowing optical measurements.

ACKNOWLEDGEMENTS

Authors are thankful to A. Bergez, L. Pontal and F. Vion for their experimental participation on the project. Experiments were funded in the framework of the project “2-D modelling of a flood plain – Representation of obstacles” from PNRH (French National Program of Hydrological Research) and of the project “Modelling of hydrodynamic pro cesses with free surface in case of singularities” from the ACI (Concerted Action) “Prevention of nat ural catastrophes” funded by the French Ministry of Research.

Local velocity at bridge abutments on plain rivers

B. Gjunsburgs & R. Neilands

Riga Technical University, Riga, Latvia

ABSTRACT: Scour phenomena at bridge abutments on plain rivers in flood were studied. A differential equa

tion for the bed sediment movement for clear water was used, and a new method for computing the development

of scour depth with time at the abutments in flood was elaborated. The method was confirmed by experimental

data. Laboratory tests were made in flumes with fixed and sand beds. The tests showed the streamline concentra

tion, a sharp drop in water level, and a rapid increase in

velocity at the corner of the abutment. The local velocity

with a vortex structure, which formed a scour hole at the abutments, depended on the open flow parameters,

magnitude of backwater, contraction rate of bridge crossings, scour depth, and flood parameters. A formula for

the local velocity was derived. It was found that the flow structure at the abutments differed from that near the

piers: there was no runflow and downflow. Whether the equilibrium stage of scour can or cannot be reached

depended on the characteristics of flood and river bed. It was also found that tests in the conditions of a steady

flow did not reflect the changes in real flow and scour during the flood.

1 INTRODUCTION

Bridge failure during the flood as a result of scour at

piers and abutments can lead to considerable environ

mental damages and losses.Although the problem is of

great importance, scour at bridge abutments on plain

rivers has not been studied much.

An analysis of the literature shows that there is no

common opinion concerning the velocity that forms

scour holes and no unified methods for calculating the

local (maximum) velocity at the abutments.

Methods and formulas for calculating the depth of

scour at the abutments employing the mean velocity

of open flow, the Froude number with this velocity,

or the mean velocity of the flow near the abutments

were used by Laursen & Toch (1956), Froelich (1989),

Richardson et al. (1990), Melville (1997), Melville & Coleman (2000), Kothyari & Ranga Raju (2001), and Radice et al. (2002). The existence of the maximum (local) velocity near the abutments has been confirmed in laboratory tests by Latishenko (1960).

Some authors consider that the flow pattern and scour at the piers are of the same structure as near the abutments – Laursen (1963), Kothyari et al. (1992), Melville (1997), Kothyari & Ranga Raju (2001), and that downflows at the piers and the abutments are identical – Kwan (1984, 1988).

In the majority of methods and formulas, the equi librium scour depth at bridge abutments has been calculated; however, Radice et al. (2002) failed to reach the equilibrium stage of scour in long-term tests. In the present study, a differential equation of equilibrium of the bed sediment movement for clear water is used and a new method for calculating the scour development with time at the abutments during the flood is elaborated. The method is confirmed by experimental data. In our tests, the concentration of streamlines, a sharp drop in water level, a local increase in the velocity, and scour hole are observed at the corner of the abutment. It is found that, due to the vortex system, the movement of sediments starts at a lower velocity. The flow pattern at the abutments is not the same as that near piers. There is no runflow and downflow, since on the plain rivers the streamlines go around the abutment. Whether the equilibrium stage of scour can or cannot be reached depends on the flood and river-bed parameters. Tests in the conditions of a steady flow do not reflect changes in the real flow during the flood. The local velocity depends on the characteristics of the flow, magnitude of backwater, contraction of the flow, scour depth, and flood parameters. A formula for the local velocity is proposed. 2 EXPERIMENTAL SETUP Tests were carried out at the Transport Research Institute (Russia) in flumes 3.5 m wide and 21 m long Table 1. Experimental data

and at the Budapest Technical University (Hungary)

in flumes 1.35 m wide and 9.0 long.

Experimental data for the open-flow conditions

were presented in Table 1.

The tests with a fixed (cemented) bed were per

formed for different flow contractions, in order to

investigate the velocity and the water level changes

in the vicinity of the embankment, along it, and near a

modelled abutment. The aim of tests with a sand bed

was to study the scour processes, the changes in the

velocity with time, the effect of hydraulic parameters

and the contraction rate of the flow, grain size of the

bed material, and the scour development in time. The

openings of the bridge model were 50, 80, 120, and

200 cm in the first flume and 44.5, 57.5, 77.5, and

97.5 cm in the second one. The contraction rate of the

flow Q/Q b (where Q was the discharge of the flow and

Q b was the discharge of the flow in a bridge opening

in open-flow conditions) varied from 1.25 to 5.69 at a

depth of floodplain of 5, 7, and 13 cm, and the Froude

numbers varied from 0.078 to 0.151. The slope was

0.0012 and 0.0015 for the first and second flumes,

respectively.

The tests with a sand bed were carried out in the

conditions of clear water. The sand was placed 1 m

up and down the contraction of the flumes. The mean

size of grains was 0.24 and 0.67 mm in the first flume

and 0.5 and 1.0 mm in the second one with a standard

deviation. The condition that Fr R =Fr f was fulfilled,

where Fr R and Fr f were the Froude numbers for the

plain river and for the flume, respectively. The tests in

the flumes lasted for 7 hours, the vertical scale was

50 and the time scale was 7. With respect to the real

conditions, the test time was equal to 2 days. This was

the mean duration of time steps, into which the flood

hydrograph was divided.

The development of scour was examined with

different flow parameters in time intervals within

one 7 hours step and within two steps of hydrograph,

7 hours each. 3 METHOD The differential equation of equilibrium for the bed sediment movement in the conditions of clear water has the form: According to laboratory tests, w= 1/6πm 2 h 3 s , where t is the time and Q s is the sediment discharge out of the scour hole. The left-hand part of Eq. (1) can be written as where h s is the scour depth and m is the steepness of the scour hole. The sediment discharge was determined by the Levi (1969) formula: where B=mh s is the width of a scour hole, V l is the local velocity at the abutment, and A is a parameter in the Levi (1969) formula: Here, γ is the specific weight of

sediments, β is the coefficient of reduction in velocity V o due to the vortex system, V o is the velocity required to start the movement of sediments, d is the size of grains of the bed material, and h f is the depth of water in the floodplain. The sediment discharge upon development of the scour is

where b=Am ·V 4 l ; k is the coefficient of changes in

the discharge due to the scour. The hydraulic charac

teristics, the contraction rate of flow, the velocities V o

and V l , the grain size in different layers of the bed, the

sediment discharge, the depth, and the width of the

scour hole varied during the flood.

Upon development of the scour, we have

Taking into account formulas (2) and (5), differential

equation (1) can be presented as

According to the method presented, the hydrograph

was divided in time steps, and each step in turn

was divided into small time intervals (Fig. 1). It was

assumed that D was constant inside the time interval.

After integration with new variables, x= 1+ h s /

2h f , h s = 2h f (x – 1) and dh s = 2h f dx we obtain

where N i = 1/6x 6 i – 1/5x 5 i and t i is time interval.

Using the graph N = f (x) or the data of Table 2 for

the calculated N i , we find x i and the depth of the scour

at the end of time interval:

To determine the scour depth development during

the flood, the hydrograph was divided into time steps

with duration of 1 or 2 days, and each time step was

divided into time intervals up to several hours. In lab

oratory tests, the time steps were divided into 20 time t 1 t 2 t 1 t i t n t Q Time steps Floodplain flooded Time intervals Figure 1. Hydrograph divided in time steps and time intervals. Table 2. The value of N i as a function of x i . x i 1 1.2 1.4 1.6 1.8 Ni -0.033 0.0002 0.18 0.70 1.90 xi 2 2.2 2.4 2.6 2.8 Ni 4.29 8.62 15.98 27.2 46.07 intervals. For each time step, the following parameters must be determined: h f – depth of water in the floodplain, Q/Q b – contraction rate of the flow, h – maximum backwater, d – grain size, H – thickness of the bed layer with d, and γ – specific weight of the bed material. As a result, we have V l , V o , A, D, N i , N i-1 , and h s at the end of time intervals and finally at the end of the time step. For the next time step, the flow parameters changed because of the flood and the scour developed during the previous time step. 4 RESULTS When approaching the contraction of the bridge, the streamlines were bended by the embankment, and then the flow went parallel to it. The velocities along the extreme streamline dropped down almost to the minimum and then gradually increased (Fig. 2), and a spiral vortex system developed. At the corner of the abutment, the concentration of streamlines, a sharp drop in water level, and a rapid increase in the velocity were found (Fig. 3). A horizontal vortex developed, which reduced the opening of the bridge. As was found in the tests, the local velocities near the abutments existed at any contraction of the flow. To calculate the local velocity, we used the Bernulli equation for two cross sections of a unit streamline. Then the formula for the local velocity near the abutment was where ϕ was the velocity coefficient and Z was the difference in water levels at the corner of the abutment. 403020100 50 60 70 80 90 3.1 2.68 3.05 6.48 14.18

We checked it for different values of the opening width, discharge, flow depth, and Froude numbers. The maximum backwater was determined by using the Rotenburg (1969) formula. The velocity coefficient in Eq. (10) depended on the rate of contraction of the flow (Fig. 4). Table 3 presented a comparison between the experimental and calculated data for local velocities at the abutments. The discharge across the width of a scour hole before and after the scour was as follows: Q f = k ·Q sc , where Q f was the discharge across the width of the scour hole with a plain bed and Q sc was the discharge across the width of the scour with a depth h s . The local velocity at any depth of the scour hole can be determined from formula (11): According to the experimental data, the coefficient k depended on the contraction of the flow (Fig. 5). Using formulas (10) and (12) we can find the local velocities at any depth of scour around the abutment and for any step of the hydrograph. Table 4 presented a comparison between the

experimental data and computed scour depth with the use of local velocity. The flow parameters varying with each step of the hydrograph affected considerably the depth of

the scour. For example, in test SL4 at Q= 16.6 l/s,

h f = 7 cm, Q/Q b = 3.66, d = 0.24 mm, and Δh=

1.19 cm, the scour depth was 10.1 cm after 7 hours. In

test SL 19 at Q= 35.48 l/s, h f = 13 cm, Q/Q b = 4.05,

d = 0.24 mm, and Δh= 1.42 cm scour depth was

13.6 cm after 7 hours.

In test TL1, we modelled two (SL4 and SL19) steps

of the hydrograph. The scour depth after 14 hours of

test TL1 was 14.3 cm, which was not equal to the sum

of the values obtained in two separate tests, namely

23.7 cm.

Figure 7. Scour development in time under unsteady flow

conditions.

local increase in the velocity the depth of scour around

the bridge abutments on plain rivers was higher than

in opening of the bridge.

The flow structure at the abutments was not the same

as that near the piers. The streamlines flew around the

abutments, and there was no runflow and downflow as

in the case at the piers.

The local velocity with a vortex structure formed

scour holes and depended on the characteristics of the

flow, magnitude of backwater, contraction rate of the

bridge crossings, and the depth of scour. A formula

for the local velocity was derived. The local velocity

reduced in time because of the scour and changed with

the flood.

According to this method, the equilibrium stage of

scour can or cannot be reached, depending on the flood

and river bed parameters. The tests in the steady flow

conditions did not reflect the changes in the real flow

and scour during the flood.

A differential equation for the bed sediment move

ment for clear water was used and a new method for

computing the scour depth development in time at

the abutments during the flood was elaborated. The

method was confirmed by experimental data.

Performance of lateral velocity distribution models for

compound channel sections

J.F. Weber

Universidad Nacional de Córdoba and Universidad Tecnológica Nacional, Córdoba, Argentina

A.N. Menéndez

INA (National Institute for Water) and Universidad de Buenos Aires, Buenos Aires, Argentina

ABSTRACT: In this paper, the scope of 2D-Horizontal and 1D-Lateral models for lateral velocity distribution

is addressed, and their relative and absolute performances are tested by making comparisons between their

predictions, on the one side, and experimental and field velocity data, on the other side.The models considered are:

the Divided Channel Method (DCM), the Lateral Distribution Method (LDM) and a 2D Horizontal hydrodynamic

finite-element model (RMA2).

1 INTRODUCTION

Hydraulic engineering studies related to floods usu

ally require the lateral distribution of flow velocity

across the compound channel section, constituted by

the main channel and the floodplain. 2D-Horizontal

numerical models (such as the public domain soft

ware RMA2 of USACE) are now broadly accepted

as an appropriate theoretical model to solve this prob

lem. However, as in the majority of applications the

longitudinal scale of flow variation is much larger

than the lateral scale of variation (given by the flow

width), the longitudinal and lateral flow variations can

be accounted for separately (Menéndez 2003); the first

one, through well-established 1D-Longitudinal mod

els based on de Saint Venant equations (Cunge et al.

1980), while the second one, using 1D-Lateral models.

1D-Lateral models, which solve the lateral distribu

tion of the longitudinal depth-averaged flow velocity,

have become the subject of analysis and application

in recent years. They run between simple and rela

tively old empirical and heuristic formulations – such

as the methods of Lotter (1933), or Divided Channel

Method (DCM, used in software HEC-RAS, 2001),

Horton (1933), and Pavlovski (1931) – to physically

based equations, like the Lateral Distribution Method

(LDM) proposed by Wark et al. (1990).

2 MODEL DESCRIPTIONS

In the following paragraphs, the three models used

in the present work are briefly described: the DCM; the analytical solution proposed by Shiono & Knight (1988, 1991) to the LDM, and the RMA2-WES 2D-Horizontal hydrodynamic finite-element model (Donnell et al. 2001).

2.1 DCM model

Lotter (1933), and later Einstein & Banks (1950) divided the cross section into subsections, and assumed that the energy grade slope was the same for any subsection, and that the interfaces between them behaved as impermeable boundaries, i.e., that there was no diffusion of lateral momentum (leaving the friction as the only energy loss), to calculate the partial discharge Q i for any such subsection: where S 0 = longitudinal slope; and K i = hydraulic conveyance, given by where A i = flow area, R i = hydraulic radius, and n i =Manning’s roughness coefficient for subsection i. The lateral velocity distribution, V i , can then be obtained as

This is the method implemented in software HEC

RAS (HEC 2001) as Flow Distribution Option.

2.2 LDM model

The LDM (Wark et al. 1988) is based on the steady state continuity and momentum depth-averaged equations of motion. Combining both equations, and neglecting longitudinal derivatives, the following expression is obtained

where ρ= density of water; g= gravitational acceleration; Y = local flow depth; f =Darcy's friction coefficient; V = depth-mean velocity; s= lateral bed slope; y= lateral coordinate; and λ= non dimensional Boussinesq eddy viscosity.

Equation 4 takes into account the effects of friction and diffusion as dissipative terms. The source term represents the effect of water weight.

Shiono & Knight (1988) obtained the analytical solutions of Equation 4 across subsections where the depth (Y) is constant or a linear function of the lateral coordinate. These solutions are given in equations 5 (for constant depth) and 6 (for linear depth). In these expressions, η, ψ, and ω are constants given by equations 7-9. Coefficients a and b in equations 5-6 must be calculated solving a linear system of equations. This system is obtained by imposing the matching conditions expressed in equations 10-11 at the interface between subsections. For a section com

posed by N subsections, 2N − 2 equations result from

applying 10–11.

Although Abril (2003) showed that the boundary

condition given by Equation 11 is not strictly true, it

will be consider as correct for the present work. Figure 1. Scheme of a simplified compound channel section. The remaining two equations arise from the boundary conditions at the two extremes. For example, in the case of a cross section as shown in Figure 1, the two boundary conditions correspond to the no-slip condition at point p and zero derivative in point m (symmetric section). 2.3 2D model The RMA2 model (Donnell et al. 2001) is a 2D depth-averaged finite-element hydrodynamic numerical model. It was originally developed by Norton, King and Orlob (1973) and actually supported by WES-USACE. It solves the shallow water equations, i.e. (neglecting wind shear stress and Coriolis acceleration):

where u and v are the x and y components of the

velocity vector, respectively, and ε is the horizontal

eddy-viscosity, calculated as:

The numerical solution of equations 12–14 is imple

mented through the finite-element method. The pro

gram uses both quadrilateral and triangular elements.

The weighted-residuals Galerkin method is used for

spatial integration.An explicit finite-difference scheme

is used for time integration.

3 EXPERIMENTAL DATA

Two sources of experimental data were used for vali

dation: those from the SERC Flood Channel Facility

experimental flume (Shiono & Knight 1988, 1991),

and measurements from river Severn at Montford, UK

(Knight et al 1989).

3.1 Laboratory data

The SERC Flood Channel Facility is a laboratory flume 56 m long and 10 m wide, with discharges up to a maximum of 1.1 m 3 /s. Velocities were measured by means of mini propeller current meters (Shiono & Knight 1991).

For the present work, eight experiments, distributed in two groups according to floodplain width, are con sidered. Taking as a reference Figure 1, the total half width B is 3.15 m for Group A and 1.65 m for Group B; the main channel half-width is the same for both groups, and equal to 0.75 m; the longitudinal slope is fixed in 0.001027; the main channel depth relative to floodplains (h) is 0.15 m. The total depth H and the discharge Q vary for each case, as shown in Tables 1 and 2. These tables also present the non-dimensional geometric parameter D r , defined as:

Manning's roughness coefficient n was used instead of Darcy's coefficient f to characterize channel rough ness. Coefficient n was assumed constant and equal to 0.0104. It was verified (Weber 2003) that results are relatively insensitive to which of the coefficients is considered as a constant.

The relation between parameters n and f is the

following: Table 1. Hydraulic parameters for experimental data. Group A. This is the longest river of England. Its mean discharge is 43 m 3 /s. The longitudinal slope at the surveyed location is 0.0002. Table 3 shows the discharge and depth associated to the three cases considered. Roughness coefficients were taken as reported in the original work (Knight el al. 1989). For the application of DCM and RMA2 models, the corresponding values of Manning's n were obtained. Table 4 shows all these values.

4 MODELS APPLICATION

Applications of the three models to the two sets of

experimental data are described in the following.

4.1 DCM model

The DCM model was applied through software HEC

RAS (HEC 2001). This soft, aimed at solving grad

ually varied flow with a 1D-Longitudinal model, has

a feature called Flow Distribution, which calculates

(using the DCM) the lateral velocity distribution in

specified cross sections. Users can control the points

where they want to obtain the results, through the

specification of a ∂y value.

For the application of HEC-RAS, a rectilinear pris
matic channel, with the known flow depth imposed as
downstream boundary condition, was considered. The
lengths of the 1D models were 56 m for the labora
tory flume experiments and 10,000 m for River Severn.
The results for middle-located stations were used for
comparison with experimental data, in order to avoid
influence from the boundary conditions.
In order to investigate the influence of lateral dis
cretization on the accuracy of the predictions, different
discretization steps were tested. Figures 2–3 show
the lateral velocity profiles predicted for two cases
in the laboratory flume (Case 1 with H = 0.169 m
and Case 5 with H = 0.288 m). Figures 4–5 are the
velocity profiles computed for two cases in River
Severn (Case 1 with H = 7.81 m and Case 3 with
H = 6.15 m). It is observed that a finer discretiza
tion does not necessarily means higher precision for
the DCM.

4.2 LDM model

The analytical solution of LDM was applied using
a specially-developed software, named “Lateral”
(Weber & Menéndez 2003).This soft proceeds through Case 1 y

because Y = 0. Then, this condition was slightly

modified to:

where δY =minimum imposed depth considered in

calculations, and δV =minimum imposed velocity

corresponding to depth δY . Although δY and δV

appear as new parameters, experience shows that they

have only a local influence. Values of 0,001 m and

0,1 m were used for δY in laboratory flume and in

River Severn, respectively. The minimum velocity δV

was taken as 0,1 m/s for both cases.

Instead of working with V (y), function V 2 (y) was

used, which allows to deal with a linear system of alge

braic equations. Solution to this system were obtained

through Gauss Elimination Method.

shown in Figure 10. The length of the channel was taken as the minimum one necessary to achieve a stabilized solution. It resulted lengths of 10 m for the laboratory cases and 600 m for River Severn. The Δx step was assumed fixed at 0.1 m for laboratory cases and 4 m for River Severn. Case 1 river Severn 0.5 0.0 1.0 1.5 2.0 0 50 100 y (m) V (m / s) field data LDM ground Figure 8. The turbulence parameter E= ρε was correlated with parameter λ used in LDM model through Equation 15. For the laboratory cases, artificially high values of E were taken, in order to assure numerical stability. Values between 14.2 to 114.4 Pa · s were used for field data and 3 to 20 Pa · s for laboratory data. The known water level was imposed as the downstream boundary condition. Figures 11-14 show the lateral velocity distribution as calculated by RMA2. 5 MODELS PERFORMANCE Absolute and relative performances of the used models are discussed next. 5.1 DCM model The Divided Channel Method

main limitation is associated to the absence of lateral momentum diffusion. As a consequence, the lateral velocity profile tends to copy the channel bottom form (see Figures 4-5). This limitation is particularly significant for skewed V-shaped sections, where diffusion plays an important role. Another consequence of this lack of diffusion is that the lateral velocity distribution depends strongly on the discretization step. Specifically, it is better to minimize

the number of subsections considered, as recom

mended in HEC-RAS user's manual (HEC 2001),

which constitutes a way of artificially smoothing out

the profile.

For laboratory cases, the DCM model tends to over

estimate main channel velocities and underestimate

floodplain velocities. This anomaly increases as flood

plain flow depth increases (see Figures 2-3).

5.2 LDM model

As was presented in early works (Shiono & Knight

1988, 1991), the LDM model adequately predicts the

lateral velocity distribution, particularly for laboratory

cases. Dispersion in the prediction of velocity profiles

for natural rivers is a frequent feature, although there

are some examples of very satisfactory applications of

LDM model to natural streams (Weber &Tarrab 2003).

Additionally, LDM model results an adequate pre

dictor of stage-discharge relation, as can be seen in

Figure 15, related to Group A of laboratory cases.

Weber (in press) shows an example of application of

the LDM model to predict the stage-discharge relation for a natural stream.

Predictions are relatively insensitive to non dimensional eddy viscosity values for the floodplains over a relatively large range (Weber & Del Prete 2003). On the contrary, main channel λ values are decisive to perform a good prediction.

5.3 2D model

RMA2 model shows limitations to predict the lat eral velocity distribution for laboratory cases, due to excessive artificial eddy viscosity necessary to guar antee numerical stability, thus producing excessively smoothed-out profiles. This effect is more significant as floodplain depth decreases (see Figures 11-12). This is not the case for field data comparisons (River Severn). Instead, the limitations are associated to assuming constant E values.

In contrast to the LDM model, RMA2 model is not a handy tool to predict stage-discharge relations in com pound channels, due to the relatively large amount of time-machine necessary to perform the calculations.

5.4 Relative performance of models

Figures 16 and 17 show the lateral velocity distribution predicted by the three models considered in this paper, together with the experimental data, for Cases 4 and 7,

respectively, of SERC channel. For common parame

ters, the same or equivalent values are assumed. It can

be clearly noted the absence of diffusive effects in the

DCM prediction, and, on the contrary, the excess of

diffusion showed by the 2D model. Rating Curve - group A

Experimental ground DCM RMA2 Figure 17. Comparisons among
DCM, LDM and 2D models predictions for Case 7 of SERC
channel. With the DCM model, the velocities in the
floodplain are usually better represented than in the main
channel, where the models tend to give a more uniform
profile. The calculation gets poorer as the water depth in
the floodplain increases, and its use is not recommended
for relative depths over about 0.4.

The LDM model has the possibility of considering

the energy loss due to the vertical-axis eddies which

develop in the shear layer between the main channel

and the floodplain.

Additionally, LDM model can include a sink term

to account for the longitudinal-axis eddies, known as

secondary currents, which take place at the toe of the

main channel bank, acting as an apparent shear stress at

the main channel-floodplain interface (Wormleaton &

Merrett 1990) and, hence, producing an additional and

significant momentum transfer from the main chan

nel to the floodplain. As a consequence, the LDM can

provide a much better agreement, if properly tuned.

Regarding 2D-Horizontal models performance, it is shown that it is better for natural than for laboratory channels. In the last case, the difficulty lies in the fact that the artificial viscosity necessary to attain numeri cal stability (at least for RMA2) is usually higher than the physical eddy viscosity; hence, velocity gradients are smoothed out.

The agreement of this solution improves for higher floodplain water heights, and gets acceptable for rel ative depths over about 0.4, thus complementing with the DCM model. On the other hand, for natural chan nels the agreement is relatively satisfactory for the whole range of water depths.

In any case, 2D-Horizontal model could not match the LDM performance, and this is due to the fact that there is no formulation yet to account automatically for the effects of secondary currents at the toe of the main channel (RMA2 already includes an implementation of a parametric formulations to represent the effects of secondary currents in curved flow).

6 CONCLUSIONS

The main conclusions from the present work are the following:

- The DCM model (through software HEC-RAS), in spite of its simplicity, gives a reasonable pre

diction of the lateral velocity distribution from the engineering point of view.

- The main limitation of DCM model is associated to the absence of momentum lateral diffusion, which lowers precision specially in the calculated main channel velocity values.

- The LDM model adequately represents both the lateral velocity distribution and stage-discharge relation.

- 2D-Horizontal models performs better for natural than for laboratory channels. In the last case, the difficulty lies in the fact that the artificial viscosity necessary to attain numerical stability (at least for software RMA2) is usually much higher than the physical eddy viscosity; hence, velocity gradients

The conveyance capacity of compound channels with large scale

floodplain roughness

A.R. Heanen, W.R.C. Myers & J.F. Lyness

University of Ulster at Jordanstown, Belfast, UK

ABSTRACT: Accurate prediction of river conveyance during over-bank flow especially in the urban environ

ment is a topic which is of increasing significance in today’s society and is of interest to insurers and home

owners alike. The problem has been investigated experimentally by means of a straight compound channel with

large scale block roughness which simulates urban development on the floodplains. Asymmetric compound and

simple channel geometries have also been investigated. Stage discharge relationships have been determined,

together with 2D velocity distributions using a Nortek two dimensional Acoustic Doppler Velocimeter, for sev

eral roughness cases. The data has been analysed to yield zonal discharges and flow resistance characteristics

as well as transverse velocity profiles. The research highlights the effects of large scale vorticity, previously

unrecognised in floodplain research and goes on to review the suitability of using 1D roughness coefficients and

draws conclusions as to the limitations of such methods in light of the present findings.

1 INTRODUCTION

Rivers represent one of mans most important assets,

this being the case towns and cities have historically

tended to develop on the banks of rivers. Much of this

development has taken place within the confines of the

rivers floodplains, leaving a legacy of what are often

prime buildings liable to severe flooding. Often there

is no viable way of preventing this flooding and engi

neers are left with the task of predicting the magnitude

of the flood and the extremities of the area that will be

affected in order to be able provide reliable advice to

those occupying the affected buildings. This process

of flood estimation is a very complex problem, with

variables such as rainfall runoff rates requiring accu

rate prediction, in order to have a value of the discharge

a river may have to accommodate.

Once the amount of water going into the river sys

tem has been calculated, a stage discharge relationship

for the channel must be estimated in order that the level

the water is going to rise to can be predicted. It is the

estimation of such stage discharge relationships that

this paper is primarily concerned with.

In the mid 1960s, first Sellin (1964) and then

Zhelezenyakov (1965, 1971) reported the difficulties

involved with discharge estimation in compound chan

nels. Since then a wide range of methods have been

suggested to estimate stage discharge relationships

for rivers that have over-topped their main channel

banks, inundating their floodplains. These range from

one dimensional models, such as those suggested by Ackers (1991), Lambert and Myers (1998) to complex two and three Dimensional models, a summary of which has been given by Wright (2001). Due to the complexity of 2D and 3D models, the majority of river engineers still prefer to use the more simplistic 1D models. Thanks to the large amount of empirical data relating to such models it is possible to generate accurate estimates for the majority of cases. A large amount of empirical data relating to such models has been made available through the work that was undertaken at the UK Flood Channel Facility, HR Wallingford, England, the conception and nature of which are described by Knight and Sellin (1987). Wark et al (1994) present the data from phases A and B of this program in the form of a design guide for river engineers. There is however a lack of empirical data relating to cases where urban development has taken place on the floodplain. Due to the large amount of urbanisation that has taken place on the banks of many rivers, it is obvious that this is an area that needs attention. This paper presents data forming part of a large body of research that has been conducted at the University of Ulster with the aim of addressing this issue. 2 EXPERIMENTAL PROCEDURE The Experiments were carried out in the Hydraulics Laboratory at the University of Ulster, Northern Mobile Access Platform

Figure 1. Schematic plan of the compound channel. NB: simple channel had same basic layout.

Ireland. Two main channel geometries were used:

1. An 18 m long compound channel:The basic channel geometry (Fig. 1) consisted of a straight main chan nel with symmetric floodplains. The trapezoidal main channel had a top width of 500 mm a bank full depth of 50 mm and side slopes of 45 ∘ . The floodplains were each 700 mm wide; giving a total compound channel width of 1900 mm. Tapping points were located on the side slopes of the main channel at 1 m centers.

2. A 10 m long rectangular channel designed as a 1:1 scale of one of the compound channels floodplains. This provided a means of comparing the compound channel floodplain data with data from a floodplain not subject to interaction forces from the main chan nel flow. The geometry consisted of a 700 mm wide rectangular channel, with tapping points located in the centre of the channel at 1 m centers.

During the experiments discharge was measured using two electromagnetic flow meters. The channel bed slope (So) was 0.00185 in all cases. Uniform flow was ensured in all test series through control by a hinged

weir across the full width of the channel. A minimum of three water surface profiles were measured for each discharge, two of which where of a lesser slope than the bed slope and one of which was of a greater slope than the bed slope. The correct tailgate setting was then found by plotting these slopes against the tail gate setting and casting a polynomial curve through them. The correct tailgate setting was then established from this curve. Water surface profiles were mea sured with pointer gauges in stilling pots connected to each of the tapping points. Flow velocities where measured using a two-dimensional side facing Nortek Acoustic Doppler Velocimeter (ADV). Flow patterns where investigated using dye injection and time lapse photography

than 0.99, indicating the reliability of the results is

quite high.

3.1.1 Compound channel

Figure 3 illustrates the influence of varying roughness

on the left floodplain on the compound channel stage

discharge relationship.

Comparing the discharge relationships for the smooth compound channel (Series C1) with that for the compound channel with a single row of rough ness elements set 50 mm back from the main channel edge (Series C2), it can be seen that a significant reduction in discharge capacity is experienced. This is what would be expected from the presence of large scale roughness in this vicinity of the channel, as when placed here the roughness elements cause turbulence in the area most significant to the total com pound channel discharge (i.e. the main channel) This turbulence acts to significantly reduce the mean down stream velocity (as can be seen in Fig. 10). When the second row roughness elements is added (Series C3) there is little variation in the stage discharge relation ship, however, there does appear to be a slight increase in discharge capacity. This is not as expected, as the

Figure 4. Main channel stage discharge diagram.

blockage area has been increased by the presence of the second row of roughness elements and the area affected by turbulence has also been increased by its presence. When the third row of roughness elements are added (Series C4) the discharge capacity can again be seen to increase and this time the increase is quite significant. This is unexpected as both the blockage area and the area of the floodplain subject to high turbulence levels have been increased. Obviously the compound channel is not behaving as expected. The increase in the compound channel discharge

capacity would appear to be attributed to the un-roughened portion of the channel becoming more hydraulically efficient as roughness is added behind the initial row of roughness elements. Consideration will now be given to the elemental stage discharge diagrams in order to confirm this. 3.1.2 Zonal stage discharges: main channel Figure 4 above shows the stage discharge relationships for the main channel. The trend noted in the whole channel results, of a reduction in capacity when the first row of roughness elements is added followed by incremental increases in capacity as rows of roughness elements are added behind the initial row can be seen to be repeated here, however the increases are more pronounced. This would point to the fact that increases in the discharge capacity of the main channel plays quite a significant role in the whole channels discharge capacity increasing. The increase in discharge capacity which occurs between series C2 and C5 can be seen to result in the main channel being almost as efficient as for the smooth channel case. It is clear from these results that as the number of rows behind the initial row of roughness elements is increased the main channel is becoming more efficient. The proposed reason for this is that a reduction in turbulence is caused by the presence of the additional rows of roughness elements behind the initial row. Section 4 below considers the cause of this. In series C6 and C7 the left floodplain is blocked. Series C6 approximately conforms to the discharge

Figure 5. Left hand floodplain stage discharge diagram.

data for the smooth case. This is as would be expected, as a smooth wall set at the main channel face of the roughness elements is used to block flow down the left hand floodplain, no turbulence would then be caused to slow down the main channel flow.

Series C7 also appears to conform to the discharge data for series C6 but this is not what was expected as the wall baffling the left hand floodplain has this time set behind row 1 of roughness elements, leaving row 1 exposed to the flow. It would therefore have been expected that the main channel discharge would have been reduced slightly by turbulence caused by the presence of the roughness elements. This is not the case however as can be seen from Figure 4, although at first this result seems slightly ambiguous, it can be explained by considering secondary flow structures discussed below in Section 4.

3.1.3 Zonal stage discharges: left (roughened) floodplain

Figure 5 presents stage discharge relationships for the roughened, left hand, floodplain. Also shown are mea surements taken in the 700 mm wide simple channel indicated by dashed lines l. The simple channel results have the purpose of providing data for a non interact ing floodplain, in order to determine the effect, main

channel/floodplain interaction has on the discharge characteristics of the floodplain.

Considering the interacting roughened floodplain it can be seen that, as expected the discharge capacity is reduced as the number of roughness elements is increased. The most pronounced reduction being that which takes place when the first row of roughness elements is added, It can also be seen that the stage discharge relationship for series C2 has a greater gradient than that of series C1. This is due to the increase in turbulence as the water depth increases.

Comparing the stage discharge relationships obtained in series C1-C5 it can be seen that the reduction between series C2 and C3 is of approximately equal magnitude to the reduction between series C3 and C4. When the half row of roughness elements is added (Series C5) the magnitude of the reduction is approximately a half of the previous reductions when rows of full roughness elements were added. Considering the simple channel results it can be seen as expected, that the discharge capacity of the channel is reduced as the number of rows of roughness elements is increased. In this case however the reduction in capacity is quite regular from the addition of the first row, whereas in the interacting floodplain case the first row of roughness elements caused a much more pronounced reduction in discharge capacity. Figure 5 shows that as expected the interacting and non-interacting smooth channel stage discharge relationships lie approximately on top of one another. This helps to clarify the accuracy of the results and illustrates that the two channels are directly comparable. Figure 5 also shows that the interacting floodplain is significantly less efficient than the non interacting floodplain, Indeed for any given discharge the increase in stage experienced in the interacting floodplain would

appear to be almost twice that experienced in the non-interacting floodplain. When the second row of roughness elements is added however the reduction in the discharge capacity of the non-interacting floodplain is larger than that of the interacting floodplain. While this is true, it is still seen however that the non interacting floodplain is more efficient than the interacting floodplain. When the third row of roughness elements is added again a larger reduction occurs in the non interacting floodplain than occurs in the interacting floodplain. The larger reduction in the non interacting floodplain this time results in its becoming less efficient than the interacting floodplain with the same roughness present. When the row of half roughness elements is added to the two channels (Series C4 and S4) the reduction in the capacity of the non interacting floodplain is greater than the reduction experienced in the interacting floodplain. The difference in the way the interacting and the non-interacting floodplains react to the presence of rows of roughness is something which is significant. It is obvious that interaction with the main channel remains greatly significant even at maximum floodplain roughness This contradicts the intuition that as roughness increased the interaction effects would become less apparent. 3.1.4 Zonal stage discharges: right (un-roughened) floodplain Figure 6 illustrates how variations in the roughness on the left floodplain affect the discharge capacity of the right floodplain, which has not undergone any variation in roughness. The variations apparent on Figure 6 are therefore due to momentum transfer. It would be expected that the stage discharge relationships would 0.05 0.06 0.07 0.08 0.09 0.1 0.11 0.12 0 0.005 0.01 0.015 0.02 0.025 0.03 Q(m 3 /s)

Figure 6. Right hand floodplain stage discharge diagram.

act in a similar manner to those found for the main

channel Figure 6 shows that when the first row of

roughness elements is added (Series C2) the discharge

capacity of this floodplain reduces considerably. At

low depths this reduction is not so apparent but as the stage increases the reduction in capacity becomes more and more prominent.

When the second row of roughness elements is added the discharge capacity of this floodplain improves marginally, as was the case in main channel. The third row of roughness elements causes another improvement in this channels discharge capacity.

Figure 6 shows that the stage discharge relationship recorded for this floodplain when 3 rows of roughness are present on the opposite floodplain is approximately concurrent with that recorded for it when the oppo site floodplain was smooth. This is what would be expected, considering the very minor difference in the stage discharge relationships in the main channel.

Considering the stage discharge relationships dia grams obtained for the case where the left floodplain is completely blocked (Series C6 and C7). Figure 6 shows that series C6, which has a smooth wall placed 50 mm back from the main channel approximates the stage discharge relationship of series C1, C4 and C5. Figure 6 also shows that the stage discharge relation ship curve for series C7 lies approximately on top of that relating to series C6, This is as would be expected given the main channel acts in a similar manner .

3.1.5 Zonal stage discharges: floodplains

Figure 7 shows the stage discharge analysis for the

two floodplains. The discharge capacity can be seen to

reduce significantly when the first row of roughness

elements is added. The addition of the second row of

roughness elements produces an increase in discharge

capacity. If we bear in mind that the left hand flood

plains discharge capacity reduces when the second row

is added (as seen in Fig. 5) it is evident that the dis

charge increase in the right hand floodplain (noted in

Fig. 6) is greater in magnitude than the reduction in

the left hand floodplains and actually acts to improve 0.05 0.06 0.07 0.08 0.09 0.1 0.11 0.12 0 0.02 0.03 0.04 0.05 Q(m 3 /s) D (m) C1 C2 C3 C4 C5 0.01 Figure 7. Qrf/Qlf vs. relative depth for the straight compound channel. the over all discharge capacity. This then shows that overall the discharge capacity of the floodplains is actually improved by the presence of a second row of roughness elements behind an existing row at the main channel edge. When the third row of roughness elements is added (Series C4) the discharge capacity is seen to reduce somewhat, however the floodplains remain more efficient than was the case in series C2. The addition of the row of half roughness elements (in Series C5) has no discernable impact on the discharge capacity of the floodplains. 3.2 Roughened/un-roughened floodplain ratios Figure 8 illustrates how the contribution of the left and right hand floodplains vary with depth as well as roughness. As expected Figure 8 shows the Q rf /Q lf ratio increasing as roughness is added and the contribution of the roughened floodplain reduces. Considering the case were just one row of roughness elements is present on the left floodplain, Figure 8 shows that the ratio remains approximately constant with depth. When the second row of roughness elements is added the ratio increases quite significantly with depth 0.2

pound channel.

from around 2 at a relative depth of around 0.35 to

around 2.7 at a relative depth of about 0.55. When the

third row of roughness elements is added the increased

significance of the right hand floodplains contribution

is apparent by the quite large increase in the Q rf /Q lf

ratio. The addition of the row of half roughness ele

ments can be seen to cause a further increase in the

ratio, although lesser in magnitude than the previous.

Figure 9 illustrates how additional roughness affects

the ratio of the Q rf /Q c , ie the ratio of the
un-roughened

floodplain discharge to the main channel discharge.As

expected the floodplain becomes more significant as

depth increases. The initial row of roughness elements

causes an increase in the Q rf /Q c ratio, indicating that

the rightfloodplain’s contribution to the total flow in

the un-roughened channel is increased when rough

ness is added to the left hand floodplain. This is as would be expected if we consider what is happening in this portion of the compound channel. The main chan nel discharge is reduced with the addition of the first row of roughness elements. The right hand floodplain discharge is also reduced indicating that turbulence is carried over to the right hand floodplain from the left hand floodplain. Obviously the turbulence will have been retarded somewhat before it reaches the right hand floodplain and therefore the reduction in the right hand floodplain would be expected to be less than the reduction in the main channel, a fact indicated by the Q rf /Q c ratio increasing.

When the second row of roughness elements is added it can be seen that the ratio again increases some what at high relative depths, with subsequent rows of roughness elements causing little variation in the ratio.

3.3 Velocity profiles

3.3.1 Symmetric compound channel

Figure 10 presents depth averaged cross sectional velocity profiles obtained at 40% depth for the

compound channel. The normal depth is constant at -10 0 10 20 30 40 50 60 70 80 0 500 1000 1500 2000 (mm) (c m / s e c) 0 100 200 300 400 500 600 700 800 C1 C2 C3 C4 C5 C6
Figure 10. Cross sectional velocity profiles (Water depth = 99 mm). 100 mm for all roughness cases illustrated. In the smooth boundary case the floodplain velocity increasing as it approaches the faster moving main channel. The velocity

then steps up as the water depth suddenly changes before stepping down again in a symmetrical fashion at the right hand bank of the main channel. When a single row of roughness elements is added (Series C2) the velocity in the roughened left hand floodplain does not increase as it approaches the main channel, rather it is reduced, forming a velocity profile between the row of roughness elements and the left hand floodplain wall, rather like that you would expect to find in a simple channel. The velocity in the main channel is reduced significantly in series C2 peaking at around 0.62 m/s, around 20% less than the peak experienced in the series C1. The peak velocity now occurs in the proximity of the main channel edge, the step then experienced between the main channel and the right hand floodplain is much less pronounced than that experienced in the series C1. The velocity profile in the right floodplain runs approximately parallel to the that measured in the smooth channel, but at around 15% less. Considering the measured velocity profile for the compound channel with two rows of roughness elements (Series C3), Figure 10 shows that the peak velocity experienced in the left floodplain between the floodplain wall and the row of roughness elements is approximately equal to that experienced in the same place when only 1 row of roughness elements was present. The velocity then reduces sharply about 150 mm before the edge of the row of roughness elements. The sharp reduction in velocity between the peak velocity and the low velocities inline with the roughness elements is notable when it is compared with the increase in velocity in the same area when only one row of roughness elements is present. The increase recorded when two rows of roughness elements are (MAIN CHANNEL) Row 1 Row 2 Row 3 Row 4 Sub-channel 1 Sub-channel 2

Sub-channel 3

Figure 11. Vortices trapped between the roughness

elements.

present is more akin to what would be expected from

a smooth boundary.

The velocity in between the two rows of roughness

elements can be seen to be very low. The velocities in

the main channel and right hand floodplain run par

allel with those recorded for the series C2 at around 3 cm/sec faster.

The velocity profile recorded when 3 rows of rough ness elements were present (Series C4) appears to indicate that the maximum velocity behind the rough ness elements occurs quite rapidly. It appears also that the maximum velocity recorded on the floodplain is again similar in magnitude to that recorded for series C2 and C3. Comparing the peak velocities between rows 1 and 2 and rows 2 and 3 and those behind row 3 there appears to be a stepped increase as distance from the main channel increases.

This phenomenon was not predicted, although it would fit in well with the hypothesis of secondary flow structures being set up between the roughness elements (see Fig. 11).

The velocity in the main channel for series C4 appears to peak at around the vicinity of the main chan nel right hand bank.The peak velocity on this occasion is seen to be approximately equal to that recorded in the main channel for the smooth floodplain case. The velocity profile goes through a transition stage simi lar to that experienced in the smooth case as the water depth reduces coming onto the right hand floodplain.

The right hand floodplain velocities again run approx

imately parallel with those recorded for the smooth

case (Series C1) but at around 0.7 m/s faster.

When the row of half roughness elements is added

(Series C5) at the left hand floodplain wall, it would

appear that the secondary flow structures are com

pletely stabilised. The stepped increase in velocities

occurring between the rows of roughness elements is

again apparent on the left hand floodplain, this time

quite a regular increase appears to have occurred.

The maximum velocity in the main channel has

been offset to the right bank of the main channel, and as was the case when three rows of roughness elements where present,The maximum velocity occurring is slightly greater than that which occurred in the smooth case. The expected transition in velocity between the main channel and the floodplain does not occur; instead the high velocities carry over into the floodplain, resulting in a velocity profile similar to what would be expected at much deeper flow depths, when the compound channel begins to act as a single channel. 3.3.2 Asymmetric compound channel Figure 10 shows that the velocity profile for the asymmetric channel with a smooth wall baffling the left hand floodplain (Series C6) approximates to that recorded for the symmetric channel when no roughness was present on the left hand floodplain. The same is true for series C6. The velocities occurring in the main channel when 3.5 rows of roughness are present are slightly higher than these. This indicates that not only do the secondary flow structures set up between the roughness elements cause an effective ‘hydraulic smoothing’of the row of roughness elements they also appear to cause an acceleration of the flow near the unroughened floodplain edge. This acceleration may be caused by the flow structures somehow acting to linearise the flow paths of the water particles in the main channel or vortices between the roughness elements may act to speed up the water. It must be borne in mind when reading the results that the velocity profile comparison in Fig. 10 is for a relative depth of around 0.5. At lower depths the velocity profile obtained for 3.5 rows of roughness elements does go through a transition stage between the

main channel and floodplain. 4 COMMENT The results presented in the previous section highlight behavior which was not predicted at the outset of the experimental program. When a single row of roughness was added to the compound channel, it significantly reduced the channels discharge capacity. The magnitude of the reduction in capacity was greater than that which was expected. The elemental stage discharge relationships indicated that the roughness elements not only reduced the capacity of the floodplain they were present on, but actually reduced the capacity of the main channel as well as the un-roughened floodplain. The cross sectional velocity profile illustrates how the reduction in capacity is spread across the channel. The velocity in the portion of the left hand floodplain which is behind the roughness elements is reduced from what was recorded in that area when the floodplain was smooth. This is what was expected, as

turbulence in the area would be expected to have

increased.

When a row of roughness elements is added behind

the roughness elements there is a slight increase in dis

charge capacity overall as can be seen in Figure 3. Fig

ures 4 to 9 show that this increase in discharge capacity

is attributable to the main channel and the right hand

floodplains discharge capacity increasing. Figure 7

shows that the floodplain on which the roughness ele

ments are actually placed reduces in discharge capacity

as would be expected, however the reduction in the

capacity of the left hand floodplain when row 2 was

added is only about a half of the reduction in the capac

ity experienced when row 1 was added. The increase in

capacity in the main channel and left hand floodplains

are greater in magnitude however and overall the result

is that the compound channel is more efficient.

When the third row of roughness elements is added the increase in the discharge capacity of the com pound channel is much greater. The elemental stage discharge relationships show that the roughened flood plains reduction is similar to that experienced when the second row of roughness elements was added, however the increase in the capacity of the main channel and right hand floodplain is much more significant than that experienced when row 2 was added.

The addition of the half row of roughness elements has little impact on the main channels discharge capac ity however it causes a slight increase in the capacity of the right hand floodplain. The left hand floodplains capacity is reduced slightly, as expected.

5 VORTICITY

It would appear from the behavior of the main channel that as rows of roughness elements are added behind the initial row the turbulence in the main channel is reduced. It may be assumed therefore that the pres ence of rows of roughness behind the initial row causes an effective hydraulic smoothing of the ‘surface’ of the row of roughness elements. The reason for this ‘hydraulic smoothing’ may be that eddy structures are developed between the roughness elements, as shown

in Figure 11 below

It would be reasonable to assume that the size of

the vortex developed either side of the block depends

on the velocity differential, ie: if the velocity of the

water at side 1 is significantly lower than the velocity

of the water on side 2, then the vortex that is devel

oped on side 2 will be much larger than that which

is developed on side one. The larger and stronger the

vortex developed, the smoother the side will effectively

become.

Figure 12 below illustrates a possible mechanism of

vortexes, based on the principles highlighted in Fig

ure 11 above. Figure 12 represents the case when 3.5

rows of roughness elements are in place. Figure 12. 10
Second exposure of water surface floats traveling
downstream between roughness elements. The arrow size used
in the Figure 11 represents the velocity magnitude in each
of the sub channels. The fast moving main channel on the
right of row 1 causes quite a large, strong vortex to
develop between the roughness elements of row 1. This
causes the right hand surface to be ‘hydraulically
smoother’ for the water in the main channel, by reducing or
preventing water from the main channel being drawn in
between the roughness elements, as well as reducing the
amount of outflow from the floodplain into the main channel
between the roughness elements. This then permits the flow
paths of the water particles therein to linearise. Because
the vortex on the right side of row one is so strong, it
only permits a small vortex (or perhaps none at all) to
develop on the left hand side, meaning that the surface of
the roughness elements is ‘hydraulically rougher’ on the
right side of sub-channel 1 (Fig. 11). Because this is the
case, then the vortex developed at the left side of
sub-channel 1, is also weak, due to the low velocities
caused by the right hand side. Hence the vortex at the left
side of row 2 has more chance to develop, resulting in a
smoother surface on the left of row 2, allowing the

velocity in sub-channel 2 to develop slightly higher. Sub-channel 3 develops to a still higher velocity via a similar process. Surface floats and dye injection techniques were used to try to capture the above vortex structures. Figrue 12 is an image of luminous floats traveling down the roughened floodplain. The image was captured over a ten second time period. The variation in the velocity of the three sub-channels is apparent in the picture by the variation in the distance traveled downstream in each of the sub channels over the 10 second time period. Some indication of the eddy structures (MAIN CHANNEL) Row 1

Flow enters between the

roughness elements, and

rather than commencing to

swirl, it is carried

downstream by the flow on

the other side. This works in

both directions as shown

Figure 13. Schematic of flow interaction between main

channel and floodplain, when 1 row of roughness elements

is in place at the main channel edge.

can also be seen, as well as some interchanging of

flow between the sub-channels.

Video was also used to capture the patterns of

the floats flow paths. Analysis of these indicates that

there are secondary flow patterns within the sub

channels themselves (indicated by the dashed vortices

in Fig. 11). These secondary flow patterns would act

to stabilize the vortex structures between the rough

ness elements, preventing the flow in the faster moving

main channel from destructing the vortex structures as occurs when a single row of roughness elements is present (see Fig. 13 above).

Flow visualization indicates that there is mass transfer between the roughness elements in both directions when only one row of roughness elements is present on the floodplain, as shown in Figure 13 above, although most transfer seemed to be taking place from the flood plain to the main channel, indicating that the main channel was effectively sucking the slower moving water in the floodplain into itself.This obviously would cause turbulence on both sides of the roughness elements. When only one row of roughness elements was in place irregular, unstable ‘gushing’ was observed between the roughness elements, also pointing to flow structures such as the above.

6 CONCLUSIONS

1. When a single row of roughness elements is added beside the main channel a significant reduction of around 20% in the capacity of the compound channel is observed.

2. When subsequent rows of roughness elements are added behind the initial row of roughness elements it has a positive effect on the compound channels discharge capacity.

A study of turbulent flow structure in a partly vegetated river reach

T. Sukhodolova, A. Sukhodolov & C. Engelhardt

Institute of Freshwater Ecology and Inland Fisheries, Berlin, Germany

ABSTRACT: The development of macrophytes in rivers modifies hydrodynamic variables and complicates

prediction of retention of particulate organic matter in fluvial systems. The paper presents some results of a field

study designed to explore distribution of turbulence characteristics in a cross-section of a low land river partly

inhabited by submersed macrophytes. The analysis is focused on applicability of semi-analytical solutions to

describe spatial structure of the flow as a combination of simple flow models. Particular, it is shown that flow in

macrophyte stands can be described by the mixing-layer model, while between the stands the flow approaches

conventional logarithmic law. A comparison with the flow non-affected by vegetation is also presented and the

differences quantitatively evaluated.

1 INTRODUCTION

Although freshwater macrophytes colonizing small

lowland rivers produce considerable biomass – a source of fine particulate organic material utilized by invertebrates (Cushing & Allan 2001), the role of macrophytes in ecosystems is generally associated with their effect on river flow and habitats of sundry species of the aquatic life (Carpenter & Lodge 1986).A quantitative assessment of the effects of macrophytes represents therefore a challenging task for ecologists, river practitioners, and the community of hydrodynamic scientists (Denny 1988; Nepf 1999; Righetti & Armanini 2002). Numerous difficulties make the field studies scarce and the quantitative methods are mainly developed in laboratory flume studies (Stephan & Gutknecht 2002). Therefore application of methodological approaches always requires verification and adaptation to the conditions of natural streams and is presently precluded by the lack of field data.

Macrophytes form patchy patterns composed of stands variable in dimension and locality, having well defined margins leading to the development of significant gradients in flow velocities. Within the stands the flow is reduced due to the shading by stems and leaves of plants and hence the sedimentary deposition processes are enhanced. Spatially the stands are separated by areas of free flowing water that promote active

transport of bedload (Sand-Jensen & Pedersen 1999).

The patchiness of spatial patterns and spatial variety in

species composition of stands are prominent proper

ties differentiating flows in natural streams from their

laboratory surrogates. Complexity of the spatial patterns results in the subsequent complexity of flow patterns that absorb wakes behind stands, internal boundary layers developing over plant canopies on the general pattern of the openchannel flow (Nezu & Nakagawa 1993). Because the quantitative assessment of those flow patterns (wakes, mixing and boundary layers) requires consideration of turbulence characteristics (Nepf 1999), the field study's design should consider the measurements of turbulence characteristics and turbulent stresses as the most essential variable. Unfortunately available field studies are limited to the measurements taken on some verticals along the stand's length and provide only turbulence fluctuations as the measure of turbulence (Sand-Jensen & Pedersen 1999). Theoretical basis for assessment of peculiarities of velocity field in geophysical flows is provided by the logarithmic law where U , U * =mean and shear velocity respectively, k = constant, z= vertical coordinate originating at bed, and z 0 = hydrodynamic roughness. For flows over vegetation equation (1) is modified by the introduction of displacement height δ (Figure 1). δ z U

Figure 1. Scheme of the flow over vegetation.

In the laboratory flows the thickness of macro

phyte layers is preserved to be small compared to the

total flow depth, thus favoring the application of equa

tion (2). However, the height of macrophyte stands in

natural streams may reach the values comparable to

the local depth of the flow, consequently making (2)

insufficient if not inapplicable. Raupach et al. (1996)

have suggested using mixing layer analogy for the flow

inside and on the upper edge of the vegetation canopy

and consequently the mean velocity profile can be

described as (Michalke 1965)

where U s =ΔU/2,ΔU = difference in the mean

velocities across the mixing layer.Application of equa

tion (2) to the river flow conditions requires knowledge

of shear velocity, then hydrodynamic roughness can

be evaluated by fitting the measured velocity profile.

Local shear velocity value can be estimated only from

the measured distribution of turbulence stresses since

in the spatial complex flow with vegetation its value

is supposed to deviate substantially from the value

corresponding to the uniform flow condition

where g= gravity acceleration, h=mean flow depth,

and S = slope of the free surface. Close examina

tion of turbulence characteristics and their comparison

with the typical distributions in mixing layers are also

required for equation (3) which has not yet been so

popular as equation (2) in river flow applications.

Developments in the acoustic methods for mea

surements of turbulence characteristics (Kraus et al.

1994) and their success in river flow applications

(Sukhodolov et al. 1998; Rhoads & Sukhodolov 2001) inspire to perform advanced field studies. This paper represents some results of a study conducted: i) to explore spatial structure of the flow in a partly vegetated channel of lowland river; ii) to verify applicability of the conventional logarithmic law (equation (1)), modified

logarithmic law (equation (2)), mixing layer analogy (equation (3)); and iii) to portray the spatial patterns of turbulence characteristics in the crosssection of the river and relate them to the integral characteristics of mixing and hydraulic retention. 2 FIELD MEASUREMENTS 2.1 River reach The study is based on turbulence measurements carried out in the Spree River near the village of Freienbrink, 10 km east of Berlin, Germany. In the study reach the channel is straight with stonearmored banks and with a bed covered by sands of about 1 mm mean diameter. Measurements were performed in July 2000 at water discharge of 3.25 m 3 /s that provided following bulk characteristics of the flow: mean velocity 0.19 cm/s, river width 20.6 m, averaged depth 0.83 m, free surface slope 1.18× 10 −4 , Froude number 0.07, Reynolds number 0.2× 10 5 , shear velocity according to (4) 3 cm/s. The typical macrophytes in the study reach were Sagittaria Sagittifolia, Potamogeton Crispus, and Ceratophyllum Demersum (Figure 2). 2.2 Measuring system and equipment Instantaneous velocities were recorded in this study with the acoustic doppler velocimeters (ADV) manufactured by Sontek, Inc. ADV consists of a field probe connected to splash-proofed electronics. The probe has a sampling volume of 0.125 cm 3 located 10 mm from the probe head. The resolution of ADV is 0.1 mm/s with a noise level of 1% of the velocity range at sampling frequency of 25 Hz. The probe was mounted on a special tripod (Figure 3) enabling accurate vertical alignment of the device and preventing the flow-induced vibration. Alignment of the probe, positions of the vertical profiles, and determinations of the water slope were performed with a laser total station. 2.3 Measurements and data processing Velocities were measured at 10 vertical profiles uniformly spaced across the river width. Eight velocity profiles included 5-point measurements over the local depth and two profiles comprised of 12 points each. The time of velocity recording was 3 minutes, providing sufficient accuracy for computing turbulence characteristics (Sukhodolov et al. 1998). (a) (b) (c)

Figure 2. Sagittaria Sagittifolia (a), Potamogeton Crispus

(b), and Ceratophyllum Demersum (c).

Time series of velocity measurements were inspec

ted visually during sampling to identify obvious errors,

such as systematic acoustic noise caused by leaves of

plants on the sampling volume of sensor or the sen

sor itself. When necessary, the sampling duration was

increased to obtain a clean record of data. The effect

of doppler noise was evaluated by placing the probe

in a bucket of still stream water, obtaining velocity

measurements over an appropriate sampling interval

(Nikora & Goring 1998). These tests indicated that the

variance of acoustic noise for each velocity component

is a least 2 orders of magnitude less than the variance of Figure 3. The ADV probe mounted on the tripod in the vegetated reach of the Spree River. each measured velocity component. Following the recommendation to perform as little conditioning of the data as necessary, based on its quality (Stull 1988), no lowpass filtering of the data at high frequencies was conducted. Under low noise conditions such filtering can modify the data to a greater extent than the noise (Bath 1974). However, a few of the time series contained spikes caused by the interruption of acoustic beams by leaves. Such spikes typically span 3 to 6 individual velocity readings (at 25 Hz) and have a noticeable influence on high-frequency portion of power spectra (Sukhodolov & Rhoads 2001). A 3sigma filter, where sigma is the standard deviation of the data, was used to remove spikes from the time series.Application of the filter removed spikes without altering the rest of the time series. 3 RESULTS AND ANALYSIS A coordinate system with a streamwise x direction, a transverse y direction of positive values toward the right, and a vertical direction z originating at riverbed and directed toward the free surface is adopted herein. The corresponding velocity fluctuations are u ′ , v ′ , and w ′ , respectively. 3.1 Flow field overview The records of velocity time series were processed to obtain mean values and turbulence characteristics. Total turbulence shear stresses were computed as and turbulent kinetic energy in accordance with 0 30 U h , c m / s 1.2 1.0 0.8 0.6 0.4 0.2 0.0 h , m 5 1 0 1 2 . 5 1 5 2 0 2 2 . 5 2 5 2 7 . 5 3 0 2 5 1 5 1 7 . 5 2 0 2 2 . 5 5 2 . 5 1 0 1 2 . 5 (a) 1 2 0 5 τ h / ρ , c m 2 / s 2 0 . 1 0 . 5 1 . 5 1 . 0 1 . 0 0 . 5 1 . 5 1 . 5 2 . 5 1 . 0 3 . 0 5 . 0 7 . 5 8 2 . 0 0 . 5 2 . 0 4 . 0 2 . 0 2 . 5 2 . 5 1 2 1.2 1.0 0.8 0.6 0.4 0.2 0.0 h , m 3 . 0 1 . 0 0 . 1 (b) 0 4 8 12 16 20 0.0 0.5 k h / U h 2 0 . 3 0 0 . 2 5 0 . 1 5 0 . 2 0 0 . 1 2 5 0 . 1 0 0 . 0 5 0 . 1 5 0 . 1 7 5 0 .

Figure 4. Distributions of mean velocity (a), shear stress (b), and turbulence intensity (c) in a cross-section of the Spree River

near the village Freienbrink. Banners indicate the locations of the profiles surveyed with extended resolution. Shaded areas

indicate projections of the macrophyte stands. Depth-averaged values are shown on the top of correspondent cross-sectional

plots.

Obtained values were used to plot spatial distribu

tions of local mean velocities (Figure 4a), turbulence

shear stresses (Figure 4b), and dimensionless values of

turbulence kinetic energy I = k/U 2 often called turbu

lence intensities. The distributions of plants species,

abundance, and depth-averaged flow characteristics

are also shown in Figure 4. In the crosssection of the

river, the macrophytes formed four well-distinguished

stands (Figure 4).

Two stands were attached to the riverbanks; two oth

ers were located at offsets 5–6 m and 13–15 m from the

left bank respectively. The stands in the central part of

the flow were exclusively formed by Sagittaria Sagit

tifolia. Owing to elongated and streamlined leaves,

Sagittaria Sagittifolia sustains relatively high veloc

ities developed in the central part of the channel.

Potamogeton Crispus was present in the stand attached to the left bank and exposed to the north. Cerato phyllum Demersum was growing in the stand at the right bank, and obviously increased the density of vegetation distribution inside the stand.

Close examination of spatial distributions of the three principal quantities of the mean flow and tur bulence characteristics (Figure 4) indicates a notable difference between flow patterns over stands in the central part of the channel and those attached to the banks. The distributions of flow characteristics near the banks are nearly uniform over flow depth and gradually change toward the water’s edge. In contrast, the flow patterns over the stands in the central part exhibit variations in both the vertical and transverse directions. Although the depth averaged mean veloc ity distribution (Figure 4a) displays reduced values for areas with stands, significantly increased val ues of turbulence stresses are only attributed to the Sagittaria Sagittifolia stands in the central part of the cross-section (Figure 4b).

Two vertical profiles of turbulence characteristics were measured with greater spatial and temporal reso lutions. The locations of these profiles are shown with banners in Figure 4. Profile 1 was sampled in the area

between macrophytes stands, and profile 2 inside the stand located in the central part of the flow. The results and analysis described in the following sections will be dedicated to the examination and comparison of distributions of characteristics for those profiles.

3.2 Vertical profiles of turbulence characteristics

Distributions of turbulence primary shear stress over flow depth- u ′ w ′ = f (z/h) measured at verticals 1 and 2 are shown in Figure 5. The stresses values for the profile 1 were scaled with the local shear velocity U ∗ = 1.38 cm/s; the value determined fitting the linear regression as (Nezu & Nakagawa 1993) 0 0.2 0.4 0.6 0.8 1 0 0.2 0.4 0.6 0.8 1 z / h ▯u▯w▯ / U 2 0 0.005 0.01 0.015 0 0.2 0.4 0.6 0.8 1 z / h -6 -4 -2 0 2 4 z / δ m (a) (b) 1 2 equation (7) Wygnanski & Fielder (1970) Fischer et al. (2003) ∗ ▯u▯w▯ / ▯U 2 Figure 5. Distributions of turbulence shear stresses over the flow depth (a) in the area between stands, and (b) in the stand of macrophytes. For the comparison with the conditions of vegetationfree channel in the same river reach, the dimensionless data by Fischer et al. (2003) are also presented in Figure 5.

Stresses measured in the macrophyte stands (profile 2) were scaled with the mean velocity difference across the mixing layer ▯U = 30 cm/s to fit the similarity curve by Wygnanski & Fiedler (1970). Momentum thickness of the mixing layer δ m equaled 11 cm, and its averaged center position was located at z/h= 0.6.

Obtained local value of shear velocity was used to scale values of mean velocity for profile 1. Fitting conventional logarithmic law (1) to the dimension

less data, the value of hydrodynamic roughness height z 0 = 0.013 cm (von Karman parameter equaled 0.41) was assessed. The mean velocity values measured in macrophyte stands (profile 2) were scaled accord ing to equation (3) using the values U s = 15 cm/s and U 0 = 11 cm/s. The results of measurements are presented in Figure (6).

Vertical distribution of turbulence kinetic energy in the open-channel flow obeys the semi-theoretical relation proposed by Nezu & Nakagawa (1993) where D k = 5.72, and C k = 1.0 – empirical coeffi cients (Sukhodolov et al. 1998). Measured k values scaled with U ∗ and U , defined from stresses distri butions for profiles 1 and 2 respectively, are shown in Figure 7. A dimensionless curve by Wygnanski & Fiedler (1970) is plotted in Figure 7b for comparison.

3.3 Turbulence spectra and scales

Turbulence spectra are often used to assess turbu lence energy generated by the interaction of mean flow with vegetation. Golovatiuk & Nikora (1984) and Nepf (1999) report existence of two wellseparated, narrow energy supply regions in turbulence spectra attributed to shear turbulence (lowfrequency) and wake turbu lence (high-frequency) because of separation of flow on plant stems (Nikora 2000; Nepf 2000). In addition,

the dissipation rate values and, respectively, the inter

nal scales of turbulence (Kolmogorov scale) can be

obtained processing the turbulence spectra in the frame

of homogeneous isotropic turbulence theory (Monin &

Yaglom 1971).

Turbulence spectra were calculated using the auto

covariation functions and smoothed with the Tukey's

correlation window (Jankins & Watts 1968). Typical

turbulence spectra measured in this study are presented

in Figure 8.

Owing to relatively low turbulence level, the spectra

were affected by acoustic noise at higher frequen

cies. Averaged noise spectra, obtained in still river

water as recommended by Nikora & Goring (1998)

are shown in Figure 8. Integrating spectral densities

over different frequency bands provided the quantita

tive estimates of noise impact. It was obtained that on

average, noise contributed 1–5% extra energy into the 0.01 0.1 1 0 0.2 0.4 0.6 0.8 1 z / h (a) -0.5 0 0.5 1 1.5 2 0 0.2 0.4 0.6 0.8 1 z / h -6 -4 -2 0 2 4 z / δ m (b) 1 2 equation (1) equation (3) Figure 6. where ν= kinematic viscosity. Dimensionless distri

butions of the Kolmogorov’s scales are presented in Figure 9.

3.4 Hydraulic effect of vegetation

The overall hydraulic effect of in-stream vegetation is generally perceived through the increase of the mean depth, decrease of mean velocity, and, respectively, in the enhanced hydraulic retentivity of the stream as compared to the non-vegetation conditions. For the investigated river reach such a comparison is possi ble because of availability of a comprehensive set of measurements of water discharge, mean flow veloc ities, and depth. The observations formed this data set were conducted systematically as one measure ment per month during a period of three years. The measurement program was comprised of mean veloc ity measurements with electromagnetic current meter in 5 points at every vertical. Verticals were located every 2 m across the width of the river. The data and empirical relationships between discharge and bulk flow parameters for nonvegetation conditions are pre sented in Figure 10. For discharge Q= 3.25 m 3 /s, from the empirical relationships U = 0.14Q 0.47 , the value of mean velocity equals 0.24 m/s, and mean river depth from H = 0.43Q 0.42 equals 0.71 cm. Thus, velocity was reduced about 27% whereas depth increased 17%.

The low-transit flow areas sometimes called dead

zones are recognized for extended hydraulic retentivity

and can be described in the frame of the longitudi

nal model with dead zones (Valentine & Wood 1977, 0 10 20 30 Q, m 3 /s 0 0.2 0.4 0.6 0.8 U , m / s a) 0 10 20 30 Q, m 3 /s 0 0.4 0.8 1.2 1.6 2 H , m b) Figure 10. Measured bulk velocity (a) and depth (b) as the functions of discharge for the experimental river reach. Czernuszenko et al. 1998) where ε= dead zone parameter, A d = area of dead zone in the cross-section, B=width, and h=mean depth of the flow. Assuming that the projection of macrophyte stands on the cross-sectional area approximate the area of dead zones, it is possible to assess the effect of macrophytes on the hydraulic retention of dissolved matter in the flow using the relationship by Czernuszenko & Rowinski (1997) where T = retention time, D= longitudinal dispersion coefficient, U =mean velocity, and x= distance from the point of release. As the first term in (12) represents the initial size of the contaminant cloud, it can

be neglected for the fixed distance x. With this sim

plification, the ratio between retention time T M of the

vegetated channel and retention time T of a vegetation

free channel can be represented as

and gives a value of 1.67 for this case study.

4 CONCLUSIONS

The results of this study contribute to the under

standing of the three-dimensional spatial and temporal

structure of turbulence in partly vegetated sandy bed

lowland river. Analysis of cross-sectional patterns of

mean velocities and basic turbulence characteristics

indicates that submersed macrophyte stands located

in the central part of the flow produce flow pat

terns different from those formed by macrophytes in stands attached to the river banks. Flow pattern and composition of stands were interrelated: plants with streamlined morphology of stems and leaves were dominant in the stands of the central part of the stream, while those attached to banks stands were more diverse and dense. Consequently, the descriptive analysis of flow patterns and their quantitative characterization require different models to serve as the conceptual framework for the analysis.

In this study two approaches were examined: an application of the open-channel plane quasiuni form flow for the vegetation-free patches between stands and the mixing layer analogy for the flow over macrophyte stands. The analysis is concerned with the distribution of mean velocities, shear stresses and turbulent kinetic energy over the river depth.An agree ment between theoretical and experimental results was established, favoring therefore the application of hybrid models for quantitative analysis of complex flow patterns.

The overall hydraulic effect of in-stream vege tation was estimated. Obtained results indicate the significance of the macrophytes' effect on retention processes in natural streams and outline the necessity

for complex field investigations comprised of tracer

experiments on longitudinal dispersion and investiga

tion of complex spatial patterns of velocity field and

turbulence characteristics.

Open channel turbulent data modeling using fractal geometry

A.N. Ziaei, & A.R. Keshavarzi

Irrigation Department, Shiraz University, Shiraz, Iran

H. Emdad

Mechanical Eng., Department, Shiraz University, Shiraz, Iran

ABSTRACT: Fractals are objects that display self-similarity or self-affinity over a wide range of scales. Fully

developed turbulence indeed consists of a hierarchy of eddies, or scales of various disorders. Thus, this can be

one type of fractal. Turbulence can be studied in velocity field. Time series of velocity components are very

irregular. Modeling of such velocity fluctuations using Euclidean functions is almost impossible, however, fractal

interpolation functions (FIF) can be attractive tools to fulfill this desire.

In this study, FIF was used to model more than 200000 time series of velocity fluctuations and Reynolds

shear stress in open channel flows. Fractal dimension of velocity fluctuation components and shear stress

was calculated using FIF. Fractal dimensions of u', v', and $u'v'$ were found to be 1.615, 1.657, and

1.559, respectively. The relationships of fractal dimension with Froude and Reynolds numbers were also

investigated.

1 INTRODUCTION

In the most basic sense, fractals are objects that display

self-similarity over a wide range of scales. Analogous

to the Euclidean dimension of classical objects, each

fractal object, or turbulent eddy, is associated with

a characteristic dimension called the fractal dimen

sion. It forms a basis to measure the fragmentation or

roughness. Richardson (1922) pointed out that fully

developed turbulence indeed consists of a hierarchy of

eddies, or scales of various disorders. Turbulent eddies

have their corresponding large, little, lesser, and least

wiggles-down to where viscosity stops the process.

Thus this can be one type of fractal. If we consider

these turbulent eddies as fractal objects, then the the

ory of fractals may be applicable to turbulence (Jaw &

Chen, 1999).

Fractal geometry concerns with complicated subset

of geometrically simple space such as R 2 . In deter

ministic fractal geometry the focus is on the subset

of a space that are generated by simple contractive

geometrical transformations of the space into itself. A

transformation f: X→X on a metric space (X, d) is

called contractive or contraction mapping if there is a

constant 0≤ s< 1, such that: d(f(x), f(y))≤ s d(x, y)∀

x, y∈X. A general affine shear transformation can be defined as: where a n , c n , d n , e n , and f n are transformation parameters. This means that on the x-y plane, lines parallel to y-axis are mapped into lines parallel to y-axis. Every contractive mapping on a complete metric space has a fixed point on that metric space. To define a fractal object, it is first necessary to define iterated function systems (IFS). 1.1 Iterated function systems An iterated function system (IFS) consists of a complete metric space (X, d) together with a finite set of contraction mapping W n : X→X with respective contractivity factors s n , for n= 1, 2, … , N. The notation for the IFS just announced as {X; W n , n= 1,2, … , N} and its contractivity factors is S=max {s n , n= 1,2, … , N}. Let now {X; W n , n= 1,2, … , N} be an iterated function system with contractivity factors. Then the transformation W: H(X)→H(X) defined by

W(B)=∪W n ; n= 1, … , N for all B∈H(X) is a con

traction mapping on the complete metric space (H(X),

h(d)) with contractivity factor S. That is, h(W(B),

W(C)) ? S h(B, C) for all B, C∈H(X). Its unique

fixed point,A∈H(X) obeysA=W(A)=uW n (A) and

is given by A=Lim n→∞ W on (B) for any B∈H(X).

The fixed point A∈H(X) described above is called the

attractor of the IFS. The attractor is the fractal object.

In order to show a very irregular and ragged curve

of turbulent properties such as temporal variations of

velocity fluctuation components and Reynolds shear

stress is a fractal object, it should be accurately mod

eled by a set of self-affine maps. Fractal interpolation

function (FIF) is a very powerful tool to modeling of

such curves. The graph of an FIF is the attractor of an

IFS that passes through the given interpolation points.

In other words, FIF also provide a new means for fit

ting experimental data such as velocity components

data. Moreover, one can ensure that the fractal dimen

sion of the graph of FIF agrees with that the data over

an a - propriate range of scales.

Let a set of data {(x i , F i)∈R 2 : i= 0, 1, 2, … , N}

(interpolation points) be given. The attractor, which is

denoted by G, is the graph of a continuous function f:

[x 0 , x N]> R which interpolates the data. If an IFS of

the form {R 2 ;W n , n= 1,2, … , N} is considered, where

the maps are affine shear transformations, the trans

formations are constrained by the data according to:

for n= 1, 2, … , N. The situation is summarized in

Figure 1.

Let d n be any real number, the above equations can

always be solved for a n , c n , e n , and f n in terms of the

data and d n . i.e.

Then the fractal dimension of the FIF can be calcu

lated by: Figure 1. Construction of FIF using IFS of shear transformation (after Barnsley, 1993). Figure 2. Schematic of fixed points and target points distribution (after Marvasti & Strahle 1995). where D is the fractal dimension. Up to now it is explained how to calculate a n , c n , e n , and f n , but two other parameters are unknown; the first one is number of transformations (N) and the second one is d n , which is afterwards called vertical scaling factor (VSF). Strahle (1991) presented a simple method to calculate the VSF. It suffers from some shortcomings. Marvasti & Strahle (1995) improved the previous method. Their algorithm also starts by categorizing the data into fixed and target points. But unlike the Strahle's method, the number of target points between each pair of fixed points is declared as a variable. This scheme is shown in Figure 2. The dark solid points are the fixed points and the smaller ones are the target points. What remain to be determined are N and d n . This scheme doesn't suggest any idea for selection of N, but the vertical scaling factor d n is obtained by first drawing a line between the first and the last data point (i.e. (x 0 , F 0), and (x N , F N)). Next the point which has the longest vertical distance to the line is calculated. This is designated as μ in Figure 2 that can be positive (point above the line) or negative (point below the line). A line is then drawn between the fixed points on

the nth interval and the distance of the farthest target

point above or below this line is calculated.This is des

ignated as ν n in Figure 2. The vertical scaling factor is

then defined as:

Although this scheme doesn't have some of the pre

vious method's difficulties, but the minimum essential

target point to generate accurate model is unspecified.

Mazel & Hayes (1992) presented geometric and analytic methods to calculate the VSF. The geometric method is the same as Marvasti & Strahle method. The analytic method is based on least square optimization. Furthermore, they presented an iterative algorithm for finding both the interpolation points and the VSF for a given arbitrary data set. The algorithm is based on the property that the resulting fractal function is self affine. By the collage theorem, if the function can be covered with affine transformation of itself, and have the distance between the function and the collage of the function small, the attractor of the IFS will be a close approximation to the function. However, since the algorithm uses exhaustive search, it is too time consuming to be of practical use.

Vines (1993) compared results of different methods for one-dimensional signal modeling. He suggested using local extremums of the data sequence as the fixed points of the maps. The extremum points are obtained by introducing some filters, and selecting those points which have the most deviation. Vines (1993) showed that this method is very efficient and the results are comparable with exhaustive search. In this manner, even without the effect of the IFS, the model roughly

follows the original data using a series of straight-line segments. Then the mapped data portion can be used to further increase the accuracy of the model. Due to advantages of the last approach, in this study it is used with few improvements for turbulent data modeling.

In this study, the improved FIF is used to model time series of certain flow properties such as u', v', and $u'v'$ in open channel flow. It is utilized to prove that these properties can be categorized as fractal objects. The reliability of the method for calculating the fractal dimension of data set is also scrutinized. Then it is applied to calculate the fractal dimension of the turbulent data. The relationships between fractal dimension of the flow properties and Reynolds and Froude numbers are also studied.

2 DEVELOPED COMPUTER PROGRAM

The Vines (1993) and Mazel & Hayes (1992) methods were incorporated to obtain the efficient number of interpolation points and suitable vertical scaling factors. The required computer program was developed using Matlab Language. The program consisted of a main body and five subroutines (Figure 3). The program is based upon the flowchart shown in Figure 4.

EXTREMUM MAIN BODYLFIF FD VSF VFLUC Figure 3. Structure of the developed computer program.

2.1 Input file

Input file includes velocity components U and V that were measured during a period of time in a laboratory flume in different distances from the bed. Therefore, every input file consisted of an M× 3 matrix; M is the number of time intervals, in which the measurement was made.

2.2 Flowchart

In the main body of the program, after reading the input file, the VFLUC subroutine is called. In this part, velocity fluctuations components

(u ′ , v ′) are calculated. Turbulent shear stress (u ′ v ′) is calculated as multiplication of the velocity fluctuation components. Afterwards, t, u ′ , v ′ , and u ′ v ′ are stored as column vectors. According to sign of u ′ and v ′ , u ′ v ′ values are divided into four quadrants. i.e. u ′ v ′ in different quadrants accompanied with their related time values and they are saved in separated matrices. All of the above matrices (i.e. t, u ′ , v ′ , u ′ v ′ , Quadrant 1, Quadrant 2, Quadrant 3, Quadrant 4) are stored in a cell array and returned to main body. Now turbulent data matrices are ready to fractal modeling. The next step is determination of fixed points. In order to determine fixed points (the number of maps), EXTREMUM subroutine is called. In START INPUT t, U,V u´=u-U , v´=v-V , u´v´= u´*v´ Quad 1-4 OO = {t, u´, v´, u´v´, Quad 1, Quad 2, Quad 3, Quad 4} i =1 X= OO{1} Y= OO{i} Determine local extrema and set as fixed points Determine data points between each pair of fixed points Calculate a n , c n , d n , e n , and f n Compute Df Eq. 6 n <= N Yes n = n+1 B = w n (X)=A n × X + T n n = 1, 2, …,N Attractor=B oj j = 1, 2, … i <= 8 i = i+1 Yes Store output files and plot graphs Stop

Figure 4. Flowchart of the developed computer program.

this subroutine, the local extremums of data set are

specified using a number of filters. They are:

- The extremum is a point on which the sign of

numerical derivative changes.

- Each maximum should be followed by a minimum

and vise versa.

- Sequential extrema which have a specific trend

should be removed i.e. (Figure 5),

The number of maps is equal to the number of

sequential pair of fixed points. To calculate the val

ues of a n , c n , d n , e n , and f n , after determination of

fixed points, the data points between each pair of fixed

points are specified in the main body. Every data set is Filter Figure 5. Sequential extrema with a trend. divided into N section (the number of maps or transformations). Each section as an array is entered into VSF subroutine to compute the largest distance between the line that connect two endpoints of the section and the data points. This value is v n . The average value of distances is also stored as g n . These values are returned to the main body. Then d n is calculated as: The values of mapping parameters a n , c n , e n , and f n are calculated in LFIF subroutine according to Equations 2-5. The fractal dimension is obtained by solving Equation 6 numerically in FD subroutine using Newton-Raphson method. Afterwards, since mapping parameters and the number of maps is known, the fractal interpolation function can be constructed. 3 DATA SET DESCRIPTION In this study the turbulent data, which had been measured by Keshavarzi (1997), were used. The data include time series of velocity components that are measured in experimental flume using 2D electromagnet velocity meter. Data sets comprised of different flow conditions in term of discharge, flow depth, velocity and in sequence, Reynolds and Froude numbers. Uniform and non-uniform flow conditions were stabilized using a gate at the end of the flume. Each test which was specified by a letter, consisted of several time series of velocity components measured in different distances from the flume bed. 4 RESULTS AND DISCUSSIONS The result of this study can be categorized in two main parts as follow: - u ′ , v ′ , and u ′ v ′ data modeling. - Fractal dimension of turbulent data.

Figure 6. Comparison between observed and computed u ′

(first iteration) for some data sets. 4.1 u ′ , v ′ , and u ′ v ′ data modeling The model has determined suitable local extremums which roughly follow the original data. Therefore, it was expected that the attractor be close enough to the data. The results of first iteration of the model are compared with measured turbulent data in Figure 6. According to collage theorem, the closer this run of model is to the data, the fractal interpolation function (attractor) closer to the given data set. The results revealed good agreement between measured and simulated data. In some data set there exist some deviations which are to some extend because of unsuitable local extremums. Using more restricted filters may decrease these discrepancies. Modeling the whole length of every data set is very time consuming. Thus only a small part of a couple of data sets were modeled. The computed fractal model using five iterations are compared with observed values for some

data sets in Figure 7. 4.2 Fractal dimension of turbulent data The strahle (1992) and marvasti and strahle (1995) methods were used to calculate VSF, and in sequence the fractal dimension. However, they required great number of data points to calculate accurate fractal dimension. Furthermore, for some data sets the calculated d n was greater than unity which was unacceptable. The results of the extremum method for a number of data sets are presented in Figures 8 and 9. The fractal dimension reached a constant value with about 500 data points. Therefore, the presented model is able to compute accurate fractal dimension with only 500 data points. This method can be a good substitution for the Box-counting method because the latter method has been very unreliable for some turbulent data sets due to the elusiveness of the flat region on the logarithmic plot (Marvasti and Strahle, 1995). 4.2.1 Fractal dimension of u ′ , v ′ , and u ′ v ′ data sets The fractal dimension of u ′ , v ′ , and u ′ v ′ for all data sets were calculated. All the values were averaged to calculate the mean fractal dimension of turbulence properties.The fractal dimension of u ′ , v ′ , and u ′ v ′ were found to be 1.615, 1.657, and 1.559, respectively. The mean fractal dimension (Df) of each test, averaging from different depths at which velocity measurements were made, and related flow conditions are tabulated in Table 1. These values are plotted versus Reynolds and froude numbers in Figures 10 and 11, respectively. It seems that Df is independent of Reynolds number. While Df and Froude number are somehow correlated. The results are reasonable because of dominancy of gravity force in open channel flows. As can be seen inTable 1, Fr greater than 0.6 belongs to uniform conditions. It is obvious that uniform flow

Figure 7. Comparison between observed turbulent data for

small parts of some data sets. Figure 8. Fractal dimension versus number of data for some data sets. Figure 9. Fractal dimension versus number of data for some data sets.

decreases the turbulence intensity and in consequence the fractal dimension of the velocity component and Reynolds shear stress. All the above results revealed that fractal dimension can be used to characterize turbulence properties. In other words, all wide range of length and time scales can be reduced to single parameters such as fractal dimension.

5 CONCLUSIONS

Fractal interpolation functions were successfully used

to turbulence properties modeling. Extrema method

found to be a good approach to find the desirable Figure 11. Fractal dimension versus Froude number. number of affine transformations. It was also more efficient than exhaustive search to find the optimum number of transformations. Moreover it was able to calculate accurate fractal dimension of the 1-d fractal curve with using the minimum number of data points (only 500 data points).

Time series of velocity fluctuation components and

turbulence shear stress were approximated using frac

tal interpolation functions. The approximation can be

improved by improving the extremum selection fil

ters or even by selecting them manually. There were

not a specific relationship between normalized depth

and fractal dimension of u ′ and v ′ for all data sets.

Fractal dimension of u ′ , v ′ and u ′ v ′ were correlated to

Froude number and somehow with Reynolds number

of the flow and this relationship was different in uni

form and non-uniform flows. The fractal dimension

of u ′ , v ′ , and u ′ v ′ range from 1.4 to 1.8 and the aver

age of them are 1.615, 1.657, and 1.559, respectively.

These values can be used for turbulence modeling in

open channel flows.

Expeditive methodology for river water discharge evaluation

M. Greco & D. Mirauda

CIMA-Department of Environmental Engineering and Physics, Basilicata University, Potenza, Italy

ABSTRACT: Recent aims and developments in water resource policies and management have been to achieve

a high level of protection in both river systems as well as in the environment by natural hazard prevention

and/or reduction. In river water management, the lack of direct field measures resulting from the necessity

to dedicate long periods of time and effort represents a weakness in control and forecasting procedures. This

paper is in reference to a detailed series of monitoring activities performed on Lucanian Rivers by applying the

expeditive methodology for water discharge measurement and assessment, which is capable of maintaining a

high quality data and results. Furthermore, this analysis allows us to show the results obtained by adopting the

entropy velocity distribution (Chiu 1988) on the data collected using the reduced point method and by performing

sensitive analyses on the entropy parameter, thus showing low variation in the estimation of water discharge.

1 INTRODUCTION

The need to design and construct systems of moni

toring and control for water resources that are able

to produce uniform, trustworthy and comparable data

comes from various needs in management, planning

and projects developed for the performance of ordi

nary and extraordinary operations of preservation and

conservation for the involved territory as well as for

the surrounding environment.

The crucial element of these interventions lies in

the availability and reliability of field data. Availabil

ity time is especially important in cases of emergency

and disaster. The limits of availability are due in part to

the heterogeneous area covertures of measuring sys

tems and their partial interconnection and integration and in part to constant conflicts between those organizations responsible for carrying out controls and measures, thus slowing down the information flow. Furthermore, the crucial need to maintain product efficiency in the system of measures is associated to this problem because it requires both innovative technologies (used in order to perform remote data acquisition and to successively transfer the data in real time) as well as continuous and systematic gauge calibration through integrations with ground data. This need is transversally present for monitoring physical, chemical and environmental parameters and it assumes a primary role in order to perform procedures under conditions of emergency.A prime example of this is the need for flood risks of a constant upgrading of depth/discharge scales in control sections. This upgrading represents a critical element in the chain of warning. Under this context, field operation efficiency is not a secondary aspect in order to have a correct level of operation for controlling and forecasting procedures which more often than not are considered less important than the performance of upgrades for modeling and measurement techniques. In the case of water discharge measurement, the difficulties encountered, occurring during the field activities, encourage the development and implementation of models of computation or measuring technologies developed in order to reduce the time of data acquisition and processing without having to sacrifice measurement precision. In this work, a detailed description of a series of monitoring activities performed on the principal rivers of Basilicata Region has been reported and a comparison between the possible methods of field measurement of liquid discharge has been made. Regarding to normative methods,

the reduced point methods (the three-point methods, the one-point method) have been employed maintaining the quality level of the final data product, dramatically reducing acquisition time. A further help is given applying mathematical models, derived from the application of maximization theories of the informational entropy (Chiu, 1987, 1989, 1991 and 1995), to the data collected in order to evaluate the flow field and compute the water discharge. The entropy velocity distribution, in fact, requires the assessment of one parameter, M, which can be

obtained through the knowledge of the mean – maxi

mum flow velocities ratio (Chiu, 1987). Moreover, the

extension of such law to natural flow allows sufficient

reliability also in condition of geometric irregularity

and for ordinary flow regime (Greco et al., 2002). The

application of the entropic profile to river flow deals

interesting results also for practical purposes in order

to define the velocity distribution in the cross sec

tion and provide an expeditive method to compute the

water discharge reducing the time for surveying and

computation.

2 FIELD MEASUREMENTS

The results presented and discussed below are in refer

ence to field measurements collected during surveying

and calibration activities performed on hydrometri

cal gauge stations managed by local Authorities for

the control of the main rivers of Basilicata Region

(Southern-Italy). Several measures were performed

at different cross sections of the Basento, Bradano,

Cavone, Agri and Sinni Rivers (Fig. 1) for the period

between February 2002 and March 2003.

The sections for the Basento River are located both upstream (BA1 station), in the mid-valley zone (BA2 station) and downstream (BA4 station and BA5 sta tion). The sections for the Cavone (CA2 station) and Sinni Rivers (SI1 station) are located in the mid-valley areas close to the delta, while the section for the Bradano River (BR1 station) is located in the mid valley zone and the section for the Agri River (AG1 station) can be found on the Sauro Torrent, which is the main tributary in hydraulic left bank.

The evaluation of river water discharge can be per formed according to the ISO 748/1997, using the velocity-area method which represents an efficient and reliable tool. Operatively, computations require the dividing the section areas into several verticals and a further subdivision of each vertical into discrete points, in order to evaluate the mean velocity of the flow along each vertical.

The velocity measurements were performed by using a current meter, a suitable diameter and a pitch propeller (Fig. 2a).The measurements were performed through wading by using a graduated rod and a mobile trolley system with a single drum winch fitted on it (Figs 2b,c). All field activities were recorded and in

field reports, information such as cross section data

(measurement code, river name, location name, sta

tion name, date and time of measurement, section

width, etc.), instrument data (propeller diameter, pro

peller pitch, measurement duration, calibration lines,

etc.) and row measurement data (distance, water level,

number of rounds, etc.) were included. SELE OFANTO BASENTO BRADANO CAVO NE AGRI SINNI LAO NOCE SI1 CA2 BA5 BA4 BR1 BA2 BA1 AG1 Mar Tirreno Mar Jonio Figure 1. Positioning of measurement stations. a) b) c) Figure 2. a) Current-meter for wading; b) equipment for performing measurements from bridge; c) sounding weight. 3 NORMATIVE METHODS The number of verticals and the distribution inside the cross section is chosen case by case based on section width, riverbed geometry and flow regimes and characteristics, while the measurement points are fixed according to the measurement methodology used, that is, by wading or bridge, and to technique. The main objective was to obtain a correct evaluation of the mean velocity for each vertical and measurement section which is related to a reliable reconstruction of field flow obtained through velocity point measurements in diverse positions of hydraulic sections distributed between the surface and riverbed. The most rigorous approach must strictly follow the criterion that the difference in velocity between two

consecutive points must be less than 20% compared

to the higher measured value and that the points found

close to the riverbed and to the surface must be fixed

according to the dimensions of the instrument used.

Once the velocity for each point along the vertical

has been obtained, it should be possible to calculate

the velocity distribution by which the mean veloc

ity for the vertical considered can be obtained. In

order to carry out a very accurate measure, the method

requires a long time and therefore it is not likely to be

applied in cases of systematic field measurement. In

order to avoid these difficulties, reduced point methods

are being used more frequently during field activities

because they require short periods of time and they

maintain a good level of accuracy as well.

These methods are classified as follows:

(a) two-points method: velocity observations are collected for each vertical by placing the currentmeter at 0.2 and 0.8 of the total depth measured below the surface. The average between the two values should be the mean velocity along the vertical:

(b) one-point method: velocity observations are collected for each vertical by placing the currentmeter at 0.6 of the total depth measured below the surface. The observed value should be the mean velocity along the vertical:

Methods much more refined and precise, but requir

ing long measurement times, propose the use of

equations in which velocity measurements are taken

at several different depths.

For example, in the six-point method the average

velocity is obtained by the following relation:

for the five-point method:

for the three-point method:

where v s and v b represent velocity observations near

the surface and the riverbed respectively.

Once the mean velocities of each vertical are eval

uated, it is possible to compute the water discharge using the mean-section method or mid section method. In the first

one, the partial discharge is computed by multiplying the average value of mean velocities of two adjacent verticals times the area included in the respective verticals. The equation of the partial discharge between two verticals 1 and 2, with depth d 1 and d 2 , mean velocities v 1 e v 2 and b horizontal distance between the two verticals, is the following: The total discharge is obtained by summing the partial discharges calculated. In the second method the partial discharge between two verticals is obtained as the product of each value of the mean velocity multiplied by the depth d i and the sum of the semi-distance between the adjacent verticals. The total discharge is obtained by summing these partial discharges in the following way: The latter method was used in the following elaborations in alternative to the mean-section method, because it gives more precise results and reduces computation time. Table 1 shows the discharges computed by applying the reduced point methods (one and three-point methods) and the six-point method for different rivers and periods. Particularly, the six-point method was the most ideal for calculating the most precise discharge value, according to the large number of measurements performed in the cross section and for each measuring vertical. Figures 3, 4, 5 and 6 show the comparison between the area-velocity curves derived using the mean velocity values computed on each vertical, starting from the measurements obtained through different methods. The graphs show the measuring sections of different rivers at various sampling times. The figures and table show a negligible difference between the discharge computed through the use of different methods and the relative uncertainties. There are slight deviations between the deviations SQ 6/3 and SQ 1/3 computed between the discharge measured through the three-point method, taken as datum discharge, and the discharges measured using the six-point and one-point methods respectively, as well as between the deviations I 6/3 e I 1/3 defined as:

uncertainty values (Table 2), it is seen how the

observed deviations, in absolute value, are always

lower than the minimum and maximum uncertainty

values. Therefore, deviations existing in the different

methods applied herein are very moderate compared

to systematic and random valuable errors. 4 ENTROPIC MODEL AND ANALYSIS Based on a probabilistic approach and using the concept of the informational entropy of physics system, Chiu (1988) derived the following relation of the velocity profile on a vertical: where u is the local velocity, § is a dimensionless variable, depending on the reference system adopted, § 0 and § max are the values to which correspond the minimum of the velocity (u= 0) and the maximum (u= u max) respectively, while M is the entropy parameter controlling the profile shape. The following relationship defines the coordinate §: where D is the maximum depth of the flow in the investigated cross section coinciding, in the present study, to the variable h max , h is the depth from the free surface in which the maximum of the velocity

is observed and y is the local coordinate perpendicular to the bottom, at which the zero velocity takes place. In the case of natural and artificial free surface flows, in which the current width is significantly greater than the height (wide cross section), it is commonly supposed that velocity grows monotonically with the height y, passing from zero at the bottom to the maximum at the free surface (h= 0), thus, the Equation 11 becomes: The entropic parameter M has been evaluated according to the classical formulation of Chiu, as a function in the relation between the mean and maximum cross section velocity: Following the entropy theory, data processing allows us to evaluate the parameter M for each used measuring method: the six-point, the three-point and the one-point methods. Although the maximum velocity occurred below the free surface for each section, Equation 12 was used to represent the coordinate § in order to quicken the computation process of discharge. This assumption, even if it implies having to assume greater approximations in the computation of the final values, is acceptable, especially if it is considered in an operative simplification and automation context for discharge computation

More detailed, the analytic and graphic representations plot the entropic parameter M value computed on the basis of field data acquired when applying the six-point, three-point and one-point methods. The generic M i (i= 1, 3, 6) (Figs 9, 10, 11, 12) represents the value computed applying the Chiu model to the mean and maximum velocity values obtained from the sampling with the “i” point method. It is seen that the value Q Mi is the discharge obtained from entropic distribution of measurements acquired through the use of the relative reduced point method. The value Q oss is the discharge observed, when applying normative methods, using the highest number of points acquired during field measurements. Figures 9, 10, 11 and 12, useful for graphically representing discharges by unit of width, show a typical “behavior” of an entropic model in relation to flow concentration as seen in an irregular geometric section. It is important to note that in Figure 12 the evaluated model averages the specific flows rendering the whole section a contributor to the outflow and cause the

energetic information coupled to graphic representation to be lost. 0 5 10 15 20 25 30 35 0 5 10 15 20 25 30 35 Q oss Q M 6

Figure 15. Comparison between observed discharges com

puted with entropic distribution and with value of M1.

The entropic model response, in fact, is reliable

enough to evaluate discharges, in terms of absolute

value, indistinctly for M 6 , M 3 , M 1 estimations, as is

observed in the graphs (Figs 13, 14, 15) which show

the observed value versus the calculated value and the

confidence band at 10%.

The deviations observed, of the order of 7–12%, are

generally very negligible considering the approxima

tion coming from the possible errors when measure

ments were taken. This leads to the uncertainty values

included in the ±10% interval.

Procedures for water discharge measurement in a

Integrated approaches for modeling sediment transport

J.-M. Hervouet & C. Villaret

Laboratoire National d’Hydraulique et Environnement
Electricité De France, Research & Development,

Chatou, France

ABSTRACT: This paper exemplifies, in the field of sediment transport, the need for an integrated approach

coupling all physical phenomena. Three cases are successively dealt with, in the framework of the Telemac

hydroinformatic system: coupling of hydrodynamics with bed-load transport, simultaneous treatment of bed

load and suspended sediment transport, and finally integrated computation of hydrodynamics and suspended

sediment in 3 dimensions.

1 INTRODUCTION

Sediment transport, be it on a shoreline, in an estuary or

in a river, is highly depending on complex interactions

between currents, waves and turbulence. In a field

where physical laws are mostly empirical and some

times insufficiently known, expertise will always

remain a key asset, but numerical modeling gives more

and more relevant information. Recent progresses

stem from an integrated approach where all the phys

ical phenomena are concurrently dealt with, either

within the same computer program, or by means of

coupling techniques.

Numerical simulations show that a correct represen

tation of different physical phenomena is obtained only

with a close coupling between computer programs, in

order to update currents, waves, and bottom elevation.

The framework of the developments described here

after is the Telemac hydro-informatic system, namely its 2 hydrodynamic modules: Telemac-2D (Shallow water equations in 2 dimensions) and Telemac-3D (3-dimensional Navier-Stokes equations, either with or without hydrostatic pressure assumption, see [1]), as well as its sediment transport module Sisyphe (a co-property of CETMEF, UTC, EDF, and SOGREAH). Sisyphe solves the equation of the bed evolution, using various bed-load transport-rate formulas. This model has been recently updated to deal with sus pended sediment transport. In 2 dimensions, a step-by step coupling between Telemac-2D and Sisyphe has been implemented, with significant improvements, as discussed in paragraph 2.

The influence of waves is also a key parameter in coastal zones, and so far we have treated it by adding forcing terms in the shallow water equations, which is actually only a chaining of programs, namely Telemac-2D and the module Tomawac, the latter computing the generation of waves under the influence of wind. This chaining is classical and will not be detailed here. The two different kinds of sediment transport are bed-load and suspended load.The first one is treated by means of an empirical transport formula, whereas the latter can be tackled by an advection–diffusion equation. This approach will be detailed in paragraph 3. A concurrent treatment of bed-load and suspended sediment transport enables a more realistic behaviour when dealing with non-equilibrium flows, and this will be exemplified on the example of a trench migration. In 3 dimensions, the advection–diffusion is fully integrated in the Telemac-3D hydrodynamic module, to take into account suspension, with all its interactions

with the flow, due to the modifications of density. We describe in paragraph 4 a validation test-case with an analytical solution based on the Rouse profile, with an improvement to prevent unrealistic solutions near the bottom. 2 COUPLING HYDRODYNAMICS AND BED-LOAD TRANSPORT 2.1 Chaining and coupling The close interaction between bed evolution and currents proves to be so important that it cannot be neglected in many cases. Before implementing internal coupling we resorted to a simplified approach consisting of a first computation of hydrodynamics with Telemac-2D, without any feedback of bed evolution, followed by a computation of bed-load transport with a rough updating of velocities with respect to bed evolution. As a matter of

Figure 1. Importance of a coupling of hydrodynamics with bed-load transport.

fact, we assumed that the product of depth and velocity

remains locally constant, so that the velocity decreases

in erosion zones and increases in deposit zones, which

is the required effect.

We compare here this simplified approach, here

after denoted as ‘uncoupled’, to the fully coupled

solution which consists of exchanging at every time

step the velocities and bottom elevation between the 2

coupled computer programs.

2.2 Example 1

We compute the erosion around a groyne in a flume.

The flume is 250 m wide and the groyne is 25 m wide

and about 125 m long. The average depth is 10 m and

the velocity around the groyne about 10 cm/s. The

results obtained with a time-step of 2,5 s and after

10000 s of real time are presented on figure 1 (left:

‘coupled’, right: ‘uncoupled’). There is an excess of about 20% of deposits in the ‘uncoupled’ case. As a matter of fact, the higher velocities above deposits in the coupled case contribute to limit their growth, a phe nomenon which is only partly taken into account with our simplified updating approach. This latter tech nique, though classically used in Sisyphe when run in standalone mode, is thus less efficient than a real coupling.

2.3 Example 2

Evolution and filling of a trench (depth: 15 cm and length: 5 m) under the influence of a uniform steady flow. The flow conditions are the following: depth at the entrance 0,5 m and average velocity 1 m/s. The ‘coupled’and ‘uncoupled’ results, all other parameters remaining the same, are presented on figure 2. They show, with coupling, a better numerical stability, and a more realistic physics, even if the evolution of the trench is roughly the same. 3 SIMULTANEOUS TREATMENT OF BED-LOAD AND SUSPENSION 3.1 A coupling approach The Telemac system was originally built to enable an independent treatment of suspended sediment transport (Subief 2D module) and bed-load transport (Sisyphe module). Subief-2D deals with the transport of fine and generally cohesive sediment: it solves an advection- diffusion equation for the concentration. On the bottom, erosion and deposit laws give the fluxes between the bed and the suspension. Sisyphe computes the bed-load transport of noncohesive material, using semi-empirical laws to get the transport rate. It is done under the assumption of a local equilibrium between the turbulent flow and the bed, which is generally the case when there is only bedload transport, but not as soon as suspended sediment is added.After the recent developments of Sisyphe, we can now compute in a fully consistent and

concurrent way the suspended load and the bed-load. 3.2 Principle of the model The water column is divided into: (1) A thin layer of thickness a ~2D 50 , within which the sediment is transported by bed-load, under the assumption of an equilibrium state. (2) The free water column itself, where the sediment is maintained in suspension by turbulence mixing.

Figure 2. Coupled or ‘Uncoupled’bed-load transport – evolution of a trench. Upstream flow conditions : U= 1 m/s, h= 0.5 m.

Sediments grain size: D 50 = 500µm. Computation 1 (standalone Sisyphe) and 2 (Sisyphe coupled with Telemac 2D are done

in the same conditions Dt= 0.1 s, Meyer-Peter transport formula, Strickler friction coefficient St= 40).

We assume that the suspended sediment concentra

tion behaves as a passive tracer, which means that

it just follows the mean and turbulent flow velocity,

with its downward settling velocity. After a depth

integration of the 3-dimensional advection–diffusion

equation, between the top of the bed-load layer and

the free surface, we get the following equation for the

depth-integrated concentration C:

Here E and D are the sediment (erosion–deposition)

fluxes at the interface between the bed-load layer and

the suspension. z= a stands for the top of the bed-load layer, h is the water depth. ν t is the sediment diffusivity, considered to be equal to the eddy viscosity coefficient. The bed evolution equation must also take these fluxes into account and reads: Z f is the bottom elevation, n is the bed porosity and Q c the bed-load transport rate. 3.3 Flux at the interface The net flux at the interface is:

Figure 3. Coupling bed-load and suspended sediment transport. The total transport rate Qt is decomposed into

Q t = Q c + Q s ; Q c is the bed-load transport and Q s , the suspended sediment transport (Q s = h U C). With same parameters

than figure 2.

W s (>0) being the downward settling velocity, C eq

the equilibrium concentration and C a the concentra

tion at z= a. When the equilibrium state is reached

(C a =C eq), only the bed-load contributes to the bed

evolution.

3.4 Concentration at the equilibrium state

Several formulas are available in the literature to cal

culate the equilibrium concentration as a function

of the bottom friction. The Zyserman and Fredsoe

(see [2]) formula has been programmed in Sisyphe. In

the 2-dimensional approach, the depth-averaged con

centration must be linked to the concentration on the

bottom C a . We assume here that the concentration fol

lows a Rouse profile along the vertical (equation 9

hereafter), which, combined to the fact that the veloc

ities obey a logarithmic law in the rough turbulent

regime, yields the following value of C a :

where u ∗ is the friction velocity, κ the von Karman

constant, R is the Rouse number: W s /(κ u ∗), and I the

Einstein integral defined by : I= I 1 Log(30h/k s) + I 2 ,

where k s is the bed roughness, and:

3.5 Application

This full numerical model has been applied to the same

previously described trench test-case, with the same flow and sediment parameters. Here bed-load transport is dominant, as shown in figure 3, however the effect of suspension is important and tends to speed-up the trench migration (figure 4). 4 HYDRODYNAMICS AND SUSPENSION IN 3 DIMENSIONS 4.1 Rouse profile The hydrodynamic model Telemac-3D is coupled with an advection-diffusion equation for suspended sediment, which reads: where W s is the settling velocity vector, with components (0, 0, -W s). The solution procedure is fully embedded within the hydrodynamics time loop, along with the turbulence model. The computations have been validated against an analytical solution, in the case of a uniform flow in a rectangular channel with a constant slope, without lateral friction but with a bottom friction. We choose the following mixing-length turbulence model: which is consistent with a parabolic profile of turbulent viscosity and a logarithmic velocity profile (see [3]):

Figure 4. Coupling bed-load and suspended sediment transport – evolution of a trench.

In the case of steady and uniform flows, the advection-

diffusion equation simplifies into a balance between

the turbulence diffusion and settling terms:

which after integration gives the well-known Rouse

profile of the concentration:

where C h/2 is the concentration at mid-depth (z= h/2).

The total sediment flux at the entrance of the chan

nel is Q C 0 . By integrating the Rouse profile we can

then deduce the value of C h/2 .

4.2 Numerical parameters

The upstream concentration is assumed to be constant,

equal to C 0 , and we choose C 0 = 0.02. The settling

velocity W s is 0.01 m/s.

The channel length is 500 m, its width 100 m, the

bed slope is 1.01 10 −3 . The bed roughness is k s =

0,0162 m. The flow discharge is Q = 50 m 3 /s. The

prescribed elevation downstream is 0,5 m.

With those data, the depth in the channel is con

stant and equals 0.5 m, and the depth-averaged velocity

is 1 m/s. The friction velocity u ∗ is 0.0703 m/s. The

maximum diffusivity coefficient, obtained at z= h/2,

is equal to 3.6 10 −3 m 2 /s. Telemac-3D computations

were performed with a mesh composed of 30 layers

of elements on the vertical, and 1000 time steps of 1 s

each. Figure 5 compares the theoretical and computed

values of the diffusivity coefficient. The discrepancy

is less than 1%. Figure 6 compares the theoretical and 0

computed velocity profiles.These results fully validate the
hydrodynamics. The mid-depth concentration is in this case:
C h/2 = 1.87 10 −2 . The computed value, in the same
conditions as stated above, is 1.88 10 −2 . However
discrepancies of concentration near the bottom were
observed, and were only explained by the fact that the
Rouse profile is not correct in a close vicinity of the
bottom, which led us to propose a slightly amended
theoretical solution. 4.3 Modified Rouse profile The
drawback of the Rouse concentration profile in numerical
simulations is that it gives an infinite 0 0.2 0.4 0.6 0.8

obtained with the Nezu and Nakagawa mixing-length model.

concentration on the bottom. As a matter of fact, the computations are performed up to z= 0, where the turbulent viscosity vanishes. We propose hereafter an analytical solution including the effect of a constant laminar viscosity ν, which is not negligible near the bed. Assuming that the concentration is still 0 at the free surface, we now have to solve:

which can be integrated to yield:

With this new profile the value of C h/2 has to be slightly corrected and becomes 1.90 10 -2 . The laminar viscosity precludes an infinite concentra tion on the bottom. The bed concentration C z=0 is however highly sensitive to the prescribed value of the laminar viscosity. For example, we find C z=0 = 0.233 for ν= 10 -5 m 2 /s (computed value: 0.106) and C z=0 = 0.106 for ν= 10 -4 m 2 /s (computed value: 0.0898). Finding a more accurate value of C at the bottom would require more layers of elements

Riprap failure of bridge piers

J. Unger & W.H. Hager

VAW ETH-Zentrum, Zurich, Switzerland

ABSTRACT: The entrainment of riprap elements placed around a bridge pier is investigated, using previous research relative to the Shields' entrainment function for turbulent rough flow, and its modification due to the presence of a bridge pier. A novel failure definition is offered first, based on the loss of a riprap element in the immediate surrounding of the pier. Then, the effects of approach flow conditions and pier geometry are separated from the effects of relative riprap size and number of riprap layers placed concentrically around the pier. This concept is verified with preliminary experiments conducted for a sediment mixture to result in a plot in which the individual effects of riprap and sediment diameters, sediments layers, relative bridge pier diameter, density ratio between sediment and fluid phases, and relative approach flow depth are related to the entrainment upstream velocity under which riprap failure occurs. This diagram contains also a division line between the two failure modes observed, namely riprap sliding into the adjacent sediment erosion, and riprap rolling out from the conglomerate. This paper may thus be considered a first step for the definition of a generalized riprap failure equation in relation to bridge piers.

1 INTRODUCTION

Water flow around bridge piers has received signif icant attention in the past years, because the failure of a bridge normally corresponds to the loss of an important infrastructure. The substructure of bridges is subject to a large variety of geometrical designs, such that these flows depend on a significant num ber of geometrical parameters, in addition to the most

pertinent flow features. In the following, the simplest configuration will be considered, corresponding to a cylindrical pier of diameter D, around which a con centric riprap is placed. The individual elements of the riprap (subscript R) have a diameter d R and involve n rows, as shown in the definition sketch (Figure 1). The sediment (subscript s) around the riprap has a median diameter d 50s and a non-uniformity σ= (d 84 /d 16) 1/2 ; the densities of the fluid and the sediment are ρ and ρ s , respectively. Further, the upstream (subscript o) approach flow characteristics may be described with the approach velocity V o and the flow depth h o . The problem to be attacked thus may be stated as: For a given pier protected with a riprap, what are the hydraulic conditions that result in its failure?

A literature review reveals that this problem has received some attention in the past, given the rel evance in river engineering. Hamill (1999) defines a densimetric riprap (subscript R) Froude num ber F 2 R =V 2 ρ /(g ′ d R)= 0.692 K 2 /2 with K = 1.5 for round-nosed piers and K = 1.7 for rectangular piers,

Sediment bed pier V o pier y x riprap z x riprap (n = 5) riprap (n = 5) h o (a) (b) Figure 1. Definition sketch for riprap arrangement around a circular-shaped pier (a) plan, (b) section. g ′ = [(ρ − ρ s)/ρ]g as reduced gravitational acceleration and V p as the velocity at the pier which is typically 1.5V o . Melville and Coleman (2000) list a total of 12 formulae for the prediction of the required riprap. Based on a riprap densimetric Froude number F 2 R =V 2 Rc

/[g ′ d R] where V Rc is the critical (subscript c)

velocity for the entrainment of the riprap elements

of size d R , a number of proposals are stated. Either,

an upper limit of F 2 R is indicated as a function of the

relative riprap size d R /h o or the maximum admissible

upstream velocity V o is expressed in terms of relative

riprap size and the bridge pier geometry. All equa

tions listed involve the Froude similitude although

it is known that viscous effects may occur for small

hydraulic models. The number of riprap layers around

the pier has not been accounted for systematically,

and the limitations for the various equations are not

properly stated.

Hager and Oliveto (2002) considered a simplified

version of the Shields diagram. Depending on the rel

ative sediment diameter D ∗ = (g ′ /ν 2) 1/3 d 50 , where
d 50

is the size of a uniform sediment bed and ν is kine

matic viscosity, three relations for the entrainment

(subscript i for inception) densimetric Froude num

ber F di = σ −1/3 V oi /(g ′ d 50) 1/2 were defined.
Provided

D ∗ ≥ 150, this relation simply reads with R ho as the

hydraulic radius of the approach flow

Equation (1) thus applies for relatively large sedi

ments for which viscous effects are absent.

The results were extended to bridge piers, i.e. (1)

was considered as the entrainment condition for a

bridge pier of diameter D → 0. Compared to the

arrangement tested by Shields, only the relative pier

width β=D/B with B= channel width must be con

sidered in addition to all other parameters involved.

A coefficient (subscript β for presence of pier)

β =F dβ /F di < 1 was thus introduced. For circular

shaped bridge piers, the experiments indicated that

(Hager and Oliveto (2002))

The entrainment condition for circular bridge piers

of relative diameterβ in a flow with a relative hydraulic

radius R ho /d 50 may thus be expressed as

The entrainment velocity V oβ under which scour is

initiated for flows in which viscosity has no domi

nant effect [D ∗ = (g ′ /ν 2) 1/3 d 50 > 150] at a bridge pier

in a uniform sediment surface thus depends on the

approach hydraulic radius R ho , sediment size d 50 and

relative pier diameter D/B. It is important to note that

(3) degenerates to Shields' entrainment condition for

β= 0. In the following this concept will be extended

to piers containing a riprap protection. Figure 2. Riprap arrangement about a pier, half-channel setup (D= 260 mm, n= 10, d R = 13 mm). 2 EXPERIMENTS 2.1 Experimental setup Figure 1 shows a definition plot with the main parameters V o = approach flow velocity, h o = approach flow depth, x= streamwise coordinate and y= transverse coordinate, d R = riprap size and n= numbers of layers concentrically

arranged about the pier. Up to now one sediment was employed in the VAW scour channel (Hager et al. 2002). It may be described with d 16 = 1.75 m, d 50 = 5.0 m and d 84 = 9.2 mm, thus σ= 2.29. Piers were arranged both in the channel axis and along the left channel side wall, in order to simplify experimental observations. It was demonstrated by Hager and Oliveto (2002) that the half-channel and the full channel arrangements are identical, provided that the pier diameter is larger than some 5% of the channel width, to inhibit effects of boundary layer flow along the glass wall. Figure 2 shows a typical experimental arrangement prior to a test, involving 10 riprap rows. Figure 3 shows the complete scour channel used for scour researches at VAW. Circular-shaped piers and half piers of diameters D= 110, 260 and 457 mm were used. The sizes of the riprap elements were d R = 12, 13, 19, 30, 50 mm such that the relative riprap size δ= d R /d 50s varied between 2.6<δ< 10. Depending on the experimental conditions, n= 1, 3, 5 and 10 was normally tested for the number of riprap rows. Discharges varied between 0.042 and 0.11 m 3 /s, resulting in failure densimetric particle Froude numbers F dR between 1.5 and 3.3. Table 1 gives an overview of the test conditions of the present research. It is planned to extend similar tests to sediments of other size (d 50) and non-uniformity parameter (σ) to check for these additional effects. The preparation of an experiment involved the following works (for details refer to Hager et al.

Figure 3. Test channel including PIV apparatus (left), Bridge pier (center left), Travelling mechanism (center right) and

Sediment retain and flap gate (right); (b) Schematic experimental setup.

2002): (1) Placement of the cylinder, (2) Placement of

the sediment leaving free space for the riprap, (3)

Placement of the riprap, (4) Control that the sediment

riprap surface was exactly horizontal, (5) Slow filling

of the scour channel with water up to the required

flow depth, (6) Start of pumps and slow increase of

discharge up to the required discharge, (7) Slight low

ering of tailwater depth until conditions without any

sediment movement occur, (8) Further lowering to the tailwater depth under which first particles move and setting time to zero, (9) Further slow lowering of tailwater until riprap failure, and (10) After stop of discharge observation of the riprap failure under ‘dry’ conditions.

The previous procedure was extended from experiences with bridge pier scour as described by Hager et al. (2002). The reproduction of some experiments indicated reasonable accuracy.

2.2 Riprap failure

The failure of a riprap may be defined by various methods. In the present research, a simple definition was applied: Riprap failure occurs when the first riprap element along the pier perimeter is dislodged. Accordingly, if riprap elements along the outer riprap perimeter are transported either by sliding or rolling, failure has not yet occurred. Also, because only the failure mechanism was closely investigated, one riprap layer of equal size in depth was considered. Once failure has occurred, the test was stopped. Future research has to investigate the pier scour development protected by a riprap. Two main failure types were observed for piers extended with a circular riprap plan arrangement: (1) Sliding and (2) Rolling. Sliding typically occurred when the riprap was much larger in size than the surrounding sediment, whereas rolling of a riprap element out of the entire riprap arrangement occurred typically if its size was only slightly larger than the sediment size. However, no riprap failure as previously defined was observed by rolling, because only some riprap elements rolled out without riprap stability problems. Figure 4 shows the four typical steps resulting in riprap failure by sliding. In Figure 4(a) an initial surface scour may be observed downstream of the pier,

roughly at 120 ∘ away from the channel axis. Surface erosion may lead to the loss of a riprap element by sliding into the erosion hole (Fig. 4b). No failure in the previous sense was observed for one row of riprap stones, however, because both erosion and subsequent scour start at an angle of ~75 ∘ .

The presence of the elliptical erosion surface reduces the velocity in the immediate tailwater region of the pier such that the erosion surface migrates upstream along the interface between riprap and sur rounding sediment, roughly at a location of 75 ∘ from the channel axis, if the tailwater level is slightly reduced (Fig. 4c). A further slight reduction leads to sliding of the riprap element located at the interface first, and this process continues towards the pier sur face when progressively lowering the tailwater level. Riprap failure in the present sense occurred under a well defined upstream flow depth h oi for a given dis charge and pier and riprap arrangement, such that all required information for the systematic riprap failure was available.

Figure 5 is complimentary to Figure 4. In each image, water was drained to the original sediment ele

vation, and the remaining water in the erosion surface

or the scour hole was colored white to improve visibil

ity on the photographs. Figure 5(a) again relates to the

surface erosion downstream of the riprap, with a fully

intact riprap protection. Some riprap elements are seen dislodged in Figure 5(b) due to a local scour. Reducing the tailwater slightly more results in the relatively abrupt migration of the lateral scour hole to some 75 ∘ at the interface between sediment and riprap (Fig. 5c). Reducing tailwater still more leads to the failure of riprap, i.e. a riprap element fails close to 75 ∘ away from the channel axis. It is observed from Figure 5(d) that the riprap protection is compact both at the upand downstream pier regions. Figure 6 shows typical photos of incipient erosion, and the riprap immediately after failure. Once conditions have developed to the latter state, scour advances extremely fast to reach conditions without any riprap. This development has not yet been investigated, however. 3 PRELIMINARY TEST RESULTS Based on the previous considerations on the entrainment conditions, an attempt was made to formulate riprap failure as The left side of (4) includes the effects of the failure densimetric Froude number F dR = σ −1/3 V oR (g ′ d 50) 1/2 divided by the product of relative approach flow hydraulic radius (R ho /d 50s) times a pier extension effect R similar to β previously considered for the pier extension. Evidently, R depends only on β=D/B and thus involves the relative pier width. Based on the present observation R = 1− β 0.4 fitted better for 0.055<β< 0.229 than (2) and was adopted in the following. Because all basic parameters except of the riprap arrangement are included on the left side of (4), its right side must account for the effects of relative riprap diameter δ= d R /d 50s , and the number n of riprap rows around the pier. Figure 7 shows the preliminary test results for one sediment size, five riprap sizes, and four different row arrangements. It may be noted that the data align almost linearly in a double-logarithmic plot. Also, the curves for various values of n have a common origin at (1;1), such that a relatively simple prediction of data is possible. Obviously, the case δ= 1 corresponds to a limit riprap size d R = d 50s for which the conditions predicted by Hager and Oliveto (2002) are asymptotically obtained. At the present preliminary stage, no equations are yet presented in order to come up with a final design relation that may be applied under well defined experimental limitations. It is noted that the scatter of data is

relatively large. Shields' data for the entrainment condition in the basic sediment arrangement involves a scatter of approximately ±10%. The data of Hager and Oliveto (2002) have a scatter of approximately ±15% scatter, given the additional parameter

involved. In the present configuration, two additional

parameters have to be accounted for, such that a scatter

of some±25% may be expected. This order of magni

tude is normal in fluvial hydraulics, when considering

for instance sediment transport.

Figure 8 shows the comparison between measure

ment (subscript meas) and the preliminary prediction

(subscript pred) of the Froude number F dR , of which a

reasonable correlation may be observed. The method

previously outlined must be tested for other sediments

until a generalized design is available, however. 4 SLIDING OR ROLLING? Entrainment of an uniform sediment surface as considered by Shields always occurs by rolling (or even by saltation) of sediment particles. Rolling of riprap elements may thus asymptotically be regarded as a Shields' process applied to the sediment particles of diameter d R . According to (3) rolling (subscript r) follows the relation provided F dr =V ri /(g ′ d R) 1/2 with V ri =V o /(1 − β), thereby accounting for the velocity at the pier side instead of the upstream velocity. Figure 9 compares (5) with observations, resulting in an excellent agreement. It was previously mentioned that none of the riprap failed by rolling, because all riprap stones dislodged at the pier by sliding into the adjacent scour hole. Yet, rolling was observed for n> 1, normally also at the pier side thus enlarging the scour hole and resulting in the final failure of riprap. The rolling data in Figure 7 show a trend, yet additional experiments will be needed to confirm this approach. 5 IMPACT OF PRESENT RESEARCH Riprap failure may be considered as a general case of entrainment of sediment transport in fluvial hydraulics. The present design equations for the prediction of riprap failure neglect this framework, and may thus be considered as purely experimental approaches for which the asymptotic conditions are not satisfied. Some recent proposals include the correct non-dimensional quantities and will be tested with the present approach, once the test program is concluded. It is important to note that this project separates the various effects by using a product arrangement of independent functions, each accounting for a particular effect. For δ= 1, i.e. when the riprap size degenerates to the surrounding sediment size, the final result must tend to Shields' approach. It may be seen from Figure 7 that the failure densimetric Froude number, or the failure approach velocity increases both as δ and n increase, for otherwise identical conditions. Adding more riprap rows thus allows larger upstream velocities, as do larger riprap sizes, compared to a pier without any riprap protection (δ= 1). The present research also indicates that riprap failure occurs never at the leading nor at the wake pier region but at about 75 ∘ away from the channel axis. If various riprap sizes are available, the largest elements must thus be placed close to the sides of a pier, whereas smaller elements may be located both at the upand downstream sides of the pier relative to the approach flow direction. s l i d i n g r o l l i n g

6 CONCLUSIONS

The failure of a uniform riprap arranged concentrically

about a circular-shaped bridge pier was investigated

experimentally, based on previous research on the

entrainment condition for bridge piers in the absence

of riprap. A systematic approach was introduced that

contains all determining elements without the riprap

on the left side, and only the riprap parameters on the

right side. Based on detailed hydraulic experimenta

tion, a preliminary plot was presented that shows the

main features of the expected final result.Accordingly,

the entrainment of scour around a bridge pier may be

controlled significantly by increasing both the rela

tive riprap size and the number of riprap rows placed

around the pier. More research is needed to present

a final design equation, along with limitations for

application in fluvial engineering.

Scour prediction using the Movability Number criteria for incipient motion

Neil Armitage

Department of Civil Engineering, University of Cape Town, South Africa

Caroline McGahey

Formerly Department of Civil Engineering, University of Cape Town, now HR Wallingford Ltd.,

Howbery Park, Wallingford, Oxfordshire, UK

ABSTRACT: Liu (1957) developed the Movability Number (Mn) as an alternative to the Shields' (1936)

dimensionless mobility factor for predicting the incipient motion of non-cohesive sediment subject to steady

unidirectional flow on plane channel beds. Previous work has shown how Mn may be used to predict the likelihood

of scour over a wide range of boundary conditions including laminar, transitional, and turbulent, as well as sloped

in any direction.

In this study, the commercial CFD flow solver CFX, Version 4.3 (1999) was used to simulate open channel flow conditions and predict the scour potential. Contours of predicted scour potential around a vertical weir, an abutment and two piers were generated and compared to the observed equilibrium scour patterns measured in small-scale laboratory models. The results of the numerical computations correlate reasonably well with the experimental data.

1 INTRODUCTION

The estimation of the probable maximum scour profiles around engineering structures situated within open channel flow is an essential parameter in the foundation design of those structures. This is demonstrated by the frequency of bridge failure due to the unexpectedly deep local scour at the supports, i.e. the abutments and piers, during peak flood conditions. Currently, scour prediction is based largely on the use of empirical equations (e.g. Liu et al. 1961; Breusers et al. 1977; Jain & Fischer 1979; Melville 1992; Raudkivi, 1998), or alternatively on the results derived from hydraulic scale models.

This paper investigates the use of the Movability Number criteria for incipient motion, originally developed by Liu (1957) and subsequently extended by the principal author (and others), in conjunction with commercial computational fluid dynamics (CFD) software

for the determination of scour potential. CFX Ver

sion 4.3 (1999) (CFX-V4.3) was used to solve the

conservation equations for fluid motion in the spec

ified domain around selected structures. User defined

subroutines were written into the coding to inter

pret the output in a form suitable for the Movability

Number (Mn) approach. The software was then used

to determine the scour potential upstream of a vertical weir, and around a vertical-wall abutment protruding at 90 degrees from the riverbank and two cylindrical bridge piers.The results of the numerical computations correlate reasonably well with the experimental data. 2 THE MOVABILITY NUMBER CRITERIA FOR INCIPIENT MOTION Incipient motion, in the context of sediment transport, is that critical point at which sediment particles on the boundary of a fluid (e.g. the bed or banks of a river) begin to move. In concept, if the fluid force is below that required for the motion of a particle, there will not be any movement. If it is greater than that required for motion, there will be movement. The boundary between the two may be described as “incipient” motion – i.e. the particle is starting to move. Fluid boundaries normally, however, comprise of millions of particles, each with a unique size, shape, electrical charge, density, packing and orientation, and subject to a unique instantaneous flow within the flow field. It is obvious that some particles are more easily moved than others are, in other words, motion occurs with lower fluid forces than the average. On the other hand, it is also obvious that some particles remain stationary even when subjected to

higher than average fluid forces that would move most

other particles. Taken as a whole, it is clear that the

motion might be of one or two particles only, several

particles at a time, or involve general movement of the

surface of the bed. Each level of movement is asso

ciated with its own particular “critical” conditions.

This has been recognised by many researchers over the years, notably Kramer (1935), who defined three intensities of motion (“weak”, “medium” and “gen eral” movement) near the critical or threshold condi tion. More recently, Shvidchenko & Pender (2000a, 2000b) defined I , the intensity of motion (or trans port intensity) in terms of m, the number of particle displacements during the time interval t, and N , the total number of surface particles over the sample area, such that

For turbulent boundaries, Shvidchenko & Pender (2000a & 2000b) used I ≈ 10 −4 s −1 for their def inition of incipient motion and compared it to the Kramer (1935) definition of “weak” motion. Exten sive analysis of incipient motion data obtained by many researchers since 1914 (Armitage & McGahey 2003) appear to indicate that motion is generally first observed at approximately I = 2× 10 −5 s −1 .

The onset of “incipience” can be predicted via sev eral fluid parameters of which the best known involve flow velocity, bed shear stress, or stream power. Most of the published literature uses the dimensionless mobility factor – which is derived from the bed shear stress – as popularized through the work of Shields (1936). A number of researchers, however, have pre

ferred the use of the “Movability Number” parameter

introduced by Liu (1957). He came to the conclusion

that the local velocity, and hence the various drag coef

ficients, were all functions of the particle Reynolds

Number, Re∗, defined as

where d is the particle diameter and ν is the kinematic

viscosity, whilst the shear velocity, u∗, is defined as

where τ 0 is the shear stress at the boundary and ρ is the

fluid density. Liu then developed a new dimensionless

parameter comprising of the ratio of the shear velocity,

u∗, to the particle settling velocity, v ss , which he termed

the “Movability Number”, which will hereinafter be

abbreviated to Mn. He came to the conclusion that for incipient motion, there was a unique relationship between this new parameter Mn and Re∗, i.e. A plot of the critical Mn value for incipient motion (Mn c) versus Re∗ has a similar shape to the better known plot of the critical Shields’ parameter θ c versus Re∗ (the so-called “Shields’ diagram”). However, it has the advantage that sediment parameters such as diameter, shape factor and density – which help to make up θ c – are effectively replaced by the single parameter of settling velocity. As with the Shields’ diagram, the plot does not include the flow velocity, local or average. Several researchers (e.g. Bagnold 1966, Rooseboom 1975, Van Rijn 1987, Julien 1995, and Raudkivi 1998) have noted relationships between Mn c and particle motion. Analysis of incipient motion data taken from measurements on natural quartzitic sand particles in water by numerous researchers since 1914 have enabled the senior author to develop the following relationships (Armitage & McGahey 2003) where I was determined to be in the order of 2× 10 −5 s −1 . Correction has been made for nonhorizontal beds and for relative roughness, d/Y , where Y is the flow depth. The full relationship between Mn and I , taking into account the bed slope and the relative roughness (turbulent boundaries only) is given by where ψ is the correction for

the bed-slope given by Here β is the longitudinal slope (positive if there is a fall in the direction of flow), γ is the transverse slope, and φ r is the angle of repose of the sediment. Figure 1 depicts a plot of Mn versus Re∗ for all the data used to determine Equations 5 and 6. Figure 2 shows what happens when Equation 7 is used to adjust the incipient motion criteria (related to I) for turbulent boundaries with small relative depth. Re∗

Mn Equation 5 Equation 6 Re∗

Figure 2. Plot of Mn versus Re∗ showing the impact of

varying I (Armitage & McGahey, 2003).

It is apparent that the key issue with incipient

motion is not so much the stability of the individ

ual particle, but rather the point below which the rate of scour becomes so slow that it has negligible impact within practicable time scales. For this investi gation, this was deemed to be with I ≈ 2× 10 −5 giving Mn≈ 0.17 over turbulent boundaries.

3 THE NUMERICAL MODEL

The CFD software, CFX-V4.3 a “FiniteVolume” pack age, was utilized to solve the conservation equations for fluid motion, and additional subroutines were writ ten into this software to produce the output in the desired form. Unfortunately Version 4.3, the version available at the time of analysis, did not incorporate an algorithm for modeling free surfaces and had to be adapted to simulate open channel flow. The software was used to predict the scour potential in terms of Mn in the vicinity of several simple structures. The adaptation of the CFD software is summarized below. The work is described in greater detail in McGahey (2001). 3.1 Mesh refinement A suitable flow domain in the vicinity of the obstruction was identified and modelled using the geometry description software incorporated into the CFX package. It was then divided into finite volumes using a mesh that was biased to limit the number of cells. A fine mesh was used adjacent to the bed and the region around the shapes representing the structures. Particle movement commences at the bed and Mn is at a maximum in the regions with high velocity gradients, which are in the vicinity of the bed and the structures.A coarser mesh was used elsewhere so as to reduce both the CPU time and the size of the data files to be manipulated in the post-processors.The degree of refinement was assisted by means of an initial simulation of steady uniform flow in a long rectangular channel with the same flow rate and cross-section as the test section. The simulation was carried out using a relatively coarse mesh. One of the outputs was the approximate shear stress τ

o at the bed. The shear velocity u∗ could then be determined from Equation 3. For the scour simulation, the thickness, y (mm), of the smallest cells at the channel bed was set at approximately with the dimensionless depth y + ≈ 11.84 representing the effective boundary between the viscous and turbulent zones in the boundary layer. 3.2 Boundary conditions The upstream boundary condition was assumed to be that of steady uniform flow in a rectangular channel.To reduce the length of the numerical model, a logarithmic function characteristic of the turbulent boundary layer was specified for the inlet velocity distribution. At the outlet face, the gradients of all the transported materials were specified, the pressure was extrapolated from upstream conditions and mass continuity was satisfied. The symmetry condition was used for the side boundaries when modelling a symmetrical structure i.e. piers, thus facilitating a reduction in the number of cells used. Boundaries of the flow domain representing the channel bed were set as walls with the no-slip condition typically used for viscous fluids. The sediment roughness was modelled through an additional user routine that adjusted the logarithmic velocity distribution in the boundary layer. The roughness height was interpreted as the mean sediment diameter.

CFX-V4.3 does not offer a free surface algorithm.

Three alternatives were considered for the modelling

of the free surface: a symmetry condition, a rigid-lid

incorporating an air interface, and a moving wall. The

moving wall was chosen as it most accurately predicted

the turbulent viscosity distribution with depth. Fortu

nately, the flow conditions that were being modelled

were characterized by approximately flat surfaces,

with sub-critical flow and moderate energy losses. The

moving wall was given the surface velocity of the water

to avoid the generation of spurious shear forces in the

surface cells.

3.3 Shear stress distribution with depth

In turbulent flow, the shear stresses are determined principally by the velocity gradients. In an infinitely wide, rectangular channel with steady flow, the shear stress τ (Pa) in the direction of flow on a layer with its normal orientated in the direction of increasing depth may be calculated from

where S o is the bed slope, D (m) is the total depth and y (m) is the height of the layer above the bed. Despite the specification of a logarithmic velocity distribution at the inlet, Equation 10 was only satisfied a considerable model distance downstream of the inlet. The initial run described in Section 3.1 above was thus also used to determine the distributions of turbulent kinetic energy, k , and rate of viscous dissipation, ε, as shear stress is dependent on these values. These distributions were then programmed as part of the inlet boundary con dition in the scour simulation to ensure the correct upstream shear stress distribution.

3.4 Differencing scheme

The selection of the differencing scheme was based on the modelling of a benchmark problem with widely published results. The problem selected was that of the lid-driven cavity. This is a two-dimensional prob lem, where the flow in a cavity is driven by a constant horizontal velocity over the surface, causing the flow

to slowly rotate about some horizontal axis. Results of the vertical and horizontal velocity profiles are widely published, the most well known benchmarking results being those produced by Ghia et al. (1982). It was found that the QUICK scheme provided the most accurate approximation, and was thus implemented throughout this investigation for the velocity and pres sure terms. In the case of the turbulent kinetic energy and rate of dissipation terms, however, the QUICK dif ferencing scheme gave rise to converged solutions with negative k or ε values when the grid did not adequately resolve the shear layer. These terms were therefore determined using either the upwind or hybrid scheme. 3.5 Turbulence model The selection of the turbulence model was made after comparisons had been made between the velocity and shear stress distributions obtained using the various turbulence options offered by CFX and those measured by Cellino and Graf (2000) over two-dimensional bedforms. Of the available turbulence models in CFX, the k-ε model gave the best results and was used for the two-dimensional problem involving the prediction of the scour upstream of a weir. All the more complex three-dimensional problems, however, had Reynolds numbers in the range 10 000–20 000. The normal k-ε model is known to over-predict both the shear stresses and the turbulence intensities under these circumstances. The Low Reynolds number kε model, recommended for Reynolds Numbers in the range 5 000–30 000 (CFX Manual 1999), was therefore used in its place.This model required an extremely fine mesh at the channel bed as no wall functions are incorporated into the algorithm. The two main parameters required for the turbulence models are the dissipation length scale and the turbulence intensity. A sensitivity analysis of the dissipation length scale and turbulence intensity for the lid-driven cavity benchmark problem showed that values of 0.01 and 0.05 respectively approximated the results of Ghia et al. (1982) most accurately. These were specified as input into the initial course mesh model (see Section 3.1) before being refined for the scour simulation. 3.6 Pressure correction and

solvers The default pressure correction in CFX-V4.3 is the SIMPLEC algorithm.This was used throughout except when convergence difficulties were encountered, whereupon the SIMPLE or the PISO algorithms were implemented. The STONE solver was used for the u-, vand w-velocity components; the ICCG solver was used for the pressure term; and the line solvers were used for the turbulent kinetic energy and rate of viscous dissipation. These solvers were adequate for the two-dimensional problems, however the solutions obtained with these solvers diverged for the threedimensional abutment and pier models. The BLOCK STONE solver was thus implemented for the u-, v-, and wvelocity components in the case of the abutment and pier examples described in this paper, whilst the AMG solver was introduced for the pressure term. The CFX Manual (1999) recommends this when the pressure-correction is not being adequately treated and the percentage of well-ordered blocks is low, which was the case with these examples.

3.7 Steady state versus transient flow simulation

The transient option was investigated. To reduce com

putational time, the model was initially run using fixed

time steps, and then restarted with adaptive time step

ping to adjust the time step as the solution converged.

The default backward differencing and linear time

differencing options were selected. The model out

put, however, showed no sign of the expected vortex

street. This was attributed to the suppression of the

free vortices through dampening against the moving

wall surface boundary. At the bed, the scour poten

tials were similar to those for the steady state solution.

In view of this, steady state simulation was used

throughout.

3.8 Determination of Movability Number

CFX-V4.3 is written in Fortran 77. Additional For

tran subroutines were written to access the basic flow variables and determine, inter alia: velocity gradients, shear velocities, and Mn.

4 NUMERICAL SCOUR PREDICTION

Four physical model tests were selected for which the extent of the scour was known, and that represented an increasing order of modelling complexity. The numer ical model was then used to simulate the physical models and the results compared.

4.1 Upstream of vertical weir

Harnett (1998) investigated the scour profiles upstream of a weir for a variety of sediment sizes. Uniform sil ica sand of three different diameters were separately placed onto the bottom of a 6.38 m long laboratory flume sloped at 1:127.6. The surface of the sand bed was made horizontal with a 50 mm high weir located at the downstream end of the flume. The bed was then subjected to a constant flow of clear water until a stable scour profile was achieved – generally after approximately 35 hours (Figure 3).

One run involving a flow of 3.5 l/s over a sand with a median diameter of d 50 = 0.86 mm and a settling velocity of 0.09 m/s, was simulated by the numerical model in both the initial and final conditions. To facil itate the interpretation of the plots, virtual Movability

Numbers, Mn ′ , were generated for the whole of the

water column using virtual shear velocities computed

from Equation (3) after the substitution of τ for τ 0 .

The critical value for incipient motion with a turbulent

boundary, Mn c , is 0.17 and thus the maximum value

of the Mn ′ contour plot (Figure 4) was set at this value.

In the analysis of the initial, pre-scour condition, the

value of the virtual Movability Number reaches values
Initial level profile Weir Final scoured profile (a) Before scour (b) After scour Figure 3. Scour upstream of a weir (Harnett 1998). In the analysis of the final scoured profile, the value of 0.17 is only just attained at the channel bed thus confirming that the scour profile is now approximately in equilibrium with the flow. 4.2 Determination of erosive conditions around a pier situated within a rectangular channel Midgley (2000) examined the scour of thin sediment layers of uniform quartzitic sands of various sizes placed around a 45 mm diameter circular pier centrally located in a 605 mm wide flume and subjected to a steady flow. One run involving a flow of 7.69 l/s, Mn > 0.170 0.148 0.119 0.089 0.059 0.030 ≈ 0.000 Pier

depth 74 mm, over a sand with a median diameter

of d 50 = 0.55 mm and a measured settling velocity

of 0.089 m/s, was simulated by the numerical model. The boundary was determined to be turbulent. The result is depicted in Figure 5. The modelling was simplified by assuming symmetry along the centre line of the pier and channel. The actual scour profile has been superimposed onto the model output for comparison.

The numerical simulation appears to correctly pre dict the scour zone upstream of the pier, but it suggests that the scour zone should be displaced further away from the centreline downstream of the pier. Further more, it predicts scour in the lee of the pier in what is usually a deposition zone. It is quite possible that these anomalous results can be partly explained by the use of a moving, essentially flat, boundary for the free surface. This distorts the flow patterns in the lee of the pier. In this region, the water surface would be expected to drop owing to the acceleration of the flow around the sides of the pier. Keeping the free surface artificially elevated increases the pressure on the bed, which in turn increases the local shear stresses and forces the high-speed separated jet further away from the centreline. This is exactly as observed in the case of the displaced scour zone.

The scour zone identified in the lee of the pier in

what is usually a deposition zone is a consequence of

the erroneous flow patterns computed in the lee of the

pier possibly resulting from the free-surface approxi

mation. The k-ε turbulence model is also known to be

subject to error in separated flow zones. Actual scour extent Predicted scour region Mn > 0.17 0.15 0.12 0.09 0.06 0.03 0.00 Abutment Flow Legend Figure 6. Mn contour plot on the bed of a rectangular channel in the vicinity of an abutment (McGahey 2001). 4.3 Determination of erosive conditions around an abutment situated within a rectangular channel Mitchell (2000) examined the scour of thin layers of uniform quartzitic sands of various sizes placed on a level floor around a vertical-wall abutment located in a 820 mm wide rectangular flume and subjected to a steady flow.The abutment had a length of 220 mm, was 35 mm thick, and was set at an angle of 90 degrees to the flow direction. Approximately 1 litre of sediment was sprinkled evenly over the flume bed. The flow was then allowed to scour the material around the structure until equilibrium was reached after about 3 hours. One run involving a flow of 10.2 l/s, depth 100 mm, over a sand with a median diameter of d 50 = 0.55 mm and a measured settling velocity of 0.089 m/s, was simulated by the numerical model. Once again, the boundary was determined to be turbulent giving Mn c in the order of 0.17 (Figure 6). The scour pattern that was experimentally observed has been superimposed. In this instance, the predicted scour region is larger than the measured scour region. As with the pier simulation, Mn is higher in the region downstream of the abutment than would be expected – particularly in the vicinity of the channel wall. It is likely that this is once again a consequence of the free-surface approximation. 4.4 Determination of erosive conditions around a pier situated on a mobile bed Babaeyan-Koopaei (1996) undertook laboratory investigations into the scour profiles around piers and abutments. A unique feature of his research was that the experiments were carried out in a regime flume, i.e. a self-formed laboratory channel, resulting in the mobility of the entire cross-section. These represented

natural field conditions where channels are generally

non-rectangular, with mobile banks and possible over

bank flow. The flume was 22 m long, 2.5 m wide and

had a depth of 600 mm. The particle mean diameter, d_{50}, was 1 mm.

One of these experiments, test no. 38B (Babaeyan Koopaei 1996), was modelled numerically in both the initial and final conditions. This experiment investigated the scour profile around a 48 mm diameter cylindrical pier, centrally located in the channel. The flow rate was 2.5 l/s and the average water depth was 129.5 mm. The maximum scour depth adjacent to the pier was 55.6 mm. Two conditions were modelled: prior to scour i.e. in the self-formed channel with the pier installed but before introduction of the test flow, and after development of the equilibrium scour profile around the pier. The particle settling velocity was estimated as being approximately 0.129 m/s. The model geometry for the initial case is shown in Figure 7. A three-dimensional user patch was created adjacent to the bed, and this is also depicted.

The incipient motion critical function for sediment on an uneven bed is given by:

where the subscripts indicate a sloped bed (β, γ) and a horizontal bed (0) respectively. The function was computed at a depth of 0.5 mm above the channel bed. The boundary was found to be turbulent. As the geometry for the initial condition was created with a level bed,

this critical function should have been approximately

equal to 0.17 over most of the channel bed i.e. the

value of the Mn c for incipient motion on a turbulent

boundary. This can be seen to be the case when the val

ues are graphed for each cell centre at the boundary in

Figure 8. The values that are not equal to 0.17 come

from the cells situated adjacent to the pier, where the

velocity vectors are not horizontal.

A scour potential, , was defined as the differ

ence between the Mn calculated by the program, and

Mn c(β,γ) as

The scour potential indicates the extent to which the

flow is trying to scour the bed (positive value) or

deposit on it (negative value). A zero scour potential

indicates that the flow neither wants to scour or deposit

i.e. the bed is in equilibrium with the flow at that point.

Figure 9 shows calculated by the program in

the vicinity of the pier prior to the commencement of

scour. Most of the values fall in the range 0.1 to 0.25

indicating erosive conditions. The values are highest

in the vicinity of the pier, indicating the greatest scour

potentials were close to zero. In CFX-V4.3, however,

this cannot be automated. A new geometry has to

be determined for each iteration by the operator. In

this instance, therefore, the scour potentials were only

computed for the initial and final state of the physical

model.

Figure 10 depicts the elevation, ζ, of the bed in

the physical model and the CFD model on a long

section (x-axis) through the centreline. The profile in

the CFD was created through best-fit smooth curves linking spot heights measured in the physical model. Since there is a slight deviation between the two pro files (real and modelled), this introduces a source of unavoidable error.

Figure 11 shows over the scoured boundary. The values fall in the range -0.04 near the scour hole to 0.06 further away. This indicates that the profile is now approximately in equilibrium with the flow. A more accurate rendition of the physical model profile and better modelling of the free surface might possibly have improved the accuracy.

Scouring and flow structure around an attracting groin

T. Ishigaki, T. Ueno, M.M. Rahman & A.T.M. Khaleduzzaman

Ujigawa Hydraulics Laboratory, Disaster Prevention Research Institute, Kyoto University, Japan

ABSTRACT: An attracting groin, of which the head is shifted toward downstream, is not typically used in a

submerged situation, because a flow over the groin attacks a bank and erodes it. While an attracting groin has

this disadvantage, it was used as one of the traditional counter measures for protecting bank erosion about 400

years ago. In order to clarify this contradiction, the hydraulics of the groin is investigated experimentally in this

paper. Local scour and flow structure around an attracting groin have been measured in submerged cases. It was

found that the scour holes are produced near the head of groin in shallow flow, and the holes are observed near

the root of groin in deeper flow. This result means that an attracting groin can be applied for protecting bank

erosion in restricted situations.

1 INTRODUCTION

Recently, the environmental design has become one of important factors in planning flood control measures. Hydraulic engineers recognized that some traditional counter measures for flood are good examples of the matter. Floods are not fully controlled by the traditional measures, however, the nature is not fully destroyed by them. By now the engineers have a better opinion of the engineering.

One of the traditional measures is a groin that is discussed in this paper. The attracting groin has been built 400 years ago along the Katsura river in Kameoka city, Kyoto, Japan. An attracting groin involves a head shifted downstream, and the groin is set at the angle of 65 degrees with the normal to bank.According to a leg end, the groin was set for protecting bank erosion, but scouring is generally observed near the root of attract ing groin, as shown in Figure 1. The figure shows the patterns of scour and deposit around three types of submerged groins. The objective of setting the groin contradicts the hydraulic phenomena observed around it. In order to clarify the contradiction, the hydraulic aspects of this groin are investigated experimentally in this paper.

Many researchers have studied the hydraulics of

groins, and three topics have been recently inves

tigated. These are local scour (Kuhnle et al. 1999,

Ohmoto & Hirakawa 2000, Elawady et al. 2001, 2002),

the flow structure (Tominaga et al. 1997, Uittewaal &

Berg 2002), and the mass exchange in the groin fields

(Uittewaal et al. 2001, Kurzke et al. 2002). They have

dealt with the groins of angle-30 to 30 degrees. Such

groins in this paper are out of consideration, thus scour
Attracting groin Deflecting groin Repelling groin scour
deposit Flow Figure 1. Scour and deposit around the three
types of groins. and flow structure around an attracting
groin with large angle of 65 degrees is investigated here.
2 OLD GROINS The two old groins are still remaining on the
righthand side of the Katsura river in Kameoka basin, as
shown in Figure 2.Those groins are Kami-Naizen and
ShimoNaizen named after the lord of a clan about 400 years
ago. Kami-Naizen is upstream of the Shimo-Naizen groin.
Kameoka basin is on the west side of Kyoto and the area is
about 40 km 2 . The Katsura river runs through the basin
from west to east and connects to narrow valley called
“Hozu gorge”. This gorge works as a constriction during
floods and the backwater extends over the basin. The two
groins have been used for protecting bank erosion. The
original length of Kami-Naizen was 36.9 m and Shimo-Naizen
was 90 m. Both groins were made of Kami-Naizen Shimo-Naizen
Kameoka city Katsura River

map in Oct. 2001.

rocks. Figures 3 and 4 are air photos of the two groins

in 1947 and maps in 2001. It is found that the length of

Kami-Naizen has not changed, whereas Shimo-Naizen

has become shorter. Shimo-Naizen had an original

length until 1988, then the head part was swept away by

a flood and not repaired. Figure 5 shows the present

form of Kami-Naizen of which the length is longer

than the original length of 36.9 m. Thus, some exper

iments have been done on Kami-Naizen and the local

scour and flow structure around it were investigated

by a model of 1/100 scale.

Tradition says that groins deflect the flow and pro

tect the bank from erosion, however, there seems to

be an additional function that is to keep the naviga

tion channel and make ponds behind the groins. As

logs and goods had been transported through the Kat

sura river for some ages, these navigation channel and

flow were measured under clear water scour in five cases of different water depths, which included four submerged conditions and one non-submerged case, as shown in Table 1. H/h is the relative depth, where H is the flow depth and h is the height of groin. The ratio between the friction velocity and the critical friction velocity of the bed material was kept from 0.83 to 0.91 by setting the same velocity in all cases.

A laser level meter, an ultra-sonic level meter and an electro-magnetic velocimeter were the equipments used for the measurements of bed form, water level and velocity, respectively. Flow patterns were observed on the water surface and in a cross section of flow by using normal and submergible video cameras.

3.2 Bed form and flow structure

Figure 7 shows flow patterns on the water surface for non-submerged and submerged groins. The flow pat terns were visualized by sawdust as a tracer. Approach

flow was deflected to the channel center by the groin

in the non-submerged case and the dead zone was pro

duced behind the groin. In the submerged case, the

approach flow was also deflected, however, some part

of the flow ran over the groin and to the bank. It was
Figure 7. Flow patterns on the water surface in case of (a) non-submerged and (b) submerged groin. easily anticipated that this overtopping flow causes local scour and bank erosion behind the groin. Figure 8 shows bed form measurements in the nonsubmerged and three submerged cases. The friction velocity was almost same in all cases. The measurements were done after one hour in all the cases. Dark color shows scouring parts and bright color shows depositing parts. The depth and height is shown in the difference from the original bed level. In the nonsubmerged case, a scour hole is produced near the head of groin at first, and then other holes are produced in sequence. Approach flow is deflected by the groin and converges along the groin. This flow produces the first hole and runs up the downstream slope of the hole, and then reattaches the bed and scours the next hole. This mechanism was also observed in all cases. The second figure is the bed form in the submerged case of H/h= 1.22.As the depth of overtopping flow is shallow and its velocity is slow, the bed form is not so different from the data in the nonsubmerged case. As shown in Figure 7, some part of approach flow runs over the groin, however, local scour is not observed behind the groin. This means that the local scour is not severe while the groin is submerged. The third figure for H/h= 1.41 shows that scour holes can be observed near the head and root of the groin, and the last figure of H/h= 1.62 indicates that scour holes are produced only near the root of a groin in deeply submerged cases. The longitudinal profiles of

bed form near the root of groin, y= 6 cm apart from

the bank, are shown in Figure 9. The origin of the

x-axis is the center of groin at the connecting part to

the bank. Scour holes can be observed except for the

cases of H/h= 0.82 and 1.22. Deepest scour is not

in the deepest case of H/h= 1.92, but in H/h= 1.62.

From these results, it is found that the position of the

scour hole varies with the head to root of groin when

the relative depth increases, and that the scour depth

depends on the hydraulic condition. Figure 10. Profile of water-surface (top), velocity (middle) and bed (bottom) for submerged flow. To investigate the relation between flow structure and bed form around the groin, profiles of water surface, velocity distribution and bed from were measured for H/h= 1.92, as shown in Figure 10. The water level is the difference from the mean flow depth. The two velocity components were measured at 1 cm above the groin top by

using an electro-magnetic velocimeter. Arrows in the velocity distribution are the longitudinal component of velocity u, and the contour lines show the distribution of vertical component of velocity, v. The dark color is downwelling part and the bright color is up-welling part. Notation of the bed form is identical as in Figure 8. The water level over the groin is lower than the surrounding. It means that the flow is accelerated there. From the velocity distribution, it is found that the accelerated flow goes downward and intrudes into the wake region of groin, and then scours the bed. The velocity of this intruding flow depends on the hydraulic condition as mentioned before. And the upwelling part near the groin head indicates that some part of the deflected flow by the groin runs over the groin. 4 CONCLUSIONS Scour and flow structure around an old attracting groin have been investigated by using a groin model of 1/100 scale. The conclusions are as follows: 1. For non-submerged and submerged conditions with shallow flow depth, a scour hole has been observed on the downstream side of groin head, and deep scour holes are produced on the downstream side of the groin root in another cases of submerged conditions. The location of scour hole depends on the

hydraulic condition and a hydraulic condition pre

vents severe bank erosion. There is a possibility to

make an embayment and keep its depth identical as

the old groin mentioned in this paper.

2. For the old groin, the flow velocity around the

groin becomes slow during floods of large discharge

because the floods are dammed up by the narrow

gorge in downstream and the flow velocity becomes

slow. It is presumed that the groin has been planned

with consideration of the results obtained here.

3. Results of velocity measurement and flow visu

alization show that flow over a groin makes an

important role of scouring behind the groin. It

shows that the scouring around an attracting groin

closely relates to the flow structure.

4. One of the important conclusions of this paper is

that a traditional counter measure is useful when

hydraulic engineers consider the design with nature

for flood control.

2-D Numerical analysis for flow around an oblique weir in

compound open channels

M. Iwai & Y. Shimizu

Hokkaido University, Sapporo, Japan

Y. Kawahara

Kagawa University, Takamatsu, Japan

ABSTRACT: Flood flow around the Daijyu weir inYoshino River is complicated because it includes an oblique

weir in compound open channel. To consider the safety for this weir, the analysis of the three-dimensional flow

features such as hydraulic jump, eddies, large scale of back flow region and curved flow is necessary. In this study,

a two-dimensional numerical model including friction forces from wall and bed is applied and compared with

the experiment set up with the same conditions as the Yoshino River. Friction coefficients are locally changed

because flow characteristics are different among low, flood channel and high velocity region. CIP method is

used to calculate the flow, and shown the basic characteristics of flow. However, two-dimensional model is not

sufficient to calculate hydraulic jump phenomena in flood channel. The safety for this weir is examined changing

the oblique weir height and its angle.

1 INTRODUCTION

In Japan, the oblique weirs can be found in many

places. InYoshino River, the Daijyu submerged weir is

constructed obliquely to the flow direction for the rea

sons of historical backgrounds. This makes the flows

in this river more complicated. Moreover, during flood

the combination of floodplain and submerged-oblique

weir has a complex interaction contributed to the flows

in this river. Figure 1 shows the flood in Yoshino River in September 1974. A detour flow apart from oblique weir occurred at the left floodplain. Hydraulic jump and other complex flow features can possibly be occurred around and behind the weir. These could be roughly concluded that to consider the safety function of the Daijyu weir during flood, the analysis of the three-dimensional flow features is necessary to evalu ate the safety of this river. Many researches, however, lack this kind of examples and experiments and have not clarified most of the unclear points.

The model experiment was performed for the pur pose of perceiving the fundamental of flow features around the oblique weir (Matsushita et al., 2003). Detoured flow, back flow region, complex flow fea tures were observed in the experiment. The analysis of the model experiment is significant to consider the safety of functionality of Daijyu weir.

In the experiment, three-dimensional flow is occurred because of effects from presence of flood Figure 1. Flood in Yoshino River in September 1974. channel and the oblique weir. At the downstream of the weir, a high-velocity flow, eddies and turbulence are occurred in flood and main channel. To analyze these phenomena, three-dimensional turbulence models have been developed. The classical approach would be to follow the concepts of Large Eddy Simulation (LES) model for analyzing turbulence flow. Smagorinsky model is a typical LES model. Grid scale eddies are solved directly and sub-grid scale eddies are resolved by modeling Smagorinsky constant. Horizontal

two-dimensional flow is calculated directly by numerical simulation and turbulence, which

scale is not over water height is coupled by modeling.

(Nadaoka and Yagi 1993). These models are applied

in shallow-water flows included turbulence model and

obtained good results. These models need to evaluate

some coefficients experientially. However, the process

of the numerical simulation is complicated because

in these models, the momentum equation contains

the energy from eddy effect and finally the accurate

calculation results could be obtained.

Because vertical and horizontal flows are co-existed

in the flow, then three-dimensional numerical model is

theoretically suitable for this analysis of complicated

flow features. To simplify this, two-dimensional flow

equation is chosen to study. Hydrodynamic force is

introduced into two-dimensional momentum equation.

This model was applied in the flow around sub

mergible groin. Water-jumps around groins obtained

from experiments, could be simulated.Therefore, two

dimensional analysis can be simulated partly some

features as taking into account the force which is

dominant for flow.

In this study, three-dimensional equation is simpli

fied to be a two-dimensional equation with detailed

friction model.The two-dimensional generalized coor

dinate system was applied in calculation. Friction coefficients in the basic equations were modeled in more details. The safety of the weir and its vicinity are investigated comparing with other weirs having different heights and oblique angles.

2 THE SUMMARY OF MODEL EXPERIMENT

Figure 2 shows the model channel in experiment. The height of the submerged-oblique weir is 0.046 m, which is smaller than the height of flood channel. Channel is fixed at grade of one in a thousand, with a total width of 0.5 m. Flood channel is set at left side of this compound channel. Flood channel width is 0.051 m and 0.1 m height. The oblique angle of the weir which grade is one in fifteen is 20 degrees. Figure 3 is visualization for streams used colorant injected in bottom at the upstream of the weir. The important flows observed from experiment are shown in Fig. 3. ① is represented the lower-layer flows that started from the bottom of main channel and travel along the inner wall of main channel on the left side. ② is the flow started originally on flood channel and also started from main channel in the upper layer, then overflowed to the flood channel. This flow keeps run ning on the flood channel along left wall because this flow is pushed by hydraulic jump ③ at downstream

flood channel and will not flow back to main chan

nel. This can be observed from colored flow from

upstream at flood channel will remain on the flood

channel. There are various flow patterns in the area

of the weir, going straight over the weir, circulating, 0.041m slope: 1/1000 Slope of weir: 1/15 height of flood channel angle 20˚ 0.69m 0.4m 0.5m 0.051m weir 4m the end of downstream Figure 2. Hydraulic jump can be seen behind the weir. Curved flows at②go to④ regions. Back flow region is shown marking ④, velocity distribution of this area has a direction to vertical. Complicated vortex flow is shown at boundary between back flow region at④ and fair current region at ⑤. Straight high-speed flow is shown in the vicinity of right bank. The paper written by Matushita et al., shows the other detail features of flows. 3 CALCULATION CONDITION OF FLOW 3.1 Model equations The two-dimensional, unsteady, incompressible flow which is conducted in a generalized coordinate system has been calculated using the following continuity and momentum equations.

in which, x, y are orthogonal coordinate axis, t is time,

ξ, η is plane coordinate axis in generalized coordinate,

h is water depth, H is water level, u ξ , u η is contravari

ant tensor in ξ or η direction, J is Jacobian determinant

in coordinate transformation, C b is bed friction coef

ficients. Other coefficients and diffusion term show

following.

in which, τ ab is b-axis component of a shear force that

affects the plane which is a vertical to a-axis. ρ is a

density of water. y Shear stress from wall Shear stress from fluid Shear stress from fluid and wall 1 2 3 Figure 4. Patterns of shear stress acting on fluid body.

(y-direction). 3.2 Numerical model To solve Equations (2)-(11) the CIP scheme is adopted for advection phase. This is proved to be a suitable scheme to maintain hydraulic energy in the case of energy loss flow due to hydraulic jump by a work from Shimizu et al., that CIP method was adopted in the calculation of flow with a series of vertical dropped spillway by and reproduced the hydraulic jumps. At the upstream of the weir, the viscosity is high because bed and wall of channel are smooth. Friction from wall influences on the flow at flood channel. Friction from the wall of weir influences on the flows that crossover the flood channel because the height of the weir wall is almost equal to the water depth. The main idea of this study is that the water body has shear forces acting differently on individual location, meaning that the shear stresses have to be modeled locally. To examine the above mentioned idea, shear stresses acting on fluid body are considered and classified into three types as illustrated in Fig. 4. One is that shear stresses only from fluid friction act on both sides of water column①. Two is that there is only fluid friction acting on left side of water column ②, while the right side is partly wall friction and fluid friction. Three is that take place on the left side, while on the right side shear stress is from wall friction. When Equation (10) and (11) transform discretization, difference of shear stresses is considered in this research. For example, the shear stress is included in the following equations, in which, u t , is eddy viscosity, u * is shear velocity. wall j j□1j□1

Figure 5. How to deal with shear stress by calculation step.

Shear stress from wall is assumed proportional to

velocity square adjacent to the wall. When the fluid on

the side wall has water depth higher than the height

of side wall, a viscosity term will be prorated between

water depth and the height of side wall because vis

cosity from fluid is considered as well as friction acted

by side wall. For that reason, acted② and③ is showed

Equations (15)-(17).

in which, superscript j is calculation step shown in

Fig. 5, C w is friction coefficients of wall, h w is the height of the wall. Equation (16) show ②, Equation (17) show ③. Equations (12)-(17) is transformed to generated coordinate and used in this research.

3.3 Deal with friction coefficients

Table 1 shows the calculation condition. Viscosity becomes bigger on the flood channel because Reynolds number is smaller than that in downstream main channel. In this experiment, velocity could not be measured because water depth is not high enough to measure. The flow on the flood channel is considered to be a laminar flow. On the other hand, hydraulic jump high-speed flow is distinguished around the weir. Compared with upstream of the weir, it has high Reynolds number. If friction coefficient values remain the same, calculation result will be different from experiment result, which is not supposed to be.

In this research, various friction coefficients are determined. In order to understand the changes among upstream or downstream regions of the weir, flood channel or main channel and their combinations, calculation results is compared with experiments. Table 2 shows how to give their friction coefficients. Manning

Table 1. Calculation condition. Term Value Discharge (m 3 /s) 0.0243 Water depth at the end of downstream (m) 0.066 x (m) 0.04 y (m) 0.02 Table 2. Friction coefficients on the calculation. Place Value Bed in flood channel n= 0.03 Around the weir in flood channel n= 0.02 Bed in the main

channel n= 0.01 Side wall C w = 0.02 roughness is represented a bed friction. The value of Manning roughness in flood channel bottom is given three times bigger than that of downstream main channel bottom. Velocity is amplifying around the area of the weir connected to the flood channel (assumed that 8 cm in upstream direction from the junction of the weir and flood channel) in order to curve flow on main channel into flood channel so that Reynolds' number is high as the velocity is increasing. Manning coefficient is set 2/3 of other places. Manning coefficient at sidewall is constant to prevent calculation from complexity. When Manning coefficient is 0.01–0.03, C b is then 0.002–0.04 and the C w value also falls into this range. As a result, the C w value is appropriate. 4 CALCULATION RESULT 4.1 Water depth Calculation result of water level compared with experimental data is shown in Fig. 6. Calculation time is 150 seconds, while result is averaged from 80–150 seconds for stable period. X is flow direction and y shows distance started from right bank. For convenience of plotting, location of plots from calculation differs from experimental location by 5 mm. This effect could be ignored. In the region of x= 140–160 cm and from flood to main channel, hydraulic jump is observed. Water depth is calculated smaller and smaller after the weir. It is the same to experiment. Hydraulic jump position, however, is differed in main channel. Hydraulic jump in flood channel does not appear. The results are the same when friction coefficients on bed and wall are changed. It seems that basic equations, (1)–(3), did not drive energy conservation. y=22.5cm(Exp. Cal.) Figure 6. Comparison of water depth between calculation and experiment result.

Figure 7. Velocity distribution at downstream of the weir (top: calculation, bottom: experiment).

4.2 Velocity and friction distribution

Figure 7 shows velocity vectors after the weir. In

experiment, the back flow region can be observed at

downstream of the weir and left bank of main chan

nel. In this specific location, three-dimensional flow

pattern is strong compared to other places. The veloc

ity distribution has a big change in vertical direction.

Velocity distribution of calculation has zero or minus values and indicates that there are “back flow region” or “dead flow region” at left bank of main channel after the weir. At right bank of main channel, calculation flow goes straight along the right wall as in experiment, but velocity is not same in order of magnitude. Figure 8 shows contour of friction velocity. Figure 9 shows the flow visualized by using oiled-slide method and Fig. 10 shows contour of absolute modulus value large

Figure 8. Contour figure of friction velocity.

Figure 9. Flow by visualized using oiled-slide method.

Figure 10. Contour figure of friction velocity.

of vorticity. Oiled-slide method indicates the magni

tude of bed friction and directions. Black color shows

strong bed friction.

Experiment shows strong bed friction affected on

hydraulic jump after the weir. Flow is accelerated

upstream of the weir in flood channel, then oblique

hydraulic jump occurred.

Before and after oblique hydraulic jump, shear

stress is increasing. It is shown that large shear stress leads to vortices in boundary between back flow and following region. Increasing shear stress is calculated after the weir in main channel. However, oblique hydraulic jump is not calculated, so shear stress at downstream in flood channel decreases on the against accelerated flow region at upstream is shown. Calculation results show large friction at bound

ary between back and following region, but this scale is smaller than the experiment. At the right of them, strong and small vortices, which is not appeared in the experiment is produced. It must be that downstream main flow of the experiment appears to have weak following vortices or a dead flow region. Large friction region is not appeared in the experiment but is shown in the calculation. Velocity vector at downstream of the weir is shown in Fig. 11.Three-dimensional flow affected on the weir and flood channel appear at this place. Flow, which is shown velocity vector figure of experiment, is made slower because of effect from the weir and flood channel. On the other hands, calculation flow is accelerated before the weir. It is difficult to discuss about calculation results because velocity at the same point different from surface to bottom in the experiment and velocity is depth-averaged by two-dimensional plane calculation. Flow running on flood channel is appeared at left bank of main channel. 4.3 Validity of the result Two-dimensional analysis result of model experiment that has been calculated on the channel included oblique weir is conducted a deliberation on, whether this model can be applied in safety assessment. Major obtained conclusions are here. (1) Curved flow is occurred at junction of weir and flood channel where flow characteristic is strongly three-dimensional.Two-dimensional model that is used in this study can explain gross outline of occurrence of these flow phenomena. (2) Velocity at bed differs from surface flow velocity at back flow region. Strong back flow in experiment came out as dead and back flow region in the calculation despite three-dimensional flow appeared. (3) CIP method is described as good energy conservative

Figure 11. Velocity vector at downstream of the weir (left: calculation, right: experiment).

calculation system. It can give the rough outline of hydraulic jump shown in the experiment using non-conservative equations.

Table 3. The calculation with various shape of the weir.

Case	Changing term	Value after changing
Run-0	–	–
Run-1	Angle of weir	−20 degree
Run-2	Height of weir	90% of experiment

Figure 12. Velocity vector of the calculation.

Consequently, this model is good for explaining the outline of flow but could not replicate the detail of experiment, for example vertical characteristics.

5 SAFETY INVESTIGATION OF THE WEIR

It is considered that damages of river and basin are from the hydraulics jumps and accelerated flows, which is shown in the model experiment represented for the Daijyu weir. Simulations are performed by changing of heights and angles of the weir and the safety by these changes is investigated. The calcu lation with various shapes of the weir is shown in Table 3. Velocity vector of the calculation is shown in Fig. 12. The condition of Run-0 is the same as existing condition.

In Run-1, characteristics of flow are outlined below. Detour flow originates from flow near flood channel. Flows run to flood channel and concentrate to right of

Study of sediment motion in a local scour hole through an image processing technique

S. Malavasi, A. Radice & F. Ballio

Politecnico di Milano, Dept. I.I.A.R., Milan, Italy

ABSTRACT: The kinematics of the grains on the bottom of a local abutment scour hole was filmed during a clear water experiment and analysed by means of an image processing technique. The identification of natural sediments moving on a background of similar ones is complicated, due to the absence of contrast. This complication can be overcome using a technique based on the subtraction between successive frames. The method allowed to identify the temporal and spatial variation of the grain activity, and also to display the paths of the moving particles. The scour characteristics vary as the dimension of the hole increases: the 3D horseshoe vortex structures seem to play a major role only after the initial stage, during which the process is rather dominated by the 2D acceleration due to the abutment blocking effect; in the development stage the process appears to be a succession of transport events and periods of stillness, with increasing irregularity as time proceeds.

1 INTRODUCTION

Local scour phenomena at bridge structures have been studied through experimental works for many years. Since the early 1960s equations have been proposed for the prediction of the scour depth once the control parameters of the incoming flow and of the bridge structure are known. Despite the large amount of

experimental data, many aspects of the erosion process remain unclear; the predictive ability of scour equations is, in some cases, inadequate (see for example Radice et al., 2002).

These reasons indicate that phenomenological studies at the sediment scale may be an important complement to the classical "black box" scour experiments. The evolution of the scour hole around piers and abutments is generally believed to be driven by the action of the three-dimensional horseshoe vortex system that develops in the vicinity of the obstacle. In the past, some studies that investigated the nature of the flow field have been published (e.g. Kwan & Melville, 1994; Dey et al., 1995; Mayerle et al., 1995; Molinas et al., 1998; Ahmed & Rajaratnam, 2000; Graf & Istiarto, 2002). To our knowledge, no studies considered the dynamics of the granular bed, even though the fluid-sediment interaction is a key item for the interpretation and modelling of local erosion phenomena.

It is important to remark that the usual plane bed inception and transport equations do not necessarily apply to the case of a hole eroded by a three-dimensional and spatially highly variable flow field. In this study, the kinematics of the grains on the bottom of a local abutment scour hole was filmed during a clear water experiment and subsequently analysed by means of an image processing technique. Image processing (IP) is largely used for the measurement of fluid flow fields; in such cases, the fluid

is seeded through very small, neutrally buoyant particles. Less frequently IP has been applied to problems concerning sediments. Image techniques were used in order to extract information on the granulometric distribution of still grains (e.g. Fraccarollo & Marion, 1995; McEwan et al., 2000). Other studies dealt with steady bed load (e.g. Drake et al., 1988; Lee & Hsu, 1994; Niño & Garcia, 1996; Pilotti et al., 1997; Papanicolaou et al., 1999; Strom et al., 2002) or with debris flow (e.g. Capart et al., 2002). The application of IP to local erosion sums up all the complications related to the phenomena mentioned above, and adds some further, due to the complexity of the process. Local scour is a transient phenomenon, which may take long time to develop; the spatial distribution of the moving grains may be extremely variable, ranging from sporadic dispersed movements to high density clouds of sediments at varying distances from the bottom; the geometry of the scour hole is highly three-dimensional, thus complicating the focusing of the bottom; the moving particles lay on a background of similar grains, so that their identification is not straightforward. In the mentioned literature studies, some of the quoted difficulties were bypassed through the use of synthetic multicoloured sediments; in this work we

developed a technique that is based on image subtrac

tion that can also be applied to natural sediments. The

number of particles moving in a certain time interval

was assumed as an indicator of the activity of the pro

cess. The kinematics of the grains was interpreted also

with reference to the particle paths, which were related

to the structure of the flow field near the obstacle.

2 EXPERIMENTAL SETUP AND

SCOUR TEST

The experiment reported herein was performed in a

rectangular channel, 15 m long and 0.6 m wide. The

channel was filled with approximately uniform nat

ural sediments of mean diameter d 50 = 1.9 mm. The

rectangular abutment model was made in PVC and its dimensions were b= 20.2 cm and L= 10.2 cm, respectively, in the transverse and in the streamwise directions.

The test parameters were: uniform water depth h= 9.5 cm; mean flow velocity U = 0.47 m/s; longitu dinal slope S = 0.0012. These corresponded to nearly incipient condition for the undisturbed bed (Shields parameter φ= (h · S)/(Δ · d 50)= 0.03, in which Δ= (ρ s − ρ)/ρ is the specific gravity of the sediments).

Figure 1 shows the temporal evolution of the maxi mum scour depth d s with time T for a previous experi ment having the same control parameters. Scour depth continuously increases with time, but at a decreasing rate; in the same way, the grain activity is very intense at the beginning of the process, yet becoming weaker as the phenomenon proceeds in time and the scour rate decreases.

The grain movement was filmed with a black and white CCD camera of a frame rate set to 50 fps and a resolution of 576× 763 pixel, and a PC equipped with a proper frame grabber.The duration of each recording was typically 2 or 4 seconds (100 or 200 images); the position of the films along the test duration is shown in Figure 1. Two time scales will be used in the following:

t will indicate time within a film, while T will indicate

the scour test time.

The sediment kinematics was filmed from the top;

in order to avoid image distortion due to the irregular

ity of the free surface in the proximity of the obstacle,

a wide plexiglass window just touching the water was

put on the channel, thus obtaining clear images without

disturbing appreciably the flow. Some control scour

depth values were measured also during the visualiza

tion run, resulting in negligible differences from those

plotted in Figure 1. This demonstrated that the plexi

glass window did not distort significantly the process.

The film area was rather limited, its dimensions

being approximately 11× 8 cm 2 ; thus, the CCD was

placed in different positions all around the abutment,

in order to investigate the dynamics of the grains 0 10 20 30 40 1.E+01 1.E+02 1.E+03 1.E+04 1.E+05 1.E+06 T [s] d s [c m] 5a,b 8a 8d 10a,b 6a,b 8c 9b 10a,b 8b 9a 10a,b Figure 1. images were used; the intensity value of each pixel lays between 0 (black) and 255 (white). If a parti cle is moving, its positions in two subsequent frames will be different: these locations are in the following 1 and 2. As a consequence of the particle displace ment, a change in the intensity values of the pixels corresponding to positions 1 and 2 will occur in both frames. The difference between the first and the sec ond image (which we computed as second-first) gives a third, which ideally has non-zero values in positions 1 and 2 and zero values elsewhere.The non-zero differ ence values will be positive in position 2 and negative in position 1 if a bright particle locally moves on a background of darker, and vice versa. The subtraction image, therefore, contains the image of the particle in both positions; this duplication is easily removed by filtering to zero all negative values. In this way the non zero values give a single representation of the moving

particle, corresponding to position 2 if a bright parti

cle moves on a background of darker, to position 1 in

the opposite case. Thus, the positive difference image

shows the starting position of particles that are darker than their local background and the arrival position of the ones that are brighter than it. The positive difference image was then thresholded to obtain a binary representation where a unit value was assigned to the pixels corresponding to the particle position and zero was assigned elsewhere. The binary image appeared as uniformly black with a white blob representing the moving particle. In real cases with many grains moving, the binary image was typically affected by noise (i.e. many small blobs were present), which was due to small movement or to little changes in the intensity values of the pixels that did not correspond to real displacements. The little blobs were eliminated through image filtering to obtain a clearer image, containing only the information on non-vanishing movements. The complete thresholding and filtering procedure involves four parameters: the binning threshold bin (which lays between 0 and 255), the pixel connection criterion (based either on 4 or on 8 neighbouring pixels), and two coefficients, named C and D min , for filtering. First, the binary image was computed. Low binning factors and 8-connectivity give few big blobs, when the image of a particle is connected to those of the surrounding moving grains; high binning factors and 4-connectivity give the opposite.All the blobs having a dimension smaller than D min were eliminated. Finally, the average dimension (in pixel) of the blobs was computed, and all blobs with a dimension smaller than the fraction C of the average value were eliminated from the image. High C values eliminate many blobs and vice versa. The first filter (involving D min) was required because if no appreciable movement takes place, the binary image will have very small blobs, which will not be completely eliminated by the C filter. The chosen parameter combination was: bin= 77, 4-connection, C = 0.5, D min = 30. This set of parameters was chosen by eye, comparing the result of the computation to the direct superimposition of successive frames. The calibration parameters do not need to be changed as long as the particle characteristics and the lightning are kept constant. It should be noticed that the processing technique was defined and tuned for a correct and robust identification of the number of moving particles, but not of their dimension: in particular, the resulting average dimension (in pixel) of the blobs was highly dependent on

the value of the calculation parameters, and it may be different than in the original frames. At the end, the binary image was inverted in order to have white background images with black blobs. Figure 4 shows an example of application of the described technique: images (a) and (b) are two successive frames; some of the moving grains have been circled. Image (c) is the absolute difference (b) – (a), which has non-zero values in positions 1 and 2 and small noise spots. Image (d) is the positive difference (f) (e) (d) (c) (b) (a) flow

ence image (f). In the upstream and downstream images some

of the moving particles are circled. Flow is from bottom to top. image, retaining only the positive difference values. Image (e) is the binary difference image after thresholding. Image (f) is the final binary filtered representation. 4 PARTICLE PATHS The superimposition of successive blob images allows to identify the positions successively occupied by the moving grains, and thus their paths. Figures 5 and 6 show examples of such a visualisation for the scour test. The grain paths for an initial stage of the process are shown in Figure 5 (T = 120 s): the two representations (a) and (b) are the results of two series of ten successive difference images, respectively, corresponding to t= 0.2→0.4 s and t= 1.2→1.4 s within one film. Some of the more evident paths have been highlighted through arrows; the black and white representation (a) (b) abutment abutment flow Figure 5. Superimposition of 10 successive difference images for zone 1 and T = 120 s. The interval between the two sequences in (a) and (b) was equal to 1 s. In grey is the visible part of the abutment. Some clear paths are highlighted through arrows. Mean flow direction is from bottom to top.

does not allow to identify the successive positions of

the grains, while this is evidently possible from the

single subtraction images. Figures 5a and 5b clearly

indicate the presence of a well structured and tempo

rally stable path field for the grains, which is coherent

with a typical 2D flow pattern around an obstacle;

this result would indicate the mean acceleration due

to the abutment blocking effect as the responsible of

the particle motion during the first stage of the erosion

process.The 3D effects of the vortex structures in front

of the abutment are hardly visible, due to the strong

stretching by the outer flow. Further visualisations

confirmed this result.

Visualisations of the grain paths for developed

stages of the process demonstrated a completely differ

ent phenomenology: the movement is not continuous

in time and well structured in space, but rather dom

inated by intermittent events with variable spatial

characteristics. Figure 6a (T = 120 s, t= 0.2→0.4 s) (a)
(b) abutment abutment flow

Figure 6. Superimposition of 10 successive difference

images for zone 1 and T = 11100 s. The interval between the

two sequences in (a) and (b) was equal to 1 s. In grey is

highlighted

through arrows. Mean flow direction is from bottom to top.
shows absence of appreciable grain activity. One second
later (Figure 6b, T = 120 s, t= 1.2→1.4 s) grain paths show
the presence of a flow structure sweeping the particles
away from the abutment against the main flow direction, and
a small corner structure at the side. This indicates that
in the development stage of the scour process the main

scouring agent is determined by three-dimensional unsteady vortex structures upstream of the abutment; as the scour hole becomes deeper, the vortex stretching by the outer flow is evidently weaker and the flow and grain kinematics becomes more complex. The characteristics of the sediment activity described for the initial and mature stage of the erosion process are coherent with literature descriptions of the phenomenon (e.g. Kwan & Melville, 1994; Radice et al., 2002); to the best of our knowledge, however, such characteristics had never been documented by measurements and/or visualisations. 5 MOVEMENT INTENSITY Once the moving particles were identified, a percentage index of the intensity of movement (IM) can be evaluated as: where N is the number of blobs in the thresholded subtraction image and N I is the number of particles visible in the frame. To obtain the time evolution of IM, the calculation was conducted for each couple of successive frames, so that a film of duration of 2 s (100 frames) gave 99 successive values of IM. For the evaluation of N I , particles at the image borders were visually counted, so that N I was calculated as the product of the average numbers of particles in the two directions. Any algorithm for particle identification within a single picture (e.g. McEwan et al., 2000) may be also used for an automatic evaluation of N I . IM is an average indicator of the grain activity over the measuring zone. To highlight the spatial variability of the movement intensity (demonstrated by visual observation), the measuring zone was divided into windows of inspection, and individual IM values were calculated for each zone. Results that will be presented in the following refer to a subdivision of the measuring zone into 9 windows of inspection (Figure 7 shows an example of division for zone 1); the dimension of each window was approximately 2× 3 cm 2 . Figure 8 shows the time evolution of IM over a duration of 2 s for zone 1, window 9 for increasing run times T . At the beginning of the erosion process (Figure 8a, T = 120 s, see also Fig. 5) IM values are typically 20÷ 40%, indicating that a high percentage 1 2 3 4 5 6 7 8 9

Figure 7. Typical division into inspection windows (numer

ation indicated) for an image in zone 1. Flow is from bottom

to top. The abutment can be seen at the top of the image.

of the particles move. The grain activity progressively

decreases as time proceeds, and after one day (Fig. 8d)

values of IM were reduced by one order of magnitude.

Figure 8a shows fluctuations of IM, but no period of rest; a different behaviour can be recognised for longer run times (Figures 8b→8d).This observation is in agreement with those drawn in the precedent para graph, according to which the grain kinematics was stable only in the initial stage of the scour process, while afterwards it was composed by a succession of transport events and periods of stillness. This again indicates the different temporal stabilities of the flow field along the process, where the decreasing degrees of stretching of the vortex structures by the outer flow make three-dimensional unsteady characteristics of the vortex flow field progressively more evident. Notice that such unsteadiness can not be appreciated by scour depth values (Figure 1) since the character istic time scales of the scour hole evolution are much larger than those of the flow field and, consequently, of the water-sediment interaction.

Relatively regular successions of transport events can be observed for T = 1800 s (Figure 8b); available movies are too short for definitive conclusions about intermittency periods for higher run times (Figures 8c and 8d).

Figure 9 shows the computed values of IM for zone 1 at time T = 1800 s (a) and for zone 2 at time

T = 11100 s (b).The spatial variability of the sediment

intensity of movement can be observed by the time

evolution of IM at different locations around the abut

ment.The spatial distribution of IM values is consistent

with the visualisations of Figures 5 and 6, in which the

density of the blobs in a certain area is proportional to

the grains activity at the same location.

Spatial coherence of the grain motions can be

inferred from the similarities in temporal trends of 0 10 20 30 40 50 0.0 0.5 1.0 1.5 2.0 t [s] I M [%] (a) 0 10 20 0.0 0.5 1.0 1.5 2.0 t [s] I M [%] (b) 0 10 20 0.0 0.5 1.0 1.5 2.0 t [s] I M [%] (c) 0 10 20 0.0 0.5 1.0 1.5 2.0 t [s] I M [%] (d) Figure 8. Temporal evolution of IM for zone 1, window 9. Time T = 120 s (a), 1800 s (b), 11100 s (c), 86400 s (d). neighbouring windows, for example in windows 7, 8 and 9 in Figure 9a. It is reasonable to interpret such results as the effect of coherent structures in the flow field.

(a)

(b) 1 2 3 4 5 6 7 8 9 1 2 3 4 5 6 7 8 9

Figure 9. Temporal variation of IM for zone 1, T = 1800 s

(a), and for zone 2, T = 11100 s (b). On the x axis: t [s], on

the y axis: IM [%]. Window numeration in upper left corner.

The time series of IM were averaged to obtain mean

indicators of the intensity of movement. Each mean

value was computed averaging data obtained from

three or four repeated films (thus 297 or 396 IM values

corresponding to 6 or 8 s). Then, the variation coeffi

cient CV of the same data set was calculated. Figure 10

shows the evolution of IM with run time for window 9 in zone 1 and window 7 in zone 2 (corresponding to the most active positions for each zone), and the variation coefficient CV of the intensity index. As erosion proceeds, the mean value of IM decreases and its variation coefficient increases. This observation synthesizes all those drawn above: in the initial stage of scour the grain activity is intense and rather stable; with increasing erosion depth, the mean grain activity decreases due to longer and longer periods of stillness while its unsteadiness increases, presumably reflecting a similar behaviour of the flow field.

6 CONCLUSIONS

The grain motion at the bottom of a local abutment scour hole was investigated using an image processing 0 1 10 100 1.E+03 1.E+04 1.E+05 T [s] I M [%] zone 1, window 9 zone 2, window 7 (a) 0.2 0.4 0.6 0.8 1.0 1.2 1.4 1.E+03 1.E+04 1.E+05 T [s] C V (I M) zone 1, window 9 zone 2, window 7 (b) Figure 10. Temporal evolution of mean value IM and of its variation coefficient. technique. The identification of the moving grains was achieved by computing the difference image between two successive frames. The movement intensity is variable for different locations around the obstacle. The most active positions are slightly upstream of the abutment nose and adjacent to the abutment side. Activity is rather stable in the initial stage, while it is characterized by a succession of intense transport events and periods of stillness afterwards. The mean grain activity decreases with increasing scour depths, while its unsteadiness increases. Results for the grain activity can be correlated with expected features of the flow field, and in particular with the spatial and temporal characteristics of the vortex system in front of the abutment. The indications from present visualisations and measurements may be of importance for conceptual or

numerical modelling of erosion processes: any model aiming to achieve a physically sound scour prediction should be able to reproduce and incorporate the complex spatial and temporal variability of the sediment dynamics.

ABSTRACT: This paper describes the numerical study on 3D turbulent flow structures around submerged

spur dikes. Effects of three hydraulic parameters, S/L (S: interval length of two spur dikes, L: length of spur

dikes), T/h (T: height of spur dikes, h: depth), θ (= inclination angle), are examined through the comparison of

numerical results and previous experimental results focusing on both time-mean and time-dependent aspects. A

non-liner k-ε model is adopted as a turbulence model to reproduce the vortex shedding from a tip of a spur dike

and secondary currents. The numerical results show that the flow near the bed, which is particularly important

for sediment transport, is affected by both inclination angle and the ratio of T/h. In the downstream inclined

spur dikes, the unsteady vortex shedding is generated from the first spur dike and the period is determined by

the feedback effect of impinging shear layer. The frequency jump of the vortex shedding can be seen between

S/L= 2 and S/L= 4 in the numerical results.

1 INTRODUCTION

Spur dikes (or groins) are well-used man-made river

structures for navigation and protection of riverbanks.

Recently, a new aim is added to the construction of

spur dikes, that is, spur dikes become to be focused as

structures for environmental functions.An embayment formed around spur dikes due to sedimentation, which is called “Wando” in Japan, provides favorable habitat for wide variety of fauna and flora. Figure 1 shows an example of a group of Wandos in Kiso River in Japan. However, the condition and process of formation of the embayment has not elucidated enough. Therefore, it is necessary to clarify the time-mean and unsteady behavior of the 3D flow pattern around spur dikes as well as the mass exchange between the spur dikes zone and main channels, which has a controlling effect on the environment and sedimentation.

The flow field around submerged spur dikes are characterized by a horseshoe vortex formation near the root of a spur dike, recirculations with a verti

cal axes between two spur dikes and vortex shedding from the tip of a spur dike due to the shear instability. Those flow structures have been captured both experimentally and numerically.Tominaga et al (2001) performed a laboratory test with PIV method and showed that, in time-mean flow field, the flow from the mainstream toward the inner part between two spur dikes is predominant around upstream-inclined spur

Figure 1. Spur dikes and “Wando” in Kiso River.

dikes, whereas, the flow in the reverse direction is pre

dominant around downstream-inclined spur dikes.The results in the experiment cannot be applied directly to practical purposes because the ratio of the verti

cal scale against the horizontal scale is much larger

than that of real rivers. However, the experiment with such deformed spatial conditions is effective to extract clearly fundamental properties of 3D flow structures.

Veitbrecht & Jirka (2001) also performed PIV measurements around inclined un-submerged spur dikes in a shallow open channel flow and examined the flow patterns and mass exchange processes between the groyne area and the mainstream.

Numerical simulations with URANS models have been recognized as powerful and economical tools for prediction of 3D unsteady flow structures around bluff bodies. Kimura et al (2003) performed 3D computations with a well-tuned non-linear k-ε model under the conditions of the laboratory test by Tominaga et al (2001). In the numerical results, both time-mean and time-dependent flow features around upstream/downstream inclined spur dikes were in reasonable agreement with the experimental results. The numerical results also showed that the deviation of the flow by the first spur dike of a group of spur dikes has significant influence on the vortex shedding from the edge of spur dikes. Those results found in previous investigations are helpful for understanding of fundamental flow features. However, more systematic approach is required to obtain a useful data for effective design of

spur dikes in practical river works.

In this study, 3D (three dimensional) turbulent flow structures around submerged spur dikes under various hydraulic conditions are examined numerically. Special focus is given to the influence of three hydraulic parameters: (i) the inclination angle between main stream and spur dikes, (ii) S/L (S: interval length of two spur dikes, L: length of spur dikes) and (iii) T/h (T: height of spur dikes, h: depth). A non-linear k-ε model under the generalized curvilinear coordinate is adopted as a turbulence model considering the balance between accuracy and a computational expense. The numerical results are compared with experimental results and the effects of the parameters on time-mean and time-dependent flow features are discussed.

2 COMPUTATIONAL METHOD

2.1 Basic equations

The Reynolds averaged 3D flow equations with contravariant components of velocity vectors on a generalized curvilinear movable coordinate system are used as governing equations in this study. The equations are composed of a continuity equation, momentum equations and k-ε equations as follows. [Continuity equation] [Momentum equation] [k equations] [ε equations] where § I = generalized curvilinear coordinate (see Figures 2 and 3), t= time, V i = contravariant component of the velocity vector of flows, W i = contravariant component of the velocity vector of grid motion, p= pressure,

ν=molecular dynamic viscosity, ρ= density of water, k= turbulent energy, ε= turbulent energy dissipation rate, g ij and g ij = covariant and contravariant component of metric tensor, g= det(g ij) and F i = contravariant component of gravity acceleration. ∇ i indicates a covariant differential, for instance, where '' k ij =Christoffel symbol described as To calculate a complex turbulent flow with separation and vortex shedding, a 2nd-order non-linear k-ε model by Kimura & Hosoda (2003) is adopted as a turbulence model.This model has been applied to various flow fields, such as, a flow around a square cylinder V h V j V z p, k, G ij k , g ij , g ij z j h

Figure 2. Arrangement of hydraulic variables and metric

tensors on full staggered grid. T h f l o w x y z S L

Figure 3. Schematic diagram of the flow field and notations

of symbols.

(Kimura & Hosoda 1999), a flow around a surface

mounted cubic obstacle (Kimura & Hosoda 2000) and

a compound open channel flow (Kimura et al 2001).

The constitutive equations of the model are described

as follows. The model coefficients are not constants but functions of the strain parameter S and the rotation parameter . In this study, all the coefficients are given as functions with one variable M for simplicity as follows (Kimura & Hosoda 2003). Equations (14) and (15) were adjusted through the consideration of the distribution of turbulent intensities in a simple shear flow compared with the previous experimental results (Kimura & Hosoda 2000). Equation (16) was tuned to satisfy the realizability in a simple shear flow and singular points in both 2D and 3D flow fields (Hosoda et al 2001). The standard linear k-ε model is also applied for the comparison of turbulence models. The constitutive equation of the standard model is where C μ is 0.09 (=const.). 2.2 Outline of numerical method The differential equations governing the meanvelocities and the turbulence field are solved with the finite volume method on full-staggered grid system. The arrangement of hydraulic variables on a full-staggered grid is shown in Figure 2. The metric tensors and the Cristoffel symbols are defined only at grid points to save computer memory and the values at other positions are interpolated

at each computational step. QUICK scheme is applied to the convection terms and the central differencing is used for the diffusion terms in the momentum equations. The hybrid central upwind scheme is applied to the k and ε equations for the computational stability. Adams-Bashforth scheme with second-order accuracy in time is used for time integration in each equation. The basic equations are discretized as fully explicit forms and are solved successively along the time axis step by step. The pressure field is solved using iterative procedure at each time step using SOLA algorithm by Hirt et al (1975).

2.3 Boundary conditions

Since the present turbulence model is a heigh Reynolds

number type, the wall function approach is applied as

the wall boundary conditions for k and ε. The wall

friction is evaluated by the log-law. At the downstream

end of the computational domain, the longitudinal gra

dients of all variables are assumed to be zero. At the

boundary inlet, the level of k is chosen to be (0.02U 0) 2

(U 0 = averaged velocity). The value of ε at the inlet is

determined from the value of k at the inlet and Equa

tion (18) by specifying the ratio D t /ν= 10 (Bosche &

Rodi 1998).

The free surface elevation is solved by the simple

relation in Equation (19) since the contravariant com

ponents of the velocity vector are used in the basic

equations (Takizawa et al 1992).

where ∂t= time increment and ∂h= surface eleva

tion during ∂t. To consider the rapid attenuation of

turbulent intensities in the depth-wise direction near

the free surface, the eddy viscosity is multiplied by

the following dumping function (Hosoda 1990).

where sub-s indicates the value at the surface layer.The

turbulent dissipation rate ε at the surface layer is eval

uated by the following formula proposed by Sugiyama

et al (1995) to calculate the secondary currents of

2nd kind.

2.4 Initial conditions

At the beginning of the calculation, U (=velocity in the

longitudinal direction (x-direction))=U 0 (=averaged

bulk velocity),V (=velocity in the transverse direction

(y-direction))= 0, k= k in and ε= ε in (k in and ε in are

the values of k and ε at the inlet boundary) are speci

fied over the whole computational domain. In order to

avoid the influence of the initial conditions, the numer

ical results after 50 seconds from the initial conditions

are used for the following examinations.

3 COMPUTATIONAL CONDITIONS

3.1 Hydraulic conditions

Spur dikes are constructed in a group in usual river

works. However, we consider a flow field, in which only two spur dikes with same length, height, angle, etc. are attached to the left bank, for simplicity. Special attention is given to the influence of following three hydraulic parameters. (i) θ: inclination angle between a spur dike and transverse direction of the main stream (ii) S/L: S: spatial interval of two spur dikes, L: length of a spur dike (iii) T/h: T: height of a spur dike, h: water depth The computations were performed under different hydraulic conditions as shown in Tables 1, 2 and 3. The

total number of computational cases becomes 15 and 7 cases of them coincide with the conditions of the laboratory tests by Tominaga et al (2001) or Tominaga et al (2002). 3.2 Computational domain and numerical grids The upstream and downstream ends of the computational domain are set at 3 m distances from spur dikes to avoid the influence of the open boundaries around the spur dikes. The channel width in the laboratory tests by Tominaga et al (2001) and Tominaga et al (2002) is 30 cm, however, the width of 20 cm Table 1. Hydraulic conditions of computations in Series A. from the left bank is included into the computational

domain.

Numerical grids in the x-y plane at the vicinity of

spur dikes in RunsA1 and B4 are shown in Figures 4(a)

and (b), respectively. These grids are generated with

the aid of the graphical grid generator “Rubbnet”

developed by Chiba & Takemoto (1999). The grid over

the roof of the spur dikes is moved in vertical direc

tion according with the surface elevation calculated

by Equation (19) at each time step. The number of

grid points at y and z directions in each Run becomes

30 (y-direction)× 8 (z-direction). The grid point in

x-direction in Series A and Series C becomes 104 and

that in series B is varied from 81 (Run B1) to 108

(Run B4) according with the length of the interval of

two spur dikes.

Figure 4. Examples of numerical grids around the spur

dikes in the x-y plane. 4 RESULTS AND DISCUSSIONS 4.1
Effects of inclination angle (Series A) The inclination
angle θ between the spur dikes and the transverse direction
of the channel (see Figure 3) is varied from -30 ∘ to +30 ∘
in Runs A1-A7. The most affected part of the flow fields by
θ seems to be the upper region of the first (upstream) spur
dike. Figure 5 shows the time-averaged velocity vectors in
a x-z plane near the right bank (y= 5 mm) in RunsA1,A3
andA7. The experimental results by Tominaga et al (2001)
are shown together in Figure 5. Since the experiment was
performed by PIV, the flow pattern at the backside of the
inclined spur dikes could not be captured. Therefore, the
plotted area of the velocity vectors of the experimental
result is smaller than that of the numerical result. Both
the experimental and numerical results show that a strong
upward flow is generated in the upper part of the first
spur dike and reverse flow is generated at the upstream
region in Run A1. The upward and reverse flows around the
first spur dike can be seen in Run A7 though the flows are
much weaker than those in Run A1. The flow features in Run
A4 seem to be a middle pattern between Runs A1 and A7. (a)
Run A1 (Cal.) (b) Run A1 (Exp.) (c) Run A4 (Cal.) (d) Run
A4 (Exp.) (e) Run A7 (Cal.) (f) Run A7 (Exp.) Figure 5.
Flow patterns around the first spur dike near the side wall

in the series A (x-z plane, y= 5 mm).

Figure 6. Flow deviation effects in upward and transverse directions in the series A.

It has been pointed out through the previous experi mental and numerical studies (Kimura et al (2002) and Tominaga et al (2001)) that the flow pattern near the bed between two spur dikes, which dominates the sed iment transport, is closely affected by the inclination angle. Those studies show that the flow from the main stream toward the inner part between two spur dikes is dominant around upstream inclined spur dikes, while the flow in the opposite direction is dominant around downstream inclined spur dikes. The similar features were observed again in the present numerical results in series A, that is, as θ increases the outflow near the bed becomes stronger (The figures are not shown for the saving of the space.).

The flow deviation effect is one of important roles of spur dikes for the protection of riverbanks. In order to examine the relation between the effect of flow deviation and the inclination angle, the maximum velocities in transverse and upward directions non dimensionalized by the bulk velocity, V max /U mean and W max /U mean (U mean : bulk velocity (=17.1 cm/s)) in the series A are shown in Figure 6. This figure indicates

that the effect of the flow deviation in upward direction becomes larger around upstream inclined spur dikes while the effect in the transverse direction becomes larger around the rightangled spur dikes.

Tominaga et al (2003) defined a “spur dike zone” as a region of river channel walled by two spur dikes. The clarification of the mass transport between the spur dike zone and the mainstream is important for pre diction of water quality and river environment around spur dikes. In this study, dimensionless mass exchange coefficient R ′ between the spur dike zone and the mainstream is defined as

where, V d : volume of the spur dike zone, U r : normal velocity at the surface of the spur dike zone, S: interval length of two spur dikes and A: area of the interface between the spur dike zone and the mainstream (total Figure 7. Dimensionless mass-exchange coefficients between the spur dike zone and mainstream in the series A. area of x-y and x-z planes). Figure 7 shows the dimensionless mass exchange coefficient R ′ in series A. This figure shows that the mass exchange becomes larger as the absolute value of the inclination angle becomes larger and it becomes minimum around right-angled spur dikes. The unsteady flow features around spur dikes are also important for both river environment and flood control. Kimura et al (2003) pointed out through the comparison of numerical and experimental results that the unsteady motion around the spur dikes is mainly caused by the vortex shedding from the tip of the first spur dike. Figure 8 shows the temporal variation of the velocity in the transverse direction (y-direction) in the series A. The location is the middle point of the tips of two spur dikes (see the diagram in Figure 10) at z= 3.5 cm. Figure 9 shows the experimental results by Tominaga et al (2002) in Runs A1, A4 and A7. Both the experimental and numerical results indicate that

the flow oscillation is small in the case of upstream inclined spur dikes and the magnitude of the oscillation becomes larger as θ increases. The oscillation with maximum amplitude can be seen in the case of maximum inclination angle (Run A7). 4.2 Effects of the interval of two spur dikes (Series B) Figures 11, 12 and 13 shows the comparison of the time-averaged velocity vectors in a horizontal plane at z= 5 mm in Runs B2–B4 in both the numerical and experimental results. In the numerical results, the flow from the spur dike zone toward the main channel is dominant regardless of the interval length. The qualitative flow pattern in Run B4 is slightly different from the other Runs because the vortex formed around the downstream part of the first spur dike is significantly stretched in the stream-wise direction. These flow features in the numerical results are in good agreement with the experimental results. Figure 14 shows the horizontal flow pattern at z= 5 mm in the numerical result of Run B1. The flow

Figure 8. Temporal variations of velocities in the transverse

direction (y-direction) at the center part between two spur

dikes (see Figure 10) at z= 35 mm (Series A, Cal.).

pattern in this case is very different from the flows in

Runs B2–B4, namely, the velocity between the spur

dikes is much smaller than those in other 3 cases and

the dominant flow direction cannot be clearly detected.

These numerical results indicate that the outflow from

the spur dike zone is dominant near the bed around

downstream inclined spur dikes only if the interval

length of two spur dikes is larger than the length of

spur dike.

Time dependent features were also closely affected

by the interval length. Figure 15 shows temporal

variations of velocities in the transverse direction

(y-direction) at the center point between the tips of

two spur dikes at z= 35 mm. This figure shows that

the flow in Run B1 is almost steady and the flows in

other 3 Runs yield fluid oscillation. We can see quite
Figure 9. Temporal variations of velocities in the transverse direction (y-direction) at the center part between two spur dikes (see Figure 10) at z= 35 mm. Figure 14. Time-averaged velocity vectors in the numerical

result in a horizontal plane in Run B1 (x-y plane, z= 5 mm). Figure 15. Temporal variations of velocities in the transverse direction (y-direction) at the center between the tips of two spur dikes (see Figure 10) in the computations of series B (z= 35 mm). periodic oscillations in the results of Run B2 and B4 while the oscillation in Run B3 is chaotic. In order to consider the fluid oscillation, we should notice that the flow around two spur dikes is a typical case of the impinging shear layer with a feedback loop. The formation of the feedback loop is explained as follows: (i) the separated vortex from the first spur dike impinges upon the second one, (ii) the effect of impinging stimulates the upstream sensitive region of initial separation, (iii) the stimulation cases the next vortex shedding, then a feedback loop is formed between two spur dikes and the frequency is rocked.

Rockwell & Naudascher (1978) showed the ranges of Strouhal numbers in different feedback modes as where St 1 /St 2 : strouhal number of 1st/2nd mode, f: frequency of fluid oscillation, S: interval length of two obstacle and U 0 : bulk velocity. The 1st mode indicates the feedback loop which contains only one vortex in a loop, while, the feedback loop of the 2nd mode contains two vortices in it. The numerical results show that the strouhal number in Run B2 is within the range of the 1st mode while the strouhal number in Run B4 is within the range of the 2nd mode. Consequently, it (a) t=90.2 (sec) (b) t=90.7 (sec) (c) t=91.2 (sec)

Figure 16. Computational results of vortex shedding from

the tip of the first spur dike in Run B3 (x-y plane, z= 5 mm).

is pointed out that the frequency jump from the 1st

mode toward the 2nd mode occurs between S/L= 2

and S/L= 4. The irregular oscillation seen in Run B3

is likely to be a transition flow between the 1st and 2nd

modes.

Figure 16 shows a pattern of the vortex shedding

from the tip of the first spur dike in the computa

tional results of Run B3.The similar unsteady feature

can be seen in Runs B2 and B4. Since the vor

tex disappears near the second spur dike due to the

influence of impinging, the affected area of fluid oscil

lation with large amplitude is limited around the spur

dike zone.

4.3 Effects of relative height (Series C)

Figure 17 shows the time-averaged flow patterns in a

horizontal plane near the bed (z= 5 mm) in the series

C. The flow patterns in Runs C2 and C3 are char

acterized by outflows form the inner part toward the

main-stream, which is in compatible with the common

flow pattern around downstream inclined spur dikes

reported in some previous studies (e.g., Yamashita

et al (2001), Tominaga et al (2001) and Kimura et al

(2002)). Contrarily, the flow from the main-channel

toward the spur dike zone, which has been reported as (a) Run C1 (b) Run C2 (c) Run C3 (d) Run C4 Figure 17. Time-averaged velocity vectors in a horizontal plane in the computational results of series C (x-y plane, z= 5 mm). a typical flow pattern around upstream inclined spur dikes, is dominant in Run C1. Therefore, it is pointed out that the flow direction near the bed depends on the relative height of spur dikes as well as the inclination angle. The flow pattern in Run C4, in which a large circulation with a vertical axis can be seen, is also very different from the other 3 cases. Figure 18 shows the flow patterns in a vertical x-z plane at y= 25 mm in the series C. A vortex in the clockwise direction can be seen between two spur dikes in the results of Runs C1-C3; on the other hand, a vortex in the opposite direction is generated in the result of Run C4. The results in Figure 18 (a) Run C1 (b) Run C2 (c) Run C3 (d) Run C4

Figure 18. Time-averaged velocity vectors in a vertical

plane (x-z plane) in the computational results of the series

C (y= 25 mm).

clearly show that the flows around non-submerged

spur dikes are qualitatively different from the flows

around submerged spur dikes.

Figure 19 shows the temporal variation of veloc

ities in the transverse direction (y-direction) at the

center part between the tips of two spur dikes near

the bed (z= 35 mm) in the computational results in the series C. The flow pattern in the non-submerged case (Run C4) is almost steady and the other computations with Runs C1–C3 yield unsteady flow patterns. The fluid oscillation around spur dikes is caused by the vortex shedding due to the shear instability. There are two kinds of shear layers around submerged spur dikes: one is a horizontal layer along the roofs of the spur dikes and the other is a vertical layer in an x-z plane along the tips of spur dikes. The comparison of the velocity variations between the submerged and non-submerged cases indicates that the shear layer in the horizontal plane seems to be more important to generate the fluid oscillations. The amplitudes of the oscillations in Runs C1 and C3 are smaller than that in Run C2. The reason seems to be that the development of the shear layer in the x-y plane is suppressed by the bed (Run C1) or the free surface (Run C3). Figure 19. Temporal variations of velocities in the transverse direction (y-direction) at the center part between the tips of two spur dikes (see Figure 10) in the computations of series C (z= 35 mm). 5 CONCLUDING REMARKS This paper described the numerical study on timemean and time-dependent 3D turbulent flow structures in open channel flows around submerged spur dikes. A non-linear k-ε model developed by Kimura & Hosoda (2003) in a curvilinear movable coordinate was adopted as a turbulence model and the results were examined through the comparison with the laboratory tests with PIV performed by Tominaga et al (2001, 2002). Special focus was given to the three hydraulic parameters, i.e., the inclination angle, the interval of two spur dikes and the relative depth and the

flows under 15 different conditions were considered. The major findings of our study are listed as follows. 1. The effect of flow deviation in the upward direction becomes larger as the inclination angle in the upstream direction increases, while the flow deviation in the transverse direction becomes maximum around right-angled spur dikes. 2. The mass exchange rate between the spur dike zone and the mainstream becomes larger as the absolute value of the inclination angle becomes larger. 3. The fluid oscillation, which is caused by the vortex shedding from the tip of the first spur dike due to the shear instability, is closely affected by the inclination angle. The amplitude increases as the inclination angle in the downstream direction becomes larger. 4. From the comparison of submerged and nonsubmerged spur dikes, it is likely that shear layer in a horizontal plane at the height of the spur dikes

is more important for the fluid oscillation than that

in a vertical plane along the tips of spur dikes.

5. The dominant direction of the flow near the bed

between two spur dikes, which is important for sed

iment transport, is affected by the relative depth as

well as the inclination angle.

Numerical simulation of flow instabilities in steep, stepped channels

G. Premstaller, P. Rutschmann & M. Oberhuber

Institute of Hydraulic Engineering, University of Innsbruck, Austria

ABSTRACT: This study deals with flow instabilities in steep, stepped channels. The origin of the research

is based on an incident during a twenty-year flood at the river Ruetz in Tyrol, Austria. During this flood event

flow instabilities occurred which lead to the overtopping of the riverbanks and the damaging of the revetments.

An extensive study on a physical model was carried out. Velocity and water depth measurements in physical

models can only be obtained with limited resolution and boundary conditions are hard to control and to modify.

In numerical models flow conditions can be determined at each point of the computational mesh and complete

control of boundary conditions is possible. In a first step two-dimensional investigations were undertaken in order

to verify appearance of flow instabilities for the numerical approach. Three-dimensional runs were performed in order to verify the numerical model. Finally different scenarios were calculated and evidence on the origin of flow instabilities in steep stepped channels was found.

1 INTRODUCTION

In 1991 a rare event of flow instabilities at the river Ruetz was observed. Since then no other occurrences were reported for the Ruetz or other mountainous rivers in Austria.

Herrmann (2003) described a partially comparable event at a cascade-spillway at Sorpe dam near Langscheid, Germany. Cascade waves overtopped the spillway way before design discharge was reached. Due to the scarcity of such events only few literature can be found.

Chanson (1994) basically distinguished two kinds of flows in cascades, namely tumbling and shooting flows. While for tumbling flow a fully developed hydraulic jump develops after each cascade, shooting flow is a special form of open channel flow with macro-roughness. While Chanson (1994) and Boes (2000) investigated cascades with vertical and horizontal steps, Whittaker (1982) investigated step-pools in mountain streams.

Le Fessant (2001) studied macro-roughness in

steep channels with triangular and rectangular obsta

cles. Three different flow regimes were observed at

slopes steeper than 3%: wave-trains, wave packets and

sinusoids.

Ganz (2001, 2003) investigated the origin and the

development of such instabilities using two differ

ently scaled physical models. The influence of channel

geometry, discharge, suspended sediments, viscosity,

bed roughness and bed erosion were investigated.

While bed roughness, suspension concentration, viscosity and scour holes did not influence wave occurrence significantly, bed slope, discharge and geometry had a big influence. For discharge and bed slopes upper and lower limits of wave appearance could be established. Le Fessant (2003) carried out numerical studies on this subject.The studies focused on the development of roll waves and wave trains and compared results with experimental data. In order to initiate wave development small sinusoidal perturbation were generated at the inflow. 2 NUMERICS 2.1 Numerical scheme The computations in the present paper have been performed using the commercial FLOW3D software developed by the founder of Flow Science Inc., C.W. Hirt from Los Alamos Scientific Lab. The software uses several key features invented by C.W. Hirt for numerical treatment of the Navier-Stokes equations, solutions to free surface flows and meshing of complicated geometries. The FLOW3D program uses a finite difference or finite volume solution for the Navier-Stokes equations.The two methods coalesce for rectangular cuboid blocks. In order to minimize artificial diffusion for convective processes a fully explicit treatment of the corresponding terms is implemented. It is the philosophy of the vendors that the program automatically

performs all of the possible choices for relaxation and

time stepping in order to obtain best results. As can be

assumed from the use of the program the momentum

and continuity equations must be solved in a decoupled way like in the projection method. i.e. after solution of the momentum equation pressure iteration is per formed to satisfy continuity. The convergence criteria for this iterative procedure can be controlled by the user through modification of the default values.

2.2 Free surface treatment

The difficulty of solving the Navier-Stokes equations for free-surface flow problems is the unknown position of the interface between air and water. Several options for such flows have been developed, namely:

- The marker and cell (MAC) method of Harlow & Welch, (1965) computes flow on a fixed mesh cov ering at least the maximum extent of wetted area. For the region covered with fluid the momentum equations are solved. Information on the position of the free surface is obtained indirectly using marker particles released in the water body and convected by the flow.The number of marker particles governs accuracy of the MAC Method. Therefore for a lim ited number of particles the computational time is acceptable but the free surface is only crudely rep resented. The opposite applies for a high number of markers.
- The arbitrary Lagrangian Eulerian (ALE) method

is often used in conjunction with a finite element approach favourably with space/time elements. The position of the free surface is always represented through a mesh boundary and the corresponding boundary nodes are convected in a fully Lagrangian way. Nodes in the interior of the domain may be arbitrarily shifted from time step to time step in order to ensure mesh quality. Once the quality crite ria are violated or element nodes have been twisted a complete re-meshing of interior nodes is necessary. The method is very accurate for representation of the interface however complicated to program due to the frequent re-meshing. Furthermore it fails for flows where the water body is not contiguous.

- The Volume of fluid (VOF) method which is very similar to the level set (LS) method is based on a fixed mesh covering at least the maximum extent of wetted area, (see MAC method). For the wet ted areas the momentum equations are solved and additional scalar information is convected with the flow field. The VOF and LS methods distinguish only in the scalar information being convected. For the VOF method the scalar information defines the ratio water/air for each cell, for the LS method the scalar information is the perpendicular distance

from cell mid-point to free surface. Both methods

have the advantage that they are very robust and fast, however theVOF method may be subject to numerical diffusion depending on the implementation. The LS method is more CPU intensive. However due to the continuous scalar function used the numerical diffusion can be neglected. The father of the VOF method is C.W. Hirt, see (Nichols, B.D. & Hirt, C.W., (1971) & Hirt, C.W. and Nichols, B.D, (1981)). Hirt and Nichols achieved to modify the MAC method in a way to retain the volumetracking feature without its large memory and CPU costs. The FLOW3D software claims that the implemented VOF method is at least as accurate as the piecewise linear interface construction (PLIC) method without specifying details. In the PLIC-VOF method the position of the free surface is determined in two steps:The air/water ration is computed for each cell in a convection step and a reconstruction algorithm serves to position the free surface without stair step effects as a continuous boundary. The boundary is represented by a linear straight line (2D) or a planar surface (3D) intersecting the computational cell. The position of this intersection is determined satisfying the scalar air/water function and considering the corresponding information from neighboring cells for determining the normal direction. This procedure guarantees that the pressure free surface remains a clearly defined and un-smeared interface. 2.3 Mesh generation A very important part of numerical computations is the mesh generation. Numerical schemes are also characterized by the order of accuracy both in space and time. This characterization indicates to what order terms of a Taylor-series expansion are used for the numerical approximation.A scheme with “second order accuracy in space” means that terms up to quadratic terms are considered. However the order of accuracy strictly only applies to uniform cells having equidistant spacing. If this is not the case the order of accuracy decreases and therefore also depends on the mesh used. Having this in mind it seems clear that for complicated geometries complicated meshing algorithms have to be used. In order to preserve complete freedom in meshing of complicated structures an unstructured grid is used as for most finite element codes. FLOW3D however uses a completely different approach to achieve good quality meshing by a structured grid approach namely the fractional area volume obstacle representation (FAVOR) method. In FLOW3D the computational mesh is always a structured rectangular mesh consisting of only rectangles (2D) or cuboid blocks (3D). However the overall length of the computational mesh in all three coordinate directions can be subdivided into irregularly

spaced distances. Therefore in a very simple case a FLOW3D mesh can be defined by only nine figures, namely by a triple set of information for all coordi nate directions indicating the beginning and the end coordinate and the number of cells. Of course with this information it would only be possible to work with a cuboid space representation and it would be impossible to model more complicated geometries. Therefore in FLOW3D the possibility exists to position obstacles in this very simple basic grid. The obstacles can be so called FLOW3D primitives, i.e. very sim ple geometric bodies such as cubes, cones, spheres etc., or obstacles represented through triangulated sur faces obtained either by scattered x, y, z-data or from a CAD software (STL or IDEAS files). In other soft ware packages such obstacles are often represented then by a stair-step geometry where each sub-region of an obstacle either completely fills or does not occupy a computational cell. The FAVOR method, described by Sicilian (1995), uses the same algorithms as for the representation of the free surface with VOF. Instead of using the scalar information indicated above infor mation on the blocking of a cell through an obstacle is given and this information is transferred into an accurate reproduction of the obstacle using a simi

lar technique like the PLIC method. Therefore each obstacle may intersect cells and will then be represented by a straight line (2D) or a linear plane (3D) having arbitrary normal direction. Such it is possible to correctly represent even complex geometries through a computational mesh, which is from it's origin a structured and even rectangular grid. For complex geometries FLOW3D allows to represent the computational area through a multi-block approach. The meshing technique described above has one big advantage: it decouples computational mesh and topography and therefore allows to change grid resolution with changing only three figures, namely the number of cells in all coordinate directions. This advantage has been used to assure mesh independent solutions as described in the following section.

2.4 Turbulence model

For the computations a two-equation turbulence model has been used, the well-known and well-tested k-ε turbulence model, see Harlow and Nakayama (1968) and Jones and Launder (1972), where k denotes the turbulent kinetic energy and ε the turbulent dissipation rate. Both parameters can be described by a non-linear system of PDE's. Constant terms within these equations have been found through experiments conducted

mainly for fully turbulent flow in free jets and mixing

layers. A careful comparison and state of the art paper

by Rodi (1984) shows that for the current application

the k-ε turbulence model is a good choice. However

a comparison with results from computations without

using a turbulence model or a simple Prandtl mixing length model shows no noticeable influence from this choice. 3 RESULTS AND DISCUSSION Both three-dimensional and two-dimensional simulations were carried out. While three-dimensional simulations were run to calibrate the numerical model, the faster two-dimensional simulations were run to analyse the detailed flow features and the possible origin of wave formation. 3.1 Numerical model building The geometry of the numerical model was a reproduction of the 16 meters long flume used by Ganz (2003). The mesh height was fixed at 0.4 meters, while the cross-section was different for two-dimensional and three-dimensional runs. The steps were modelled as solid obstacles. The distance between the obstacles was initially 50.5 cm, the crest width was 2.7 cm and the height 7.4 cm, see Figure 1.The mesh had to be locally refined at the steps in order to comply with the geometry of the obstacles. The intake was modelled as a cuboid box with inflow through a 1.0× 0.4 meter bottom hole. The filling of the box was modelled once. For all further simulations the filled box was used as initial condition. At the intake steady inflow boundary conditions were assumed. Since flow was supercritical at the outflow no “fixed-water-depth” boundary conditions had to be set there. FLOW3D usually works with explicit time stepping but implicit treatment of specific terms is possible. For this study a purely explicit formulation was used and the program automatically chooses a time step size to satisfy the CFL criterion. Every 0.2 seconds an interpolated output file with the main flow variables like velocities, pressure and water surface height was produced. For each space-dimension a gravitational acceleration component can be defined independently. This feature was used to simulate bed slope. Only one half of the chute was modelled applying a symmetric boundary condition at the chute centre line in order to CPU time safe. The surface roughness can be chosen independently for obstacles and mesh. According to the physical simulations described by Ganz (2001) and Clara (2002) the bed roughness was defined as k= 0.3 mm to fit the physical model. 3.2 Three dimensional verifications A

crucial part of every numerical study is the verification of the numerical model. This usually is done by

Figure 1. Definition sketch for numerical model building.

Figure 2. Cross section with mesh and obstacle in the three dimensional model.

comparing numerical results with measured physical data. Since the two-dimensional grid was not suitable for the representation of the physical model geometry used by Ganz (2003) three-dimensional runs had to be done.

Hence for verification a non-uniform structured mesh with 200 cells in x-direction, 10 cells in y-direction and 10 cells in z-direction was used. The trapezoid channel was modelled using a rough mesh wall boundary condition at the channel bottom and rough obstacles at the channel sides. Mesh and side roughness could be varied independently to allow for the representation of the laboratory conditions.

Several computations were done using different discharges and bed slopes and suspension concentrations according to the measurements done in the physical model. The water depths measured in the physical model and the ones calculated in the numerical model showed reasonably good correspondence, which is evidence, for reliability of the numerical model. Ganz (2003) found no evidence for effects in the cross-sectional plane causing flow instabilities. The investigations also showed that sediment concentrations did not affect wave formation significantly. In order to save CPU time further investigations were carried out on a two-dimensional

numerical model with very high spatial resolution to obtain correct wave formation. 3.3 Two-dimensional modelling Like in the three-dimensional case, the twodimensional simulations were performed using a 16 meter long and 0.4 meter high mesh. The same bed roughness as in three-dimensions was assumed. The grid was discretized with 521 cells in xdirection and 40 cells in z-direction while in ydirection a single cell only was assumed. 3.3.1 Variation of obstacle spacing with fixed bed slope Preliminary investigations with the two-dimensional geometry lead to a qualitative assessment at which bed slope optically good sample waves appeared. For 0.505 meters step spacing and a discharge of 0.012 m 3 /s this was the case at 7% bed slope. Consequently this slope was chosen for additional runs with differing obstacle intervals. The aim of these tests was to find out whether and how obstacle spacing influences wave development. Additionally a spacing of 1.10 meters, 0.25 meters, 0.1 meters and irregular spacing was investigated. While at small spacings like 0.1 and 0.25 meters no significant waves could be observed for a spacing wider than 0.5 meters instabilities occurred. At the interval of 1.10 meters a fully developed hydraulic jump developed between the obstacles. In Figure 3 waves propagate from one cascade to the next interfering with the hydraulic jump in the next field.

Figure 3. Flow instabilities occurring due to a fully devel

oped hydraulic jump.

The oscillations caused by the hydraulic jump

appeared to be the reason of the instabilities in the

flow field.

3.3.2 Variation of discharge and slope with fixed obstacle spacing

Due to the assumption that hydraulic jumps were caus

ing flow instabilities a single geometry was chosen

in order to simulate flows with varying discharges

and bed slopes. To check whether hydraulic jumps

appeared Froude numbers were calculated at the obsta

cle crest for each run.

For the set-up described in section 3.3.1 a spacing

of 0.25 meters did not show flow instabilities. There

fore this spacing was chosen for further investigations

where five different discharges were used and the slope

was modified until instabilities occurred.

Consecutively results were checked whether waves

appeared. Two different criteria of wave appearance

were employed (Figure 5):

- During the calculations FLOW3D allows the obser

vation of the development of state variables like Figure 4. Numerical runs at 0.25 meters obstacle spacing. Discharge and slope are varied and Froude number determined at stable condition. mean-kinetic energy, fluid surface area, volume error, time step size and others. When flow instabilities appeared mean-kinetic energy plots showed oscillations, while a smooth curve could be observed when no waves appeared. - Post-processing two-dimensional, animated plots were utilized to assess optically whether instabilities occurred or not. Each run was assessed using these criteria. For stable flow conditions no wave generation occurred and a single Froude number could be calculated at the obstacle crest. Runs were lead until instable conditions with instability generation occurred. In the case of unsteady flow instabilities the Froude number could not be defined any more. As can be seen in Figure 4 flow instabilities occurred at Froude-numbers near 1.5. This is close to the transition between an ondular and a weak hydraulic jump, which occurs according to literature at a Froude-number of 1.7.The difference between the two figures may be explained by the fact that the flow over the step is accelerated and may therefore reach higher values when hitting the subcritical water body between the steps. 4 CONCLUSIONS The present paper shows computational results for steep stepped channels where flow instabilities have been observed despite steady inflow conditions. The computations have demonstrated that instabilities can develop not only in prototype and Lab but also in numerical computations. A qualitative comparison

Figure 5. Comparison between stable flow conditions and unstable flow conditions.

between Lab data and numerical results shows rea

sonable agreement. In order to restrict CPU time with

detailed resolution in space most computations have

been performed using a two-dimensional approach.

A comparison of Lab results in a trapezoidal chan

nel and of the two-dimensional computations is only

qualitatively possible due to cross-sectional velocity

variations in the Lab flume.

The current work focused on the occurrence of

flow instabilities and aimed to resolve the underlying

mechanism. Results with fully developed instabili

ties showed the occurrence of a classical hydraulic

jump between neighboring steps. On the other hand

no instabilities could be observed for subcritical flow

conditions. As can be seen from Lab and numer

ical investigations the instabilities correspond to a

beat indicating the occurrence of two oscillations,

which differ only slightly in frequency. We therefore

assumed that one of these frequencies could be the

unsteady motion attributed to a classical hydraulic

jump. Therefore we analyzed the Froude number in

the cross-section of the steps. We investigated a particular geometry where height and spacing of the steps was fixed. Five different discharges where investigated and the slope was modified for a given discharge from flat to steep until instabilities could be detected. We could show

that occurrence of instabilities was bounded to a step Froude number larger than about 1.5. We assume that this characteristic Froude number is linked to the occurrence of a week hydraulic jump, which according to literature occurs for a Froude number of approximately 1.7. The difference between the two figures may be explained by the fact that the flow over the step is accelerated and may therefore reach higher values when hitting the subcritical water body between the steps. Even though a realistic explanation for the mechanism could be found further work has to be performed to assure this assumption. Namely a careful comparison of physical model investigations in a rectangular cross-section where the flow can be regarded as twodimensional must be performed and the comparison with numerical results must be expanded to a set of varying geometries. Also careful analysis of both

Fourier series from physical and numerical model tests

must be carried out.

Activation of scour around bridge abutment

D. Capuano & A. Carravetta

U.M. Golia

Department of Civil Engineering, Second University of Naples

ABSTRACT: Scour evolution around bridge piers and abutments is a master topic in river hydraulics for the

relevance of the process on waterworks stability. Clear

water experiments are usually employed to obtain the maximum scour depth, for given obstacle geometry and flow conditions. In this paper new experiments under clear water conditions are presented, performed in the transitional flow regime, i.e. with grain Reynolds numbers between 5.3 and 9.0. The Reynolds numbers varied between 12000 and 25000.

Time evolution of the maximum scour depth changed significantly if the same experiment was repeated, even under negligible variation of the flow conditions. Therefore, different sets of repetition of the same experiment were obtained for each flow condition and statistical properties were inferred for each set. Two scour phases were observed during the process, in agreement with the observation of others. Regression lines and confidence intervals for scour depth evolution were found for each of the two phases. An attempt was made to represent scour evolution in dimensionless units.

1 INTRODUCTION

Numerous literature is available on scour activation around a bridge abutment. An exhaustive review can be found by Melville & Coleman (2000) and in several recent papers (Oliveto & Hager 2002, Radice & Franzetti 2002a, b).

Equilibrium depth in clear water conditions is often assumed to be an upper limit for scour depth and thus useful for design purposes. Because of the long duration of scour experiments, the real presence of such an asymptotic value is a still open question. This question

is relevant also in the prediction of scour evolution.

Many of the available formulas employ the maximum

scour depth value as length scale.

Other approaches override the problem of equilib

rium scour depth. These methods are based on the

existence of two linear trends in the log-lin d(t) repre

sentation of the maximum scour depth, represented by

two equations, one for the lower and one for the higher

level. A particular dimensionless time is defined to

evaluate the dimensionless scour depth when log

lin d(t) slope changes.

New experiments are presented here, in order to

cover a range of grain Reynolds numbers, R * =

d 50 u * /ν, smaller than those usually found in literature

for clear water scour experiments.

To stress the importance of covering such conditions

it can be observed that the result of experiments on pier scour performed with R * < 10 failed to be modeled in the past (Oliveto & Hager 2002, Franzetti et al. 1994). The sediment size used in the flume −0.5 mm median diameteris of the order of that which would be used in the model of a river mouth if length scaling is maintained undistorted. The present experiments revealed some peculiarities that reflect on the application of both scour depth prediction methods. Concerning the first method, the presence of an equilibrium scour depth was not clearly stated during the experiments, especially for the largest flow rates. Additionally, abutment scour models based on the first method are not expressly developed and calibrated for the range of parameters of writers' experiments (Oliveto & Hager 2002, Melville 1997). When dealing with the second method, an evident change in the trend of scour evolution in the log-lin d(t) plot was not always observed. A large

dispersion of data was present, as observed also in pier scour at low R ∗ values (Chabert & Engeldinger 1956), making difficult to estimate the fitting lines of the two level of scour. 2 LABORATORY SET-UP AND RESULTS A laboratory flume, 0.15 m wide and 4.10 m long was partially filled with sand as a horizontal granular bed.

Sand was of 0.5 mm median grain size, with geometric

standard deviation, assuming a log-normal distribu

tion, σ g = 1.3 and γ s = 26.9 kN/m 3 . A 1/10 ramp was

located at the inlet of the channel to maintain a gradu

ally varied flow. Subcritical clear water flow conditions

were adjusted in the flume. A fixed water level was

imposed at the downstream end of the channel by inserting a weir in the terminal tank, whose upper level was above the granular bed.

Main data of experiments are summarized inTable 1 and Table 2, with symbols defined in the final nomen clature. In Table 1 the results of long duration exper iments (lasted 2–6 days) are reported. Short time repetitions of the same experiments of Table 1 are summarized in Table 2 (duration 1000–3600 seconds). During the long time experiments discharge varied by ±1% and the temperature varied up to 7 ∘ C. No sig nificant variations of discharge and temperature were observed during the short time experiments.

When steady state flow conditions were obtained in the channel, corresponding to the imposed discharge, the experiment was started by inserting a glass prism simulating the abutment, of width b= 0.015 m and length L= 0.15 m, as showed in Figure 1. No dif ferences in scour evolution were found by increasing the discharge to the given value with the glass prism already positioned in the flume.

Scour was measured for each test close to the abut ment wall (pointA in Figure 1), where maximum scour was always found to happen. Digital images were used to determine the scour extension.

In Figure 2 scour evolution is presented as measured

during all long duration experiments: maximum scour A L

reveal a large dispersion, but an interesting feature is

the presence in each single experiment of a variation

in the slope of the d s (t) data, in agreement with the

findings of others (Cardoso & Bettess 1999, Radice &

Franzetti 2002a, b). This variation reveal a peculiar

time t c in scour evolution: t c seems to be smaller for

higher flow rate.

In the regression procedure few values were excluded of testA1,A2 andA3 because an equilibrium scour depth was apparently reached. The results of the regression analysis are presented in Figures 6-8: data for t < t c and t > t c are marked with different symbols. Two 95% confidence bands are also plotted in the figures. Two different mechanisms of scour advance were observed for times smaller or larger than t c . For t < t c , an activation phase of the scour mechanism appears to occur.The scour has the pattern shown in Figure 9: the hole did not reach yet the side of the flume.

Figure 9. Plan view of the scour hole for t < t c .

Figure 10. Plan view of the scour hole for t > t c .

For t > t c , a fully activated scour mechanism was present, the corresponding geometry shown in Figure 10 where it can be seen that the scour extends up to the flume wall: in this activated phase the scour bed shape changes, with a discontinuity in the bed slope along the hole. This effect has been linked to the presence of two counter rotating vortices (Kwan & Melville 1994).

Radice & Franzetti (2002a, b) found that all data of scour evolution could collapse in two lines in the log lin representation if time and scour depth had been divided by proper dimensionless units. On the basis of a large number of literature experiments, the authors

determined the characteristic length: Q=0.8 l/s Q=1.0 l/s Eq. 3 Q=1.2 l/s Eq. 4 0 1 2 3 4 5 1,0E-01 1,0E+01 1,0E+03 1,0E+05 t/T d s / a Figure 11. Dimensionless scour evolution. and time: They proposed the following relations for the two levels of scour: Relations (1) and (2) are plotted with dotted lines in the log-lin d s /a vs. (t/T) diagram of Figure 11. In the same figure are also plotted the regression lines of writers experimental results: scour depths and times were scaled with a and T values, calculated on the basis of the average parameters for each group of discharge. The plot of Figure 11 revealed that: • the relation (3) proposed by Radice & Franzetti (2002a, b) for t/T < 30 does not represent well writers experimental results; • on the contrary, for t/T ≥ 30, the agreement between equation (4) and writers experiments is much better, for the higher flow rates; • writers' regression lines for t > t c have approximately the same unit slope, confirming the good structure of equation (4); • the change in scour level perform approximately at the same dimensionless depth, d sr (t c)/a= 1 ÷ 1.5, for all flow

rates, but for different values of t c /T ; • for the lowest flow rate the discrepancy between equation (4) and writers results becomes very large. 4 SCATTER OF RESULTS IN A SINGLE TEST Considering now that any test in each group of discharge can be considered as a repetition of the same experiment – with the exception of a small difference

tions, t > t c .

in water level between test A1 and A2, and of temper

ature between long duration and short duration test-,

then the evolution of scour depth during a single test

can be considered as a random variable.

The range of deviations d s – d sr of all data around

the regression lines for t < t c is plotted in Figure 12.

Deviations seem almost normally distributed with

differences d s – d sr as high as ±2.5 mm.

In the histogram of Figure 13 the range of d s – d sr values for t > t c is plotted. Of course, a smaller number of data is available for the long duration experiments and, therefore, the deviations d s – d sr are less representative of the randomness of scour evolution in the higher level of scour.

Nevertheless, data pattern of long duration test (Fig. 2) suggest a different explanation of the deviations showed in Figure 13: the succession of scour depth in the log-lin d(t) plot, and the position of data respect to the regression line, seem influenced by the depth value d s (t c) attained at the end of the activation phase (t < t c). Specifically, a difference in scour depth between two tests observed at the end of the activation phase will be mostly conserved also in the further scour evolution. Therefore, for t= t c , a base deviation, d b , of the data of each single test from the regression line seems present. This base deviation was set equal

to the difference between the scour depth measured at 0 10 20 30 -4,0 -3,0 -2,0 -1,0 0,0 1,0 2,0 3,0 4,0 ds-dsr-db % Figure 14. Frequency distribution of residual scour depth deviation, t > t c . the end of the activation phase, d s (t c), and the predicted scour depth at time t c , d sr (t c). Then, new deviations d s –d sr –d b for all test in the activated phase (t > t c) were calculated. The range of d s – d sr – d b values is plotted in Figure 14. The deviation of data decreases from a range of ±3 mm (Fig. 13) to a range ±1 mm (Fig. 14), not much larger than the measurement resolution expected with sediment particles of 0.5 mm. This finding seems to confirm the previous argument and stress the role of the activation phase of scour on its

further scour evolution. 5 CONCLUSIONS The results of tests performed for small grain Reynolds numbers revealed the following aspects of the scour process: • the maximum scour depth data, when represented as a function of time in a log-lin plot, spreads along two regression lines, the first valid for t < t c (activation phase), the second for times larger than t c (activated phase). Two different mechanisms of erosion seem active for the two level of scour; • regression lines and confidence interval were found for each level of scour; • single test repetition exhibit a large spreading of data around the regression line in the first level of scour; • in the second level of scour the overall dispersion around the regression was not smaller, but data from each test seems to lie on individual patterns; • scour evolution in the second level of scour was in agreement with the law proposed by Franzetti & Radice (2002a, b), only for the larger discharges. Seepage and exit gradient under impervious structures with two sheetpiles

on layer of infinite depth

G. De Martino & M. Giugni

Dip. di Ing. Idraulica ed Ambientale G. Ippolito, Università di Napoli Federico II, Naples, Italy

N. Fontana

Dipartimento di Ingegneria, Università del Sannio, Benevento, Italy

ABSTRACT: Seepage force represents one of the most common cause of failure of hydraulic structures. Several

methods are available in technical literature to provide a good estimate of the factor of safety against seepage

erosion.According toTerzaghi, the factor of safety can be determined comparing the exit gradient with the critical

gradient. Obviously, the calculation of the critical gradient is very simple, while more complex is the evaluation

of the exit gradient. In the present work is presented and discussed the analytical solution of the seepage under

a structure with two sheetpiles, resting on the surface of a infinite, homogeneous and isotropic porous medium.

A very general solution of the flow has been achieved by means of conformal mapping technique, applying the

well-known Schwarz-Christoffel transformation; so, once the

size of the structure and of the flow domain have been defined, the exit gradient can be calculated to perform a quick estimate of safety factor.

1 INTRODUCTION

Any hydraulic structure subjected to seepage underneath must be evaluated for stability with due consideration to seepage forces. To this aim various methods are available in the literature; one of the most well known is the method of Bligh and Lane (Lane 1935) which was set up after studying the behaviour of over 200 masonry weirs and dams.

The method is based on the observation that piping may be avoided if the water velocity is such as to prevent the removal of solid material at the structure's downstream toe, which is the section where the hydraulic gradient reaches its maximum value.

A different approach was followed by Terzaghi (Terzaghi & Peck 1967), who showed that the rising of a mass of soil as a result of seepage forces takes place if the average hydraulic gradient downstream of the structure i_{em} exceeds the critical gradient i_c.

The value of i_{em} can be calculated by considering the value of the average hydraulic gradient in the prism adjacent to the toe, of depth s (equal to the length of the sheetpile) and base s/2. The critical gradient instead corresponds to quicksand condition: if

we consider all the forces acting on a unit volume of

soil through which seepage occurs, it can calculated

as i c = γ'/γ , where γ' indicates the submerged unit weight of soil and γ is the unit weight of water. This makes it possible to define a factor of safety against piping: Obviously the estimate of i c is not a problem as it is related to the characteristics of the soil; in any case, when information is lacking, it is generally taken as unity. It is a more complex task to determine the value of i em , which is related to the characteristics of the flow domain and, therefore, to the size of the structure and the characteristics of the soil. By following this procedure, the present paper suggests assessing the stability to seepage forces by comparing the maximum value assumed by the hydraulic gradient (which occurs at the downstream toe of the structure) with the critical gradient i c . In a recent paper (De Martino et al. 2003) Authors have investigated the exit gradient at the downstream toe of a retaining structure with two sheetpiles resting on a finite depth layer. The present paper instead analyses the seepage established underneath of a retaining structure fitted with two cut-off walls on an isotropic and homogeneous soil of infinite depth (Fig. 1). t 1 s 1 t 2 s 2 H 1 H 2 B

Figure 1. Scheme of the geometric domain.

2 THE ANALYTICAL SOLUTION

The literature contains analytical solutions for seepage

underneath hydraulic structures, but only for sim

ple weirs or dams and for soils which are assumed

generally isotropic and homogeneous (Polubarinova

Kochina 1962, Harr 1962).

In these papers the technique of conformal mapping

is adopted, which makes it possible to derive the solu

tions of many important classes of groundwater flow

problems. In fact, if we define the complex potential as

$\omega=\phi+ i\psi$, where ϕ is the velocity potential function

and ψ the stream function, all the desired characteri

stics of the flow can be obtained once the function ω

is known in each point of the flow domain. In order to

obtain the functional relationship ω(z) which defines

the complex potential as a function of the complex

coordinate z= x+ iy, Pavlovsky (1956) showed that

the problem can be solved by introducing an auxiliary

complex variable ζ, called the parametric variable and

defined in a complex half-plane. In this way we can

map the z and ω planes onto the upper or lower half

of the ζ plane and, once the transformation functions

ω(ζ) and z(ζ) are known, we can define, by inverting

the latter, the relationship ω=ω(z).

The functions z(ζ) and ω(ζ) are determined by

adopting the conformal mapping method and the

Schwarz-Christoffell transformation is used. In fact,

for the seepage in question it can be shown that the

boundary in the complex potential plane is represented

by a polygon. The sides of this polygon are defined

by the boundary conditions on the velocity potential

and the stream function. Similarly, the boundary of

hydraulic structure foundations is generally made up of rectilinear segments, so that the flow domain can also be referred to a polygon. In the following sections, a more detailed description of the mapping procedures used for solving the problem is provided. 2.1 Mapping the geometric domain The scheme considered here is totally general, as it can envisage different lengths for cutoff walls and

different depths for the upstream and downstream plane (Fig. 2a). The solution was obtained using the technique of conformal mapping (Nehari 1952) and it makes it possible to determine all the characteristics of the flow field, thus enabling the assessment of the exit gradient i e at the downstream toe of the structure and the uplift force exerted by the water. For the considered scheme, the mapping of the flow domain into the semi-plane of the auxiliary variable ζ is as follows: In particular, we can assign arbitrarily three conditions; so we assume c 1 =-c 6 =-1, while the third condition arises from consideration that z=±∞ if ζ=±∞. After these assumptions Equation 2 becomes: 1 2 3 4 5 6 t 1 s 1 t 2 s 2 H 1 H 2 c' 7 c 1 c 2 c 3 c 4 c 5 c 6 c 7 -1 c' 7 ζ 7' ζ ζ 1 c 7 +1 ζ 6 ζ 7 1 ϕ ψ = 0 ϕ = -fH 1 ϕ = -fH 2 ΔH fΔH 7

7' B (a) (b) 7 6 7' ψ ζ

Figure 2. Geometric (a) and complex potential (b) domains.

which can be closed form integrated, giving the

following expression for z:

In Equation 3, F=F(ϕ, m), E=E(ϕ, m),#=# (n,

ϕ, m) are, respectively, the elliptic integrals of the first,

the second and the third kind (Abramowitz & Stegun

1970). The values of the argument, the module and the

parameter are defined as follows:

The constants c 2 , … , c 5 , A, C can be determined

by mapping the points on the real axis of the auxiliary variable’s semi-plane onto the points in the geometric domain: This yields a system of 6 equations in the unknowns c 2 , c 3 , c 4 , c 5 , A and C. Since the system is strongly non-linear, it was not possible to obtain a direct solution and, therefore, the Newton-Raphson method was adopted. 2.2 Mapping the complex potential domain Figure 2b depicts the complex potential domain in the case of a stratum overlying an impermeable substratum. In particular,ΔH=H 1 -H 2 represents the water level difference upstream and downstream of the structure, while f indicates the coefficient of permeability of the porous layer. In this case the Schwarz-Christoffel transformation

is written as follows (PolubarinovaKochina 1962): which yields, with the corresponding boundary conditions, the following expression of the complex potential:

Figure 3. Example of flow net for flat-bottomed structure resting on infinite depth layer.

3 ANALYSIS OF RESULTS

After mapping z andω onto the half-plane of the auxil

iary variable, by eliminating ζ from relationships z(ζ)

and ω(ζ), we can derive the expression of ω(z), which

makes it possible to define, for a generic point of

the flow domain (with complex coordinate z= x+

iy), the complex potential ω=ϕ+ iψ. It is thus pos

sible to define the flow net and all the elements of

greater interest in the flow field (hydraulic gradient,

uplift pressures, etc.). By way of an example, Figure 3

reports the flow net for a structure with two sheetpiles

resting on an infinite depth layer, with s 1 /B= 0.5 and

s 2 /B= 0.35.

In the present paper, analysis is limited to the

values of the hydraulic gradient, which is directly con

nected to the problem of stability to seepage forces

in hydraulic structures. With reference to the above

mentioned Terzaghi criterion, it is admitted that the

estimate of the piping safety coefficient is given by

Equation 1, in which the value of i em (average gradient

in the prism adjacent to the cutoff wall, of depth s and

base s/2) is substituted with the value of the exit gradi

ent i e , which represents the maximum of the hydraulic

gradient values downstream of the structure. If the soil

is homogeneous and isotropic, this value reaches its

maximum at the downstream toe of the structure and,

therefore, at point 6 (cfr. Fig. 2a). The expression of

the hydraulic gradient in a generic point is obtained

from the relation:

and hence from the ratio between the derivatives of the

functions ω(ζ) and z(ζ). Consequently, the expression of i e is given by: Using Equation 4 made it possible to obtain the diagram in Figure 4 which, for a flat-bottomed structure (t 1 = t 2 = 0), report the values of i e as the s 1 /B and s 2 /B ratios vary. The dashed line indicates the values of i e corresponding to the condition s 1 = s 2 which bounds the field of values generally adopted in technical practice (s 1 > s 2). Analysis of the diagrams allows some interesting considerations to be made: • the values of i e obviously tend to decrease as s 1 and s 2 increase. However, this reduction is more marked for a certain field of values, as can be inferred from Figure 4. It therefore follows that, above a fixed value of s 1 /B and s 2 /B, increasing the length of the cutoff walls is practically ineffective in terms of reducing the values of the exit gradient; • as pointed out in De Martino et al. (2003), the case of infinite thickness stratum gives the upper limit value of the exit gradient when the B/T ratio decreases (being T the thickness of the porous layer). So the hypothesis of infinite depth supplies the maximum values of i e , and hence reference can be made to this when working safety conditions are desired or when the depth of the layer is not known. In fact, in Figure 5 the variation of the exit gradient as the B/T ratio varies is reported for a retaining hydraulic structure.The circle, in particular, represents the exit gradient in the case of infinite depth layer

Figure 4. Exit gradient for infinite depth layer.

Figure 5. Trend of the exit gradient when the B/T ratios decreases.

and it coincides with the value inferred from the finite depth solution (De Martino et al. 2003) when B/T tends to zero.

4 CONCLUSIVE REMARKS

Seepage analysis for hydraulic structures has been developed by means of conformal mapping technique, applying the well known Schwarz-Christoffel trans formation. In particular, the flow field established underneath hydraulic structures fitted with two sheet piles on a homogeneous and isotropic soil of infinite depth has been analysed and a general closed-form solution has been derived.

The analytical solution allows to compute the maxi mum value of the hydraulic gradient (which occurs at the downstream toe of the structure) and therefore to assess stability to seepage forces by means of a factor of safety against piping according to Terzaghi. The diagram obtained for flat-bottomed structures (Fig. 4) can supply in this way a strong support in the design phase, especially when working safety conditions are desired or when the depth of the layer is not known.

Obviously, analytical modelling of the seepage can’t give complete information on stability of soils sub jected to seepage forces. In this view, Authors are currently conducting laboratory experiments at the

The effect of migrating bedforms on local scour around bridge piers

M. Bolla Pittaluga, M. Maffei & G. Seminara

Dipartimento di Ingegneria Ambientale, Universitã degli Studi di Genova, Italy

ABSTRACT: In the present paper the interaction between the downstream migration of alternate bars and the

local scour near bridge piers is investigated through experimental observations performed in the laboratory of

the Department of Environmental Engineering of the University of Genova.

If the bridge does not have aprons, it is well known that a local scour is generated around the bridge piers at

equilibrium, and its evaluation is usually performed on the basis of empirical relationships (e.g. Breusers et al.

1977), while the water level profile remains almost unaltered by the presence of the obstruction (Marchi 1996).

To the authors' knowledge there is scarce information concerning the interaction between water flow and piers

when small bedforms (dunes) or large bedforms (alternate bars) migrate through the bridge piers. We then focus

our attention on the effect of bedform migration on the intensity of local pier scour.

Experiments are performed on various settings with pier models constraining the cross section of streams

flowing on erodible beds where bedforms are initially allowed to develop. Bedform migration and its interaction

with bridge piers is carefully monitored by means of a profile indicator placed at the head of the bridge pier and

performing periodic surveys of bed topography by means of a laser system.

1 INTRODUCTION

The prediction of the maximum expected scour around

bridge piers is, needless to say, of great practical rel
evance. Underestimation of the scour depth and of its
areal distribution results in design of too shallow foun
dations which can get exposed to the flow creating
safety problems in terms of bridge stability. Great dif
ficulties are sometimes experienced in restoring pier
foundations which got exposed to the flow. On the
other hand, overestimation of the scour depth results in
uneconomical design. Several mechanisms are known
to be responsible for scouring processes in rivers, such
as lateral channel migration, long-term degradation,
narrowing of the river cross section, bedform migra
tion, interaction between flow fields and obstructions
like bridge piers or abutments, insufficient sediment
supply, etc. In the present context our attention is
focused on the estimation of the local scour at bridge
piers due to the non linear interaction between two of
the scour mechanisms mentioned above, namely the
local scour due to the horseshoe vortex flow around
the piers and bedform migration. It is well known that
the system of horseshoe vortex and associated down
flow at the pier are the main agents responsible for
the local scour at bridge piers. Several contributions
can be found in the literature on the detailed study
of the latter process, notable among them Laursen and Toch

(1956), Baker (1981), Raudkivi & Ettema (1983), Chiew & Melville (1987), Graf &Yulistiyanto (1998). Similarly, several empirical and semi-empirical relationships have been proposed to estimate the maximum local scour at bridge piers or abutments, see for instance Shen et al. (1969), Melville & Sutherland (1988), Melville (2001), HEC-18 (U.S. Federal Highway Administration, 2001). Some of them also propose approximate criteria to account for the effect of bedform propagation on the maximum local scour. Actually, the available knowledge on the effect of bedform migration on scour prediction relies heavily on the pioneering work of Shen et al. (1969), where two formulas to evaluate the equilibrium depth of scour were reported: the former by Breusers (1965) linking the scour depth to the pier width, the latter by Larras (1963) basically adding a multiplicative factor to account for the pier shape. In Shen et al.'s experiments the effect of dune migration on the equilibrium depth of scour was investigated leading to the suggestion that adding half the expected height of dunes to the estimated equilibrium scour depth for plane bed is a safe procedure to evaluate the maximum expected depth. In fact, according to the above authors, dunes affect the equilibrium scour depth by a simple additive effect whereby scour is increased as the dune trough crosses the scour hole and viceversa it is decreased as the crest passes through. Note, however,

that laboratory data of Shen et al. (1969) suggest that

the latter criterion overestimates the effect of dunes.

Due to the lacking of both theoretical and experimen

tal investigations of the effects of bedforms other than

dunes, the above recommendation has been extended

to the case of different kinds of bedforms like alternate

bars (Melville & Coleman, 1999). In spite of the fairly

wide knowledge of the main mechanisms responsible

for the formation and development of alternate bars

(e.g. Colombini et al., 1987, Seminara &Tubino, 1989,

Schielen et al., 1993, Repetto et al., 1999, Repetto

et al., 2002, Federici & Seminara, 2003), to our knowl

edge the effect of such bedforms on the scour induced near obstructions like bridge piers or abutments is, surprisingly, completely ignored. The importance of the latter phenomenon (presumably much more relevant in terms of maximum expected scour depths) is ever increasing as river regulation works, widely pursued in the last few decades, have led to an increased presence of large scale migrating bedforms in regulated rivers. Though in the case of dunes experimental observations suggest that the interaction between scour depths are at most additive, one may reasonably wonder whether a similar behaviour is to be expected in the case of different bedforms such as alternate or central bars. The laboratory experiments we have performed were indeed aimed at reaching some insight on the latter phenomenon and, possibly, suggesting corrections of design recommendations based on the experimental observations. In particular we wished to monitor the effects of the propagation of an alternate bar pattern on the intensity and spatial distribution of the local pier scour, depending on the relative position of the bridge piers in the cross section.

It will be shown in Section 3 that the interaction between the horseshoe vortex, the main agent responsible of local pier scour, and the migration of alternate

or central bars through bridge piers may lead to oscilla

tions of the local scour which can be easily linked from

a qualitatively point of view to the migration of bar

fronts. However, it turns out that the effect of the inter

action is non linear, in other words it cannot be simply

evaluated using a procedure similar to that suggested

by Shen et al. (1969) for the case of dune migration.

The rest of the paper is organized as follows. A

brief description of the experimental apparatus and the

experimental technique used is given in the next Sec

tion. Section 3 reports the experimental results while

some discussion and final remarks conclude the paper.

2 EXPERIMENTAL SET UP

2.1 Experimental apparatus

Experiments have been conducted in the laboratory

of the Department of Environmental Engineering of

the University of Genova in a rectangular straight flume with length L C = 18 m, width 2B= 0.6 m and sidewalls consisting of steel frames with plexiglass windows. The flume is filled with nearly uniform sediment characterized by a mean diameter d 50 = 1.2 mm and a density ρ s = 2650 kg/m 3 . Sediments are initially placed on the bottom of the flume in order to give rise to a uniform bed slope. The water entering the upstream end of the flume is supplied by a pump connected to an underground water tank and controlled by an electronic valve. A differential manometer is used to measure the flow discharge entering the flume. The stream flow is also fed with a solid discharge in open loop. The sediment load is controlled by a mechanical device such to provide a sediment supply equal to the transport capacity of the uniform flow for given water discharge and bed slope. At the downstream end of the flume the water and sediment mixture are filtered by a sediment

trap catching 100% of the sediment passing through. The clear water is then collected in a tank connected to the underground water tank. 2.2 Methods Every experiment consists of two parts. In the first part, starting from a flat bed, bedforms are generated and let develop until they reach a steady condition. Note that by steady conditions we mean that bedforms still migrate along the channel but display a nearly constant spatial envelope in time. During bedform growth, the bottom topography is scanned at different times by means of a laser system. Scanning is performed in a sequence of cross sections distant 0.1÷ 0.2 m from one another. In each cross section measurements of bottom elevation are performed every 3 mm.The reach of the flume where measurements were taken ranges between x= 5 m and x= 15 m. Note that the origin of the longitudinal axis is located at the outlet cross section and the positive x-direction points upstream. The upstream limit of the measuring reach (x= 15 m) is determined by the constraint that about 3 meters are required for the supplied sediment to spread all over the entire cross section. Moreover, the choice of the downstream limit of the measuring reach (x= 0.5 m) is imposed by the size of the moving carriage where the laser system is placed. Once the equilibrium state is obtained, the bottom topography is again measured and the bridge pier(s) is (are) placed into the flume. In the second part of the experiment the interaction between bedform migration and the local scour at bridge pier is analyzed by monitoring the evolution of bottom elevation at a fixed location by means of a profile indicator. The probe of the latter is placed in a position as close as possible to the head of the bridge pier. In fact, the local scour around bridge piers attains its maximum value just upstream the pier itself. The experiment is usually terminated when at least one Table 1. Summary of experimental conditions. EXP. Q (l/s) i f % Y 0 (mm) U 0 (m/s) Q s (kg/min) θ β β CR U0520 3.9 0.5 20 0.32 0.026 0.051 14.9 3.5 U0530 7.9 0.5 30 0.42 0.617 0.076 9.9 8.9 U0526 6.2 0.5 26 0.38 0.323 0.066 11.4 6.5

complete bedform has crossed the bridge. Finally, the

bottom topography is scanned once again by means

of a laser system in order to ascertain whether the

presence of the bridge has significantly affected the

bedform pattern.

A summary of the experimental conditions is

reported in Table 1. Here Q denotes water discharge, i f is the initial slope of the channel, Y 0 is the average flow depth, U 0 is the cross sectionally averaged flow velocity, Q s is the total sediment discharge, θ is the average Shields stress acting on the bottom, β is the aspect ratio (more precisely half width over depth) and β CR is its critical value above which alternate bars form (Colombini et al. 1987).

Some preliminary experiments (Table 1) have been performed in order to find the most appropriate condi tions for the formation of alternate bars. In the first run (U0520) a mixed alternate-central bar pattern formed at the beginning of the experiment, amplified until bars emerged and eventually stopped migration. This experimental condition was then not suitable to investi gate the effect of the interaction of such bedforms with bridge piers. Moreover, as the Shilelds stress was quite close to its threshold value for sediment motion, the time scale of bottom evolution was very large. In the second run (U0530) the aspect ratio of the stream was very close to its critical value for bar formation, hence the bedforms were quite unstable alternating periods of growth with periods of decay. In the third run (U0526) the most appropriate conditions were found: alternate bars formed and reached an equilibrium condition in

a time scale of the order of few hours (3÷ 4 h).

Three tests have then been conducted under the

latter conditions:

- in the first test one bridge pier was placed close to

the sidewalls of the flume (U0526_PL)

- in the second test two bridge piers were placed sym

metrically with respect to the longitudinal axis of the

flume (U0526_PS)

- in the third test one bridge pier was placed along the

longitudinal axis of the flume (U0526_PC)

3 EXPERIMENTAL RESULTS

3.1 The formation of alternate bars

As mentioned above, the first part of the experi

ment was devoted to the generation of bedforms until they reached an equilibrium condition. The Figures 1 and 2 show the typical evolution of the bed pattern in the channel at different times, showing the growth and migration of alternate bars in the experiment U0526. Note that the differences between the patterns observed after 4 and 6 hours are relatively small, hence we assumed that the configuration reached after 4 hours was at equilibrium. The distinctive features of free bars are summarized in Table 2, where L b denotes bar wavelength, H BM is the bar height defined as difference between the maximum and the minimum elevations within a bar unit, c b is the bar wavespeed estimated by comparison of the longitudinal bed profiles measured at different times and x b is the longitudinal coordinate of the position of the bar front. Note the spatially growing character of the bar envelope arising in particular in the pattern of bottom topography after 4 or 6 hours which shows that an equilibrium bar amplitude may have been reached in the downstream part of the flume. Also note that the value of the bar height farthest from the inlet is fairly close to the values predicted by the non linear theory of Colombini et al. (1987) and to the empirical formula given by Ikeda (1984) (Table 3). In Table

3, the values of the dimensionless maximum scour depths measured relative to the average bottom elevation s M /H BM are also reported and show the asymmetry of the bars over the cross section. 3.2 Local scour at bridge piers: brief literature survey Before discussing the experimental results concerning the interaction between the local scour at bridge piers and bedform migration, it may be worthwhile to give a brief summary of the state of the art. As mentioned in the Introduction, the estimate of bridge scour relies heavily on the work of Shen et al. (1969) in which two formulas to evaluate the equilibrium depth of scour are reported. Breusers (1965) suggested, for cylindrical piers, that: where d se is the equilibrium scour depth and b is the pier width. A second relationship, which accounts for

Figure 1. The pattern of bottom topography in the channel at different times, showing the growth and migration of alternate

bars.The initial bottom elevation has been filtered out. Scales are in millimeters. Flow is from right to left. (a) t= 2 h; (b) t= 4 h;

(c) t= 6 h.

pier shape is due to Larras (1963) and reads:

where the coefficient K depends on the shape of the

pier.

The effect of dunes on the equilibrium scour depth

was also investigated and led to the recommendation Table 2. Free bar characteristics. Time (h) x b (m) L b (m) H BM (mm) c b (m/h) 2.0 12.6 4.6 36 - 8.0 4.2 23 - 4.0 12.8 4.1 19 1.95 8.7 4.3 46 1.80 6.0 9.4 5.0 32 2.15 4.4 3.2 46 1.60

Table 3. Free bar heights and dimensionless maximum scour depths at equilibrium. H BM (mm) s M /H BM Experiment 46 0.71 Colombini et al. 38 0.57 Ikeda (84) 40 0.5 that adding one half of the expected dune height to the equilibrium scour depth leads to a safe estimate of the maximum expected depth. Other factors affect the scour depth. In particular, Breusers et al. (1977) proposed the following equation:

where Y 0 is the undisturbed flow depth and the coeffi

cients f 1 , f 2 and f 3 depend on the ratio of the undisturbed

average flow speed and its critical value for sediment

motion, on pier shape and on the angle of attack,

respectively.

An integrated approach to estimate the local scour

depth at bridge foundations has also been presented by

Melville (2001). The approach is based on empirical

relations, termed K-factors, that account for the effects

on scour depth of flow depth and foundation size, flow

intensity, sediment characteristics, foundation type,

shape and alignment, geometry of the approach chan

nel. The K-factors are evaluated by fitting envelope

curves to existing data. Following Melville (2001), at

equilibrium the local scour at a bridge foundation can

be evaluated by the following relationship:

where the various K’s are empirical expressions

accounting for the effects of various factors on scour

depth: K yW (flow depth); K I (flow intensity); K d (sedi

ment size); K s (pier or abutment shape); K θ (pier or

abutment alignment); K G (channel geometry). This method does not give any direct information concerning the possible influence of bedform migration on scour depth which, however, are likely to be included in the existing data used by Melville to fit his envelope curve (4).

3.3 Local scour with plane bed

A rectangular bridge pier, characterized by a width b= 110 mm, length of 300 mm and round nose, was aligned with the channel axis.

A first run has then been conducted in order to determine the equilibrium scour depth experienced with plane bed under the same hydraulic conditions (U0526) in which the tests with bedforms were later conducted.

Figure 3 shows a comparison between the experimental value of the equilibrium scour depth (d se = 66 mm) and the predictions of different empirical predictors, namely the equation of Breusers et al. (1977) and the approach of Melville (2001). Using a value for the pier shape coefficient f 2 equal to 1 (round nosed pier) the Breusers et al.'s relation under estimates the maximum scour depth (d se = 51 mm) which is highly overestimated by Melville's formula (d se = 107 mm).

3.4 Interaction between bedforms and bridge piers

Once the pattern of bottom topography has reached a

steady condition, the bridge pier(s) is (are) placed into

the flume.Three different configurations for the bridge Figure 3. The time evolution of the bottom elevation under plane bed condition is compared with the equilibrium values predicted by Breusers et al.'s (1977) and Melville's (2001) formulas. The origin of the vertical z axis is located at the initial bottom elevation. Figure 4. Longitudinal cross sections of the bottom aligned with the axis and with the two sides of the bridge pier just before the latter was placed in the flume (experiment U0526_PL). The origin of the z axis lies on the initial bottom. piers have been investigated under the same hydraulic conditions. 3.4.1 Lateral bridge pier (experiment U0526_PL) Figure 4 shows three longitudinal cross sections of the bottom observed just before the pier was placed in the flume: the cross sections were aligned with the position of the pier axis and with the two sides of the bridge pier. The axis of the pier was located at a distance of 135 mm from the right sidewall. Note that the pool of the alternate bar approaching the bridge pier is located roughly 3 m upstream the pier and exhibits a relative scour with respect to the mean bottom elevation of 20 mm. The time evolution of the bottom elevation due to the interaction between the bar migration and the local scour at the pier is shown in Figure 5. The

Figure 5. The time evolution of the bottom elevation ahead

of the bridge pier in experiment U0526_PL shows the effect

of bar migration through the bridge. The origin of the z axis

lies on the initial bottom.

Figure 6. Comparison between the bottom elevation ahead

of the bridge pier measured under plane bed conditions and in

the presence of bars (U0526_PL) and the values predicted by

different empirical formulas. The origin of the vertical z axis

lies on the initial bottom.

oscillations due to bar migration are easily detect

able when Figure 5 is compared to the case of plane

bed (Figure 3). Note that the scour depth is strongly

affected by the migration of bedforms and exhibits a

peak (d se = 98 mm) considerably greater than the one

observed in the case of plane bed (d se = 66 mm).

A comparison between the values predicted by

the above mentioned formulas and the experimental

values is reported in Figure 6, which also includes

the estimate obtained by adding half the bar height

(H BM /2= 23 mm) to the value predicted by Breusers

et al. (1977).

This first experiment shows clearly that the interac

tion between the horseshoe vortex and the migration

of alternate bars through the bridge piers leads to oscil

lations of local scour which reach a peak that cannot

be simply evaluated superimposing the two effects. Figure 7. Longitudinal cross sections of the bottom aligned with the axis and with the two sides of the left bridge pier just before the two piers were placed in the flume (experiment U0526_PS) The origin of the z axis lies on the initial bottom. Figure 8. The time evolution of the bottom elevation ahead of each bridge pier in experiment U0526_PS shows the effect of bar migration through the bridge. The origin of the z axis lies on the initial bottom. 3.4.2 Two symmetric bridge piers (experiment U0526_PS) The effect of the migration of alternate bars on local scour at piers is even more detectable in the test in which two bridge piers were located at symmetric positions close to the sidewalls of the flume. The axis of each pier was placed at a distance of 135 mm from the closer sidewall. Figure 7 shows three longitudinal cross sections of the bottom observed

just before the pier was placed in the flume: the cross sections were again aligned with the position of the pier axis and with the two sides of the bridge pier. Note that the maximum scour of the alternate bar approaching the left pier is located very close to the pier and reaches a peak of 24 mm relative to the mean bottom elevation. The feedback of bar migration on local scour is then shown in Figure 8 where the alternance of scour and deposition at the two piers is clearly detected.

Figure 9. Longitudinal cross sections of the bottom aligned

with the axis and with the two sides of the bridge pier

just before the latter was placed in the flume (experiment

U0526_PC). The origin of the z axis lies on the initial bottom.

Figure 10. The time evolution of the bottom elevation ahead

of each bridge pier in experiment U0526_PC shows the effect

of bar migration through the bridge. The origin of the z axis

lies on the initial bottom.

Also note that comparing Figure 8 with Figure 5

shows that the maximum scour depth is not affected

by the number of piers placed in the flume.

3.4.3 Central bridge pier (experiment U0526_PC)

In the next experiment the bridge pier was aligned with

the channel axis in order to investigate to what extent

the relative position of the pier in the cross section

affects the scour and deposit driven by the migration

of alternate bars. The longitudinal cross sections of the

bed aligned with the axis and with the two sides of the

bridge pier just before it was placed into the flume are

shown in Figure 9. Note that, in this case, the bottom elevation close to the pier exhibits smaller oscillations mostly associated with deposit rather than scour.

As expected, the time evolution of the local scour ahead of the pier (Figure 10) displays oscillations which are characterized by a peak similar to that observed in the case of plane bed and by an amplitude much greater than the amplitude of the approaching alternate bars. It is also worth pointing out that the pattern of alternate bars was not significantly affected by the presence of the obstruction (Figure 11). In particular, at least in the absence of bridge aprons, the presence of a constriction does not stop bar migration. 4 DISCUSSION AND CONCLUSIONS The preliminary experimental observations described in Section 3 allow us to draw some tentative conclusions. (i) The morphodynamic interaction between migrating bars and bridge piers leads to a non linear enhancement of the scour induced by the classical horseshoe mechanism. (ii) The migration speed of bars as well as the bar pattern are not significantly affected by the presence of the piers. (iii) The usual design recommendations which suggest to account for the effect of bedforms by simply adding half the bedform height to the estimated scour depth require some warning, at least for cases where the bridge piers are aligned with the pools of migrating bars. The source of nonlinearity of the morphodynamic interaction is partly due to the strongly asymmetric lateral bed profile typical of migrating bars, which makes the maximum scour s M associated with the bar larger than half the bar height (H BM /2) (Fig. 12). Moreover and more significantly, Breusers et al's equation (3) suggests that the scour depth is strongly correlated with the undisturbed flow depth Y 0 . When a bar pool reaches the pier front, the effective depth to be employed in equation (3) is the sum of the undisturbed stream flow depth plus the maximum bar scour. One readily realizes that this leads to a non linear enhancement of the scour predicted by equation (3). In particular for shallow flows, i.e. for values of Y 0 /b sufficiently small, equation (3) predicts that d se is proportional to twice the local flow depth, hence: The latter argument is clearly demonstrated in Figure 13, which shows that, applying equation (3) with Y 0 replaced by (Y 0 + s M) leads to a prediction for the scour depth much closer to the observed value. The error associated with the

additive procedure increases as the flow depth decreases (or the pier width increases) and may become fairly small for very thin piers.

Figure 11. The pattern of bottom topography in the channel at different times, showing that alternate bars are not significantly

affected by the presence of the obstruction. The initial bottom elevation has been filtered out. Scales are in millimeters. Flow

is from right to left. (a) t= 4 h; (b) t= 8 h.

Figure 12. Lateral bed profiles at the bar pool and bar front

are plot, showing asymmetry leading to the maximum scour

s M associated with the bar being larger than half the bar height

(H BM /2) (experiment U0526_PL).

Needless to say, the above results will have to

be substantiated by a wider experimental investiga

tion, examining the effects of multiple row bars, pier

alignment, transport in suspension, etc.

Moreover, the basic idea arising from our results

will deserve further thoughts concerning the interac

tion of bend scour with abutment scour of bridges

crossing meander bends.

Experimental study of the scour hole downstream of bed sills

M. Ben Meftah

Water Engineering and Chemistry Department, Technical University of Bari, Italy

M. Mossa

Civil and Environmental Engineering Department, Technical University of Bari, Italy

ABSTRACT: An experimental study on long local scouring downstream of bed sills in monogranular sand bed

was carried out in the hydraulic laboratory flume at the Mediterranean Agronomic Institute of Bari (Italy). The

main objectives of this study are the determination of the scour hole dimensions, with its maximum scour depth,

at the equilibrium stage, and the investigation of the influence of sills on the distribution of the three velocity

components through the scour hole at the same stage. Four experimental configurations were tested, the main

difference between them being the distance between sills. Based on experimental data, the classical dimensional

analysis of the variables that influence the development of the scour hole has been carried out in order to obtain

two empirical formulas predicting the maximum scour depth and the length of the scour hole at the equilibrium

stage. Moreover, it was observed that the distance between sills influences the scour hole dimension and shape.

The three velocity components of the flow, measured with an Acoustic Doppler Velocimeter (ADV), show that

in the scour hole, at the equilibrium stage, the three-components of the flow turbulence intensities are very high.

Near-bed flow vortexes in addition to secondary currents are also observed.

1 INTRODUCTION

The bed in the direct neighborhood of hydraulic struc

tures is generally protected against current and eddies.

The length of the bed protection depends on the per

missible scour (maximum scour depth and upstream

scour slope). When the length of the bed protection is

increased, the scour process is less intense due to the

decay of turbulence energy and the adaptation of the

velocity profile downstream of the hydraulic structure.

For a designer, the most important scour parameter is

the maximum scour depth in the equilibrium phase,

defined as the time when the scour hole and the bed

profile spatial characteristics along the flume do not

change any longer. Anyway, the extent of the scour

hole is strongly dependent on time. Initially, the scour

development with time is rapid, then it decreases grad

ually to reach the equilibrium stage after a long time.

The magnitude of the maximum scour depth depends

on the bed shear stress, the turbulence condition near

the bed, the sediment characteristic (density of the

bed material, sediment-size distribution, porosity,

cohesive or non-cohesive bed material, etc.).

In gravel bed rivers, bed sills are used to limit bed

degradation and to control erosion in the proximity

of bridge piers or in channels downstream of stilling

basins of dams. There is extensive literature on scour (Borman, 1988; Breusers, 1966; Habib et al., 1994; Hoffmans et al., 1995; Hoffmans and Verheig, 1997; Hoffmans, 1998; Javal and Kenneth, 1985; Kandasany and Melville, 1998; Smith and Strang, 1967; Van der Meulen and Vinje, 1995). In addition, the bed sill could have a number of impacts upon the flow velocity, and the impacts from the sill can vary spatially. Furthermore, the presence of the bed sill causes a redistribution of the flow velocity. It can decrease or increase the flow turbulence, create vortex phenomenon and/or secondary current velocity. This study is concerned with an experimental investigation of the scour hole phenomenon due to a current flowing over sills in an erodible bed of sand particles. The variation of the scour hole with time, the equilibrium water and bed profiles, in

addition to the three flow velocity components at different sections along the channel were assessed for each configuration. Two different scour hole topologies were observed, depending upon the distance between sills. 2 THEORETICAL BACKGROUND Local scour hole is typical of non-cohesive bed river, downstream of the bed sills. After a long period of time the scour hole reaches an equilibrium state. y m L S 0 S eq a l s

Figure 1. Sketch of the scour hole.

At the equilibrium, the geometry of the system under

consideration is shown in Figure 1 (Gaudio et al.,

2000).

Based on this geometric shape of the bed profile,

the maximum scour depth y m , or the scour length l s ,

can be expressed as:

where g is the gravity acceleration, ν= kinematic

water viscosity, ρ w =water density, ρ s = sediment

density, q= discharge per unit width, h u = flow depth

over the sill, d 50 = grain size for which 50% of the

total weight of the sediment is finer, L= distance

between sills, and a= difference between the level of

two successive sills, a is calculated as:

where S 0 is the initial bed slope.

The application of the Buckingham # theorem to

equations (1) leads to:

where:

The q 2 /gh 3 u ratio is the square of the Froude

number Fr, and the q/ν ratio is the Reynolds num

ber. Generally, in open-channels, the flow is almost

always fully turbulent. Thus, the dependence upon the

Reynolds number could be neglected. Since the para

meter a is determined as the product of the distance between sills L and the initial bed slope S 0 , the ratio L/h u can be removed from equations (3). Furthermore, the effect of the channel width is here implicitly neglected by choosing variables per unit width. In addition, in the present study sand grains have an almost constant value of the relative submerged particle density,, equal to about 1.65. Because of this constancy, the effect of is not shown in the present study. According to these simplifying assumptions, equations (3) can be reduced to: The determination of equations (5) was one of the main objectives of the present paper. 3 EXPERIMENTAL SET-UP The experimental work was carried out in a horizontal flume in the laboratory of the Mediterranean Agronomic Institute of Bari (Italy). This flume is 7.72 m long, 0.30 m wide, and has a depth of 0.40 m. The floor of the flume is constructed with Plexiglas, while the lateral walls are made of glass, which allows us better side viewing of the flow. Water is fed in from an upstream reservoir with a maximum charge of 54 cm equipped with stilling grid and lateral weir, which maintains a constant head upstream of a movable gate constructed at the upstream end of the flume. This gate is made of Plexiglas and allows the passage of different discharges with different corresponding channel flow depths. The flume is supplied by a pump with maximum discharge of 24 l/s through a steel pipe. To create a smooth flow transition from the upstream reservoir to the flume, a wooden ramp was placed at the inlet of the flume; the wooden ramp is 1.55 m long, 0.15 m thick and has the same width of the channel cross section (Figure 2). At the downstream end of the flume, water is intercepted by a stilling reservoir, equipped with three vertical grids to stabilize water, and a triangular weir (V-notch sharp crested weir) to measure the flow discharge. To protect against erosion of the sand bed of the flume, control sills were placed along the channel. Four sets of tests were performed during the experimental work, the difference between them being the distance (L) between sills (Set 1: L= 1 m; Set 2: L= 2 m; Set 3: L= 4 m; Set 4: L= 3 m). The sill level decreases progressively going from the upstream section to the downstream section of the channel, respecting a constant initial slope fixed at the value of 0.0086. The sills used in the experiments consisted of PVC plates 0.30 m wide and 0.01 m thick (Figure 1).

Figure 3. Grain-size distribution curve.

The flume bottom is covered with an erodible bed material layer consisting of sand particles with mean average size (d 50) of 1.8 mm and specific density of 2.65 g/cm 3 . The grain-size distribution curve of the sand is illustrated in Figure 3. The uniformity coeffi cient C u = d 60 /d 10 was equal to 1.6, where d 60 = grain size for which 60% of the total weight of the sediment is finer and d 10 = grain size for which 10% of the total weight of the sediment is finer. Thus, the sediment can be considered as uniform. Along the channel, the sand layer decreases progressively from the upstream sec tions to the downstream sections, respecting the initial slope predetermined by the sills.

During the experiments, the bed profile along the

channel at various times was marked on the glass side

walls of the flume by means of different colors. At

the equilibrium stage, the water level profile along the

centerline was measured using an electrical hydrome

ter with an accuracy of 1/10 of millimeter. At the same

stage, the bed profiles along the centerline and near the

3 25 27 two side-walls of the channel were determined using
a point gage with an accuracy of 1/10 of millimeter. In
order to study the effects of the sill upon the flow
velocity at the equilibrium, the measurements of the
three-velocity components along the flume at different
positions have been recorded during this experimental work,
using an Acoustic Doppler Velocimeter (ADV). The main
parameters of the tests are illustrated in Table 1, where,
Q= flow discharge through the channel,T=water temperature,
and t d = total duration of each test. During all the
experimental work, the measurement of the flow depth over
sills, h u , the maximum scour depth, y m , and the length
of the scour hole, l s , were assessed for each test. The
flow depth over a sill was measured as the vertical
distance between the top of the sill and the water profile.
The maximum scour depth was determined as the vertical
distance between the initial bed profile and the center of
the scour hole at the equilibrium stage. The scour length
was determined as the distance between the sill and the
point downstream of the scour hole where the slope reaches
a constant value. The aforementioned variables are shown in
Table 2. For tests T04 to T08, the scour hole occupied all
of the space between the sills, and, therefore, l s was not
determined. 4 RESULTS 4.1 Scour hole progress Examining all
the tests, it has been shown that the extent of the scour
hole is strongly dependent on time.

Figure 4. Similarity of scour holes evolution.

So, it was observed that there are three stages of the local scour hole development.

Initially, the scour hole development with time is rapid, and this is due to the high rate of solid transport achieved on the downstream end of each sill. The high rate of the solid transport is a consequence of the high forces of the bed-shear stresses exerted over the sand bed at the initial time. To study the different stages of the development of the scour hole as a function of the time for each test, and their similarity, the values of y t /y m have been plotted against t/t d (where y t is the scour hole depth at time t, and t d , as written, is the duration of each experiment, i.e. the time when the

scour hole reached the equilibrium phase). Figure 4

shows that the scour development as a function of time Figure 5. Quasi-parabolic shape. presents three different phases. Figure 4 shows, as well, that at the initial stage the scour hole depth for each test reaches about 65% of the maximum scour depth during a time less than 10% of the duration after which the equilibrium stage was reached. A second stage is characterized by an increase scour degree much smaller than the first stage. Figure 4 also shows that during this stage, the depth of the scour hole increases globally with a percentage of 25% of the maximum scour hole through a time estimated of 30% of the duration after which the equilibrium stage was reached. As is well known, the increase degree of y t /y m depends on the magnitude of the bed-shear stress. Therefore, it can be said that the shear stress acting over the bed reduces with the increase of the scour hole depth. A final slow stage is that for which the scour achieves equilibrium after a long period of time. The equilibrium phase was assumed to be reached when no transport of sediment particles is observed along the channel. Figure 4 indicates that the bed deformation or the scour hole evolution is extremely slow during this stage. It can be observed that, during a time more than 60% of the duration after which the equilibrium stage was reached, the scour depth increases only with a value around 10% of the maximum scour depth. 4.2 Scour hole shape According to the experimental results, it was observed that the scour hole shape depends strongly upon the distance between sills. It was seen that during the first set of tests with an interval length equal to 1 m, the scour hole shape is quasi-parabolic. An example (T05) of a three-dimensional scour hole is shown in Figure 5.This configuration is characterized by a scour hole which occupies all of the space between sills. It was also observed that the scour hole dimensions were

Figure 6. “Spoon” shape. -1.2 -1.0 -0.8 -0.6 -0.4 -0.2 0.0 0.2 0.0 0.2 0.4 0.6 0.8 1.0 T09 T10 T11 T12 T13 T14 T15 T16 T17 T18 T19 T20 T21 T22 x/ls

influenced by the proximity of sills, especially when the flow discharge is elevated.

Furthermore, when the interval length between sills is large such as in the cases of the second, the third and fourth sets of tests, which have an interval of 2 m, 4 m and 3 m, respectively, the scour hole shape is similar to a “spoon” profile. An example (T16) of a three dimensional scour hole profile is shown in Figure 6.

To study the similarity of the scour profile, the val ues of y x /y m at the equilibrium stage have been plotted against x/l s , for T04 to T22, as shown in Figure 7 and Figure 8. y x and y m are the depth of the scour hole at the longitudinal distance x (x= 0 m at the upstream sill position) and the maximum scour depth at equilibrium phase, respectively.

Figure 7 indicates that the scour profiles for T09 to T22 are similar in nature. This result is in agreement with the findings of other authors for other scouring processes (Chatterjee et al., 1994, Gaudio et al., 2000).

This is due to the strong influence of the distance between sills for this configuration. Thus, it should be noted that when the length of the scour hole is comparable to the distance between sills, “the sills interfere” with the development of the scour (Gaudio et al., 2000). 4.3 Scour hole dimensions at equilibrium stage The non-dimensional parameters for the experimental work discussed here have been determined for each test and illustrated in Table 3. Recall that over a sill with a small thickness, the depth of the flowing

water fluctuates around the critical flow depth. A com

parative study between the flow depth over sills, h u ,

measured during the experimental work and the criti

cal flow depth, h c , calculated for each test is presented

in Table 4. It can be seen that the maximum rate of

variation between the measured and calculated flow

depth (indicated by r%) is 11.48% and the minimum

is 0.29%. The average variation for all tests is 5.13%,

which is considered very small. Thus, the flow depth

over sill can be estimated with the formula of the

critical flow depth, h c :

According to these simplifying assumptions, equa

tions (5) can be reduced to:

The plot of y m /h u versus LS 0 /h u for the tests of

the scour hole which are similar in nature, as shown in

Figure 9, indicates that all the points fall approximately

on a single line. So, the linear regression of these points

leads to the first of equations (7) to become:

This equation is valid for 0.405≤ΔLS 0 /h u ≤ 2.142,

with a correlation coefficient R 2 = 0.88. 0.0 0.5 1.0 1.5 2.0 2.5 3.0 0.0 0.5 1.0 1.5 2.0 2.5 y m / h u ΔLS 0 /hu Figure 9. The plot of l s /h u against ΔLS 0 /h u of the same tests, as shown in Figure 10, leads to the following relationship: This equation is valid for 0.405≤ΔLS 0 /h u ≤ 2.142, with a correlation coefficient R 2 = 0.71. 4.4 Flow characteristics through the scour hole During all the experimental runs, it was observed that, at the equilibrium stage, the sediment particles through the bed scour hole move in a random fashion without leaving it. In order to study the causes of this observation, measurements of the flow velocities along the scour hole were taken. An example (T16) of flow velocity vector field obtained along the centerline of the channel is shown in Figure 11. The velocity vectors are the resulting mean velocities of the vertical and stream-wise velocity components.

Figure 11. Flow motion along the second scour hole with

x in cm and z in cm.

This figure indicates that the stream is very turbu

lent near the scour hole bed; however, it is smoother

and more orderly going toward the free-surface flow

and downstream of the equilibrium bed hole. In addi

tion, Figure 11 shows that, near the bed of the scour

hole, flow rotationality and vortex trends occurred.

Near the free surface the flow is assumed mono

directional due to the dominance of the stream-wise

velocity.

4.5 Secondary currents

It has long been established in academic literature that

flow in alluvial rivers is strongly three-dimensional

(Peters and Goldberg, 1989). The secondary currents were originally defined by Prandtl (1952) as currents, which occur in the plane normal to the axis of the pri mary flow. They originate from interactions between the primary flow and gross channel features.

The measurements of the flow velocity along dif ferent cross sections of the channel were determined during this experimental work. An example (T13) of the resulting mean velocities of the span-wise and ver tical velocities along the transversal centerline of the scour hole is presented in Figure 12.This figure clearly indicates that there is a development of cells of sec ondary currents through the central cross-section of the scour hole. These secondary currents consisted of two symmetrical cells of helical rotation located near the sidewalls of the channel. The presence of these secondary currents have a direct influence upon the transversal bed profile of the scour hole, resulting in the development of a sand ribbon in its center.

4.6 Turbulence intensity

The three-components of the flow turbulence index are defined as the ratio of the standard deviation

of the stream-wise, span-wise and vertical velocity Figure 12. Secondary flow in the cross section at x= 75 cm from the second sill with y in cm and z in cm. 0.00 0.05 0.10 0.15 0.20 0.25 0.30 0.35 0.40 0.45 0 5 10 15 20 25 30 35 z / h v x '/V x v y '/V y v z '/V z turb index of Vx turb index of Vy turb index of Vz Figure 13. Flow turbulence

intensity. fluctuation v ′ x , v ′ y , and v ′ z , by the relative flow velocity average V x , V y , V z , respectively. The plot of these components against z/h (z is the distance from the channel bottom and h is the flow depth in the section analyzed), an example (T12) is shown in Figure 13, indicates that the flow turbulence, near the bed of the scour hole, is very intensive, as shown in Figure 13, at z/h= 0.05, the turbulence index of the stream-wise and vertical velocity has a value of 7 and 2.5, respectively, increases extensively to reach the value of 20 and 37 for z/h= 0.15, and decreases gradually to reach the value of 1 and 6 for z/h= 0.4. The results of Figures 12 and 13 explain why the motion of the sediment particles is in a random fashion without leaving the scour hole location at the equilibrium stage. 5 CONCLUSIONS Four sets of tests were conducted in the hydraulic laboratory of the Mediterranean Agronomic Institute of

Bari to predict long term local scour at bed sills. One

uniform sediment was used respecting a constant ini

tial bed slop of 0.0086. The experiments show the

following results.

The extent of the scour hole is strongly dependent on

time. Three stages of the local scour hole development

were observed: an initial rapid stage, a progressive

stage, and a final decelerated stage.

The scour hole shape depends strongly upon the dis

tance between sills. Two forms of the scour hole were

discovered, i.e. a quasi-parabolic shape occurred with

a small distance and a shape similar to a “spoon” pro

file occurred with large distances. The scour profiles

are similar in nature for a large distance between sills,

but, not similar for a small distance.

Using classical dimensional analysis, the maximum

scour depth and the length of the scour hole at the equilibrium stage were articulated as a function of non-dimensional parameters. According to some logical simplifying assumptions, two empirical formulas (8) and (9) were determined to predict the maximum scour depth, y_m, and the length of the scour hole, l_s, respectively. The maximum scour depth and the length of the scour hole depend strongly upon the distance between sills.

The bed sills lead to a redistribution of the flow velocity and a flow rotationality. Intensive flow turbulence and vortex trends occurred in addition to secondary currents in the center of the scour hole.

ACKNOWLEDGEMENTS

The research described and the results presented herein were obtained from an experimental study on long local scouring downstream of bed sills in monogranular sand bed conducted in the hydraulic laboratory of the Mediterranean Agronomic Institute of Bari in 2002.

Influence of laterally placed side weirs on bed-load transport in

a prismatic channel

B. Rosier, J.L. Boillat & A. Schleiss

Laboratory of Hydraulic Constructions (LCH), Swiss Fed. Inst. of Technology, Lausanne, Switzerland

ABSTRACT: Lateral side weirs on channels are widely used in irrigation and flood regulation. They are

installed at the bank along the main-channel with the purpose to divert or spill in a controlled manner water

over

their crest when the water level in the channel exceeds a certain limit. This lateral loss of water is responsible

for the reduction of sediment transport capacity in the main-channel by decreasing the bottom shear stress. This

yields to the formation of sediment deposits which raise the bed level locally. As a consequence, the design

discharge to be diverted over the side weir is increased. By the help of an experimental setup the physical

processes in the main-channel and on the side weir were analyzed systematically. The test series confirm the

processes mentioned above. These processes are strongly transient showing a tendency towards an equilibrium

state of the river bed.

1 INTRODUCTION

The content of the present paper results from the

multidisciplinary flood protection research project

DIFUSE (Digues Fusibles et Submersibles, Fuse plugs

and overflow dams at rivers) involving governmental

offices, 1 private companies 2 and four research insti

tutes. The task of the research institutes is to establish

design criteria for fuse plugs (Ecole d'ingénieurs de

Fribourg, EIF), to investigate the stability of sub

merged river dykes including scouring at the toe (Ecole

d'ingénieurs du canton Vaud, EIVD) and to study the

effects of a side overflow on sediment transport in a

natural channel. The latter is treated by the Laboratory

of Hydraulic Constructions (LCH) and topic of this

paper.

The particular objectives of the LCH contribution

to this work is to collect experimental data which can

be used to conduct a non-dimensional parameter anal

ysis to predict the hydraulic behaviour of the diverting

weir. Combined with a photogrammetrical approach,

the purpose is to determine river bed changes and

to find empirical relationships. Furthermore, the col

lected data serves as main-input to generate a 3D

numerical model in order to analyze the effects men

tioned above in detail and to widen the application

ances des Bâtiments (ECAB), Fribourg. range from the simplified conditions of the physical model to more general cases. A better understanding of the process of sediment transport in a channel with lateral overflow will allow to develop and to provide appropriate design criteria for the engineer. This regards the residual risk and optimized geometric alignment for the side weir guaranteeing a sufficient bed-load transport capacity in the main-channel. From the total amount of 12 test series performed, the process of data collection, data analysis as well as results are described and discussed in detail for one individual experiment. 2 THEORETICAL CONSIDERATIONS 2.1 Flow equation for side weirs The equation of spatially varied flow for outflow over a weir on a fixed bed is (Borghei et al. 1999 & Singh et al. 1994): where y= depth of flow in main-channel; x= longitudinal direction; S 0 = bottom slope; S f = energy slope;

Figure 1. Definition sketch: a) longitudinal section; b) cross

section.

α= kinetic energy correction coefficient; A= cross

section area of the flow; and B= channel width

(Fig. 1).

From the constant specific energy concept (S 0 –

S F = 0), and α= 1, the general equation of weirs can

be written as follows:

and from the specific energy equation, the following

equation is obtained:

where q= discharge per unit length over the weir;

C d = discharge coefficient; g= acceleration due to

gravity; h=measured head above the crest; and

E= y+Q 2 /2gA 2 = specific energy. Substituting (2)

and (3) in (1), integrating the resultant equation and

arranging for C d , De-Marchi introduced the discharge

coefficient as follows (Chow 1973):

where L= effective length of the weir crest between

sections 1 and 2 (Fig.1); and φ= varied flow function,

expressed as:

where w= height of the weir. Knowing the flow

conditions at sections 1 and 2 and the geometrical con

figuration of the weir, the discharge coefficient C d can

be obtained.

Further, from dimensional analysis: where F 1 = upstream
Froude number in the main channel. For the constant
specific energy concept, C d is assumed to be independent

of L, hence (6) reduces to: The variation of parameters appearing in Equation 7 can be measured experimentally. Several relationships relating C d to these parameters have been developed (Borghei et al. 1999). 2.2 Sharp-crested weir The sharp-crested side weir is not only a measuring device for open channel flow but also the simplest form of overflow spillway. Using the general equation of weirs (2), the discharge over a sharp-crested weir can be expressed by (Naudascher 1992): where C q = discharge coefficient for sharp-crested weirs. According to the well-known weir formula of Rehbock, the coefficient C q in Equation 8 is approximately (Naudascher 1992): Measurements by Rouse (1957) indicate that this equation holds up to h/w= 5 but can be extended to h/w= 10 with fair approximation (Chow 1973). 3 EXPERIMENTAL MEASUREMENTS 3.1 Experimental setup The tests were conducted in a rectangular 2.0 m wide, 30 m long and 1.2 m deep flume existing at the LCH. The flume was subdivided longitudinally into two separate channels by a vertical 0.9 m high smooth wall. The first channel, being 1.5 m wide, represents the actual testing facility including the mobile bed and the side weir on the right river bank. The second one, 0.47 m wide, constitutes a lateral channel permitting to evacuate the laterally diverted discharge. A general layout of the experimental setup is shown in Figure 2. 3.2 Tested parameters and sediment characteristics In order to determine the influence of lateral overflow on bed-load transport, the main-channel discharge including flood hydrographs, diverted discharge,

channel slope, length of the lateral weir crest, num

ber of weirs and sill height were considered as test

parameters.

Table 1 gives an overview of the whole range of

test series. In the present paper, experiment B02 is

discussed in detail.

The channel facility originally possesses a horizon

tal slope. The bottom slope for each experiment is

created by adjusting the mobile bed to the requested

slope. The mean thickness of the sand layer is 0.24 m.

The bed material used in all tests consists of sand

having a mean diameter d m = 0.75 mm (Fig. 3).

Figure 2. General view of the test facility with the main

channel, the lateral side weir, the mobile bed and the

excavation channel. Table 1. Overview of the test series and parameters studied. The quantities to be supplied have been estimated according to the formula of Smart & Jäggi 1983. Sediment fed was adjusted during the test in order to maintain a constant water level for a certain discharge in the uniform flow stretch at the upstream end of the flume. The upstream discharge was delivered by the use of three pumps feeding one pipe controlled by an electromagnetic flow meter. A steady flow rate could therefore be easily set and maintained accurately throughout the duration of each test. The diverted discharge was measured by a standard sharp-crested weir installed in the excavation channel. Water depth along the main-channel as well as on the sharp-crested weir in the lateral channel were recorded continuously with a frequency of one measurement per second by the use of an ultrasonic gauge (voltage between 0 and 10V). The voltage was transformed into a distance to a reference level located 0 10 20 30 40 50 60 70 80 90 100 0. 10 1.00 10.00 Grain size [mm] P e r c e n t f i n e r b y w e i g h t [%] Figure 3. respectively.

at the crest of the side weir. The error of the level

measurement is less than 1 mm (average± 0.5 mm).

Altogether 15 ultrasonic gauges were installed longi

tudinally in the centre line of the channel, one located

upstream of the side weir, 12 in the reach of the side

weir (every 0.33 m), two downstream of the weir and

one upstream of the measuring weir in the excavation

channel (Fig. 4).

Velocities were measured with an Ultrasonic

Doppler Velocity Profiler (Metflow SA, Model UVP

XW) allowing to obtain instantaneously a 1D-velocity profile over the whole channel depth (Metflow 2000). For each 1D-profile, 128 data points in time were recorded with a spatial resolution of 128 points over flow depth. Eight probes, each inclined by 25 ∘ , were mounted on a measuring frame fixed on a traversing beam whereof four probes were orientated in the lon gitudinal channel direction and four perpendicular to the main-channel axis, thus allowing to constitute a 2D velocity field. The used probes had an emitting frequency of 2 MHz. Velocity profiles were recorded every 30 minutes for 16 cross sections, whereof three were located upstream of the weir, seven in the array of the weir (every 0.5 m) and six in the downstream section of the channel (Fig. 4). The velocity measure ments were also used to detect the bed. The surface was obtained from the signal for which the velocity as well as the variance were close to zero (Hersberger 2003).

3.4 Analysis of the bed topography

As far as the monitoring of the river bed topography is concerned, a photogrammetrical approach has been applied serving as a three-dimensional surface mea surement tool. Digital photogrammetry is based upon automated analysis of digital imagery using the basic

principle of the perspective projection. Two images of an object are acquired from two separate locations with known coordinates. If at least five points (photocontrol points) at known object locations are clearly visible on both images, a spatial resection can be carried out to derive the positions and orientations of the images. With the help of automated stereo matching, conjugate points can be identified and elevation coordinates are extracted (Geisler et al. 2003 & Lane et al. 2001). For the present study five photographs with an overlap of 60% have been taken to cover the whole channel. This has been done for the initial flat bed situation and after each experiment for the final bed situation after controlled emptying of the channel. The camera was mounted at the gantry crane at about 6.5 m above the flume and 18 photocontrol points were distributed along the channel and in the laboratory. The orientation (position and aiming angles), triangulation and the creation of a digital terrain model (DTM) have been performed on the photogrammetric workstation DPW 750 by HelavaLeica running on Unix. The program system used for the analysing process is called SocetSet. For the creation of the DTM a grid resolution of 2,5× 2,5 cm has been chosen. A quality control feature for the automatic terrain extraction may indicate a successful automatic correlation or good measurement as well as the opposite. This tool is called Figure Of Merit (FOM) and gives a numerical value assigned by the terrain extraction process. FOMs are proportional to the average correlation coefficient, so in general the larger the number, the better the measurement. During the determination of the DTM some regions especially the crest of dunes showed a low average correlation coefficient. For this reason data points possessing a lower average correlation coefficient than 54 have been eliminated by the help of a macro written in Excel. The resulting “empty” DTM regions have been filled manually by so called brake lines provided by a geomorphic editor. This treatment leads to the final DTM used for analysis. 4 RESULTS 4.1 Water level and diverted discharge Water level measurements reveal strongly transient processes. In Figure 5 the evolution of the water level for a cross section upstream (U), in the middle of the side weir (W) and downstream (D) (see Fig. 4) as well as for the sharp-crested side weir in the excavation channel are presented (time step 200 sec.). At the beginning of the experiment the water level over the measuring weir in the excavation channel rapidly increases corresponding to an increasing diverted discharge (Equation 8). With elapsing experiment time the level reaches a maximum before tending towards an almost constant value.

percentage of total discharge (Q) introduced upstream

(Q= 210 l/s).

Due to the passage of dunes, the evolution of the

diverted discharge turns out to be oscillatory (Fig. 6).

The diverted discharge amounts on average to 25%

of the total discharge introduced. Compared to the

diverted discharge for a fixed bed it can be noticed that

the ratio diverted discharge/discharge is about 43%

higher with a mobile bed.

4.2 Velocities

Qualitative velocity profiles in channel axis and per

pendicular to the weir for three typical cross sections

are plotted in Figure 7. For each cross section (U, W,

D), a profile at the beginning and at the end of the test

has been measured at 0.9 m channel width (Fig. 4).

As far as the profiles in flow direction are con

cerned, at the beginning of the experiment the veloc

ity profile is almost homogenous to become quite

disturbed in the weir alignment as well as in the down

stream channel section. The distance to the free water

surface is nearly equal for all profiles meaning that the

water depth is almost similar for the three cross sec

tions. From this, a regular and undisturbed formation

of the bed level can be concluded.At the end of the test, 0 50 100 150 200 250 300 D i s t . t o f r e e w a t e r s u r f a c e [m m] beginning end 0 50 100 150 200 250 300 D i s t . t o f r e e w a t e r s u r f a c e [m m] beginning end 100 mm/s 100 mm/s U D U DW W Figure 7. Velocity measurements parallel to channel axis (top) and perpendicular (bottom) for sections U, W and D (from left to right) at the beginning and the end of test run B02. Dashed line: v= 0 mm/s. the velocity distribution is regular for the upstream part whereas further downstream irregularities are encountered. The distance to the free water surface decreases. Assuming a horizontal water surface level, the bed level has therefore increased. The velocity profiles perpendicular to the weir are nearly constant over flow depth for the beginning of the test run.With elapsing time the velocity component towards the weir increases. The velocity measurements have also been successfully used for the detection of the bed surface. Therefore the development of the bed over time can be determined, which is not possible with the photogrammetrical treatment since only the final bed situation can be measured. The information about the ground is less dense because only eight points for the eight probes are obtained instead of 1.5 m/0.025 m= 60 points from the photogrammetry. Nevertheless, it helps to get an idea about the development of the bed over time. 4.3 River bed topography After introducing the flow to the prepared initial flat bed by a small discharge, a rapid change of bed roughness due to the formation of dunes appears. Upstream

of the side weir the dunes are of quite uniform charac

ter whereas in the reach of the weir and downstream

the regular formation is clearly disturbed. In Figure 8

the bed after 2 hours experiment is presented. From the

Figure 8. Bed topography after 2 hours test for run B02.

(between cross sections U and D). The level of the weir
crest is

7.62 m, the level of the initial bed in the middle of the weir is 7.52 m. procedure described in paragraph 3.4, the DTM for the final bed situation has been extracted (Figs 9, 10). An analysis concerning the level difference between the initial and the final bed clearly illustrates the formation of sediment deposits in particular in the reach of the side weir (Fig. 10). A volumetric balance between cross sections U and D reveals a deposited volume of 0.044 m 3 or 116 kg. Typical cross-section profiles extracted from the DTM at cross sections U, W and D are shown in

Figure 11. This figure indicates that no significant changes could be observed upstream whereas deposition processes have taken place on the right bank in the weir array nearly up to the top of the weir crest. The mean bed level elevation in this cross section amounts to 0.03 m.The initial level difference between the weir crest and the mobile bed of 0.1 m is therefore reduced to 0.07 m representing a reduction of the cross section of about 33%. Due to these deposits, the flow velocity opposite to the weir is increased resulting in an erosion process. This erosion process continues further downstream in an oscillatory manner before attenuating. Figure 11 (top) illustrates this phenomena. Sedimentation reaches on the right bank are followed by eroded reaches on the left bank. In Figure 2 these observations are pointed up in a qualitative way. at the end of the test still filled with water, is running

to the right and again to the left. In the downstream

section the mobile bed tends to keep almost the same

level as the initial bed (see also Fig. 10).

4.4 Synopsis of results

The flow is attracted by the lateral side weir leading to

a progressive modification of the bed morphology.The
diverted discharge induces an elevation of the mobile bed

near the weir alignment and erosion processes further downstream on the opposite river bank. The migration of dunes is manifested by a temporal variation of the water level and diverted discharge. These variations are representative for the interaction between the hydraulic and sedimentary phenomena. 5 CONCLUSION AND PERSPECTIVE At the actual stage of the research project, great deal of analysis remains to be carried out. However, some preliminary ideas can be expressed. The analysis of one test series confirms the formation of local deposits of sediments in the reach and downstream of the lateral side weir, particularly on the weir side of the channel. On the one hand these deposits increase the flow velocity opposite to the weir resulting in additional stress to the bank since the cross section is reduced. This aspect is indicated by eroded bed material. On the other hand the bed elevation is combined with an elevation of the water level resulting in an increased diverted discharge over the side weir. This process is strongly transient since at the beginning of the experiment the diverted discharge/mainchannel discharge ratio is low, then rapidly increases to a maximum before reaching almost a constant value. In this process, a tendency towards an equilibrium state of the river bed is observed which is also indicated by a strongly wavy water surface in the reach of the side weir at the beginning of the test which becomes smoother with elapsing experiment time. Based on the examination of the first test series, the remaining experiments will be analysed according to the same procedure to finally perform a nondimensional parameter analysis and to develop empirical relationships for the hydraulic and sedimentary behaviour. The collected data will also serve to calibrate a 3D numerical model in order to analyze the observed effects in detail and to widen the application range. A better understanding of the interaction between sediment transport and lateral overflow will allow to develop and to provide appropriate design criteria for engineers involved in the design of fuse plugs on rivers in the framework of flood protection projects. ACKNOWLEDGEMENT The authors would like to express their gratitude to the CTI (Commission pour la Technologie et l’Innovation) for their sustained funding for the research program under grant number 4898.1.

PIV investigation of flow around submerged river bridge deck

S. Malavasi, S. Franzetti, G. Blois

Politecnico di Milano, Dept. I.I.A.R., Milan, Italy

ABSTRACT: The flow field around a submerged bridge deck has been experimentally investigated here. The

deck submersion may be a critical situation for structural stability of river bridges. This problem has been not

sufficiently discussed in the past. In order to clarify some aspects of the hydrodynamic loading mechanism,

we have kinematically studied the characteristics of the large-scale vortexes in the bridge wake by an original

PIV technique. The bridge deck has been modeled by means of a rectangular cylinder. Mean and time-averaged

velocity fields have been studied for low submergence ratios of the bridge deck. The work has provided some

interesting results.The flow fields around the deck had shown a strong asymmetry and a complex vortex shedding

regime, the analysis of which has allowed us to highlight the main differences from symmetrical unbounded case

and to associate the considered kinematic behavior to the corresponding dynamic reaction.

1 INTRODUCTION

During a critical river flood event, a bridge may

become partially or completely submerged by the flow.

This situation may seriously endanger the structure

stability, as highlighted by Ballio et al. (1998) in a

survey about the vulnerability of many Italian river

bridges.

In spite of the actuality of the problem, only few

(Tainsh 1965, Denson 1982, Naudasher & Medlarz

1983, FHWA 1995). Moreover, as highlighted in a

recent paper (Malavasi & Guadagnini 2003), usually

the studies are referred to specific bridge typolo

gies, consequently the results are hard to generalize.

Malavasi & Guadagnini studied the dynamic stress on

a bridge deck due to its partial or total submersion.

They modeled the structure by means of a cylinder

with rectangular cross section. This shape mimics

quite well several bridge deck typologies. They stud

ied the dynamic behavior of the model by direct force

measurements, for several submergence levels. Their

results highlighted significant differences between the

considered asymmetrical bounded conditions and the

more studied condition of unbounded flow. Moreover,

the Authors highlighted that the worst situation for the

bridge stability occurs for low water level above the

structure, which is a realistic and relatively frequent

condition. In this situation the mean force coefficients

are significantly higher than those corresponding to

the immersion in unbounded flow. The study of fluid structure interaction between an indefinite rectangular cylinder and an unbounded flow is a basic subject of fluid mechanics, and it keeps a significant interest, as the recent literature confirms (Noda & Nakayama 2003, Hemon & Santi 2002, Shimada & Ishiara 2002, Li & Melbourne 1999, Yu & Kareem 1998, Deniz & Staubli 1997). On the contrary, the situation of the rectangular cylinder immersed in an asymmetrical bounded flow was less considered in the past. In order to clarify some aspects of the dynamic loading on inundated river bridges, in this work we have investigated the flow field structure around a specific bridge deck. It has been modeled with a rectangular cylinder of aspect ratio l/s= 3, where l is the in-flow direction length and s is the thickness of the cylinder cross-section (see Fig. 1). Instantaneous and time-averaged 2D velocity fields have

been experimentally obtained by applying an original Particle Image Velocimetry (PIV) technique. This technique allows to perform long series of instantaneous sequential velocity fields.The temporal evolution and the mean structure of the velocity fields close to a submerged bridge have been here discussed for low submergence conditions. Moreover, considering the direct relation between the hydrodynamic loading and flow structure, we have compared our kinematic results with the frequency analysis of the force components and with mean force coefficients obtained in previous works, in the same hydrodynamic conditions (Malavasi et al. 2002, Malavasi & Guadagnini 2003).

2 OVERVIEW OF THE PROBLEM

The immersion of a solid body in a turbulent flow

induces a distortion of the incoming flow field. The

process is characterized by a strong kinematic and

dynamic instability. The interaction is connected with

the shear layer separation from the body and with the

formation of coherent structures in the obstacle wake.

As above mentioned, the fluid dynamic behavior of an

indefinite rectangular cylinder submerged by a free

surface flow (Fig. 1), is not sufficiently studied in

literature. To introduce the main aspects of the phe

nomenon we refer to the unbounded flow scheme, that can be seen as a limit case of a bounded flow in which the boundary conditions have negligible effects on the flow field.

In the case of a sharp edge elongated rectangular cylinder, the flow detaches on the upstream (primary separation) and downstream corners (secondary sepa ration), and the flow distortion is a function of several parameters. The vortices generated close to the body develop and shed from it creating an unsteady wake. The characteristics of the wake are dependent on the Reynolds number of the obstacle Re=U 0 /v (where U 0 is the mean velocity of the incoming flow and v is the 5 4 3 2 1 0 -1 1.5 1.0 0.5 0.0 -0.5 -1.0 -1.5 Flow direction Figure 2. Mean flow field numerically obtained in unbounded flow around a rectangular cylinder,Yu & Kareem 1998; l/s= 3, Re= 10 5 . kinematic viscosity). The vortex shedding mechanism is the main responsible of structural excitation in a stationary flow. Figure 2 shows the mean flow field around a rectangular cylinder (l/s= 3) in unbounded flow, numerically obtained by Yu & Kareem (1998) at Re= 10 5 . The primary separation of the shear layer occurs on the leading edge. The separated flow initially diverges from the body with an angle that is function of the separation pressure and then curves toward the cylinder surface.When the reattachment occurs, the flow makes a region of recirculation known as separation bubble. In this condition the secondary separation at the downstream edge of the cylinder causes the roll up of the flow in the rear face that generates a secondary vortex, periodically shedding from the body surface. In some cases, when the reattachment of the primary separation is unsteady, the two turbulent structures interact and the vortex shedding becomes more complex. To simplify the phenomenon description, the main vortex shedding regimes have been defined and classified in literature considering the characteristics of the large vortices. In the case of steady flow condition and of rigid

obstacle, we refer to the following classification (Deniz & Staubli 1997): – LEVS (Leading-edge vortex shedding): the flow separation occurs at the leading-edge with formation of vortices, dominating the near wake of the body; – TEVS (Trailing-edge vortex shedding): a decisive flow separation at the trailing-edge occurs and vortex-shedding is analogous to the von Kármán street behind circular cylinders; – ILEV (Impinging leading-edge vortices): a flow separation at the leading-edge and impingement of the leading-edge vortices at the side surfaces and/or edges of the body are present; – AEVS (Alternate-edge vortex shedding): both the leading-edge and the trailing-edge mechanisms are present.

In unbounded flow the Reynolds number (Re), the

cylinder aspect ratio (l/s), the free stream turbulent

level Tu= u ′ rms /U 0 (where u ′ rms is the standard devi

ation of the inflow velocity on X direction) and the

incidence angle α (the angle between the mean inflow

direction U 0 and the longitudinal axis of the cylin

der X) are the main parameters which affect both the

wake structure and the force distribution. They are

extensively studied in literature.

For a large range of conditions, several studies show

the negligible influence of Reynolds number, when it

exceed the value Re= 10 4 (Okajima 1982, Deniz &

Staubli 1997).

The aspect ratio (l/s) affects significantly the vortex

shedding. When l/s< 2 only the primary separation

occurs because the shear layer, separated at the leading

edge, involves the entire side of the cylinder (LEVS);

on the contrary, when l/s> 6 the flow, separated at the

leading edge, reattached permanently; consequently the trailing-edge separation (TEVS) dominates the vortex shedding. For 2< l/s< 6 the literature indicates a complex situation of possible unstable reattachment (Shimada & Ishiara 2002, Yu & Kareem 1998, Deniz & Staubli 1997). In this case the presence of mixed structures (ILEV) is function of parameters such as the Reynolds number and the upstream flow turbulence.

Free stream turbulence level (Tu) has received a great attention in literature because it significantly influences the structure and the development of the shear layer separated off the upstream corners (Haan et al. 1998, Li & Melbourne 1999, Saathoff & Melbourne 1997, Noda & Nakayama 2003). Nakamura et al. (1996) experimentally investigated the effects both of turbulence level and scale on pressure distribution along the surface of rectangular cylinders with various aspect ratios. They found that the main effect of Tu is to shift the reattachment point. An increasing of Tu leads to a progressively shorten formation bubble and consequently to a possible strong modification of vortex shedding. Noda and Nakayama (2003) founded that turbulence shakes the shear layer over a distance comparable with turbulence scale. This

mechanism intermittently provides the shift of the separated shear layer either towards or far from the body surface.

Of course, also the incidence angle (α) affects the shedding mechanism. When α ≠ 0 the symmetry of the flow structure is compromised. Consequently, on a side of cylinder prevails the LEVS and on the other the TEVS.When this condition occurs the vortex shedding is characterized by the AEVS regime.

In the case of bounded flow, another significant parameter is the blockage ratio, which, in the case of indefinite rectangular cylinder at zero incidence, can be defined by the ratio γ b = s/h, where h is the depth of the upstream bounded flow. For a rectangular 0.5 1.5 2.5 3.5 0.5 1.0 1.5 2.0 2.5 h* C D unbounded flow a) -10.0 -6.0 -2.0 2.0 0.5 1.0 1.5 2.0 2.5 h* C L unbounded flow b) Figure 3. Dependence between mean force coefficients and submergence level h* for a rectangular bridge deck at Fr s = 0.26. (• Experimental database of Malavasi & Guadagnini 2003; - reference value in unbounded flow condition). cylinder in a symmetric flow field, Okajima et al. (1997), studying the blockage effect on the drag coefficient C D =F D /(0.5 · ρ ·U 2 0 · s) (where F D is the mean drag force per unit length of cylinder and ρ is the fluid density) and on the Strouhal number Sh= f · s/U 0 , (where f is the vortex shedding frequency), showed that both C D and Sh increases when γ b increases. In case of bounded free surface flow, Malavasi et al. (2001, 2002) highlighted how the presence of the free surface may significantly change the mean force coefficients and the Strouhal number (Sh) of the vortex shedding in comparison with the unbounded characteristic values. Moreover, Malavasi & Guadagnini (2003) extended their attention to the cases of partial and low submergence level. In Figures 3a, b, for a deck Froude number Fr s =U 0 /(gs) 0.5 = 0.26, is shown the relation between experimental drag and lift force coefficients (C D , C L), and low value of

submergence ratio h ∗ = (h u − h b)/s where h u and h b are respectively the distances between the free surface and the channel floor and between the bottom bridge deck side and the channel floor (Fig. 1), while the force coefficients are: C D =F D /(0.5 · ρ ·U 2 0 · s) and C L =F L /(0.5 · ρ ·U 2 0 · s), where F L is the mean lift force per unit length of the cylinder. Ther is a significant difference of force coefficients for bounded flow compared with unbounded flow.

3 EXPERIMENTAL APPARATUS AND METHOD

The experimental set-up (Malavasi & Guadagnini 2003) consisted in a not tilted plexiglas open water channel with rectangular cross section, 0.6 m height, 0.5 m width and 5.0 m length. Flow rate and water depth were regulated by an inlet valve and by a downstream grid weir respectively. The sharp edge rectangular cylinder employed as bridge deck model was rigidly fixed to the channel side-walls at a dis tance of 3.35 m from the inlet section and at a distance of h b = 0.14 m from the channel floor. The cylinder was placed with its generatrix parallel to the channel floor and with the front face normal to the direction of undisturbed flow.

The reference section for the control of boundary conditions was located 0.60 m upstream the leading edge of the cylinder to ensure negligible velocity deviation due to the obstacle presence. A set of three piezometric taps, evenly spaced in spanwise direction,

was used to measure the free surface level h u in the ref
erence section. The flow rate was measured by means
of a rectangular sharp-crested weir with an uncertainty
of ±0.001 m 3 /s. Mean vertical and spanwise velocity
profiles were performed by measuring the instanta
neous velocities by an impeller flow-meter (diame
ter d = 0.007 m; uncertainty u v =±1%). Acquisition
time of two minutes ensures the stability of the mean
velocity. Free stream turbulence level measured was
Tu= 14%.

The flow fields around the bridge deck model
were measured using an original PIV (Particle Image
Velocimetry) technique expressly developed thinking
to hydraulic applications. The 2D velocity fields were
obtained measuring the bi-dimensional trajectories of
seeding particles in a defined time interval.This is pos
sible by filming the seeding flow on the measurement
plane and by using a delayed exposure time. Figure 4
shows an example of acquired frame in which the tra
jectories of the running particles are well visible. The
length of each trajectory, obviously, was due to the
corresponding instantaneous local flow velocity and
to the shutter time of the video-camera. An exposure
time of 0.02 s was used.

The image acquisition rig was composed by an illu

mination system, a particle dispenser, a progressive scan camera (CCD: Charge Coupled Device) and a per sonal computer equipped with a frame grabber board for high-speed data transfer. In our arrangement we have been able to grab monochromatic images with a resolution of 763× 576 pixel at a frame rate of 50 Hz for a maximum time interval of 16 s. The mea surement plane (Fig. 1) was defined by means of a light sheet. It was 7 mm in thickness with a diverg ing angle of about 0.4 degree and was obtained by a

linear halogen lamp (1600 W power) assembled with Figure 4. Single image of the seeded flow at the bottom of the bridge deck model (exposure time: 0.02 s; Fr s = 0.26, h ∗ = 1). l and s indicate the dimension of the cylinder in the measurement plane. two slits system. White spherical polystyrene particles with an average diameter of φ= 400µm and a density of ρ ρ = 1050 kg/m 3 were used to emphasize the flow trajectories. The polystyrene density, very close to the water one and the particle dimension, ensured the minimization of gravitational and inertial effects on the particles movements. As the acquisition apparatus, the numerical analysis of the image here used differs from the correlation image method usually employed in PIV analysis. By applying the blob-analysis algorithm on each frame, we measured the geometrical characteristics of each recognized particle trajectory: location, module and orientation. The particle velocity module was obtained dividing the displacement length by the camera exposure time. The direction ambiguity was solved using the velocity information on two consecutive frames. The velocity within the time (Δt) between two consecutive frames can be assumed steady. Starting from a specific position at t i , in which a data is available, the particle position at time t i+1 can be predicted by velocity information on the image t i . The predicted position can be easily verified by available data (position/velocity) on the image t i+1 . By applying the described analysis on an acquired image sequence we obtained a series of instantaneous 2D velocity fields. This analysis provided unstructured data fields, so the data were integrated on a regular grid. A square mesh grid of

1.5 cm, with an overlapping of 50% was used. 4 RESULTS The main characteristics of the flow field generated by the interaction of the rectangular bridge model with the free surface flow are here discussed starting from streamline representations. The aim is to study

the influence of free surface on evolution of large

scale vortices and to investigate their implication on

the structure loading. Since the high submergence of

bridges have less practical interest, we have restric

ted the investigation to low submergence ratios. Low

submergences represent the most interesting condition

for the relatively high frequency of their occurrence

and for the peculiarity of their dynamic behavior

(Figs 3a, b).

The instantaneous velocity fields are averaged on

different time-windows in order to highlight both the

vortex structure evolution and the mean flow con

figuration. For the former the average-window is

determined referring to the dominant vortex shedding

frequency calculated by Malavasi et al. (2002) on the

basis of force measurements. For the latter we use the

whole acquisition interval.

An example of flow field evolution at the bottom

side of the bridge is illustrated in Figure 5 by means

of nine flow fields for the significant case Fr s = 0.26,

h ∗ = 1.4.The first picture is very similar to the last one,

highlighting the periodicity of the phenomenon. Each

flow field is calculated averaging the data belonging to 20 consecutive frames, so the time window dimension is 0.02× 20= 0.4 s. The overlapping time of 50% (10 frames) provides us to obtain one averaged field every 0.2 s. Each field is referred to the center of the corre sponding time window. The total period of a sequence constituted by n time averaged fields can be obtained as 0.2× (n− 1)= 1.6 s.

The sequence of images in Figure 5 shows at the bottom of the cylinder the unsteady reattachment of the shear layer separated on the leading edge and the consequent unsteady condition of the separation bub ble. The increasing of bubble size appears evident as its longitudinal stretching. The downstream bubble convection is clearly shown by the vortex focus dis placement. This behavior involves that reattachment point progressively shifts to the downstream corner (Fig. 5, 0.2 s< t < 1.2 s). The evolution leads to a situ ation of completely separated flow in which the bubble is no longer confined by the shear layer and goes to interact with rear vortices (Fig. 5, t= 1.4 s). On the whole, the reattachment condition prevails. When the reattachment disappears we can notice the presence of two vortices with the same rotation sense in the same step (Fig. 5, t= 0 s and t= 1.6 s). The upstream one

refers to generating bubble; the second is the bubble

in its final state of development. This evidence con

firms the presence of the ILEV mechanism, supposed

by Malavasi et al. (2002). Moreover, by considering

the time interval between the first (Fig. 5, t= 0 s)

and the last image (Fig. 5, t= 1.6 s) we can roughly

estimate the frequency of the vortex evolution that

is f 0 ~ = 0.6 Hz (80 frames, with 0.02 s of shutter time

and 50 Hz of frame rate). This value accords with

the result of the frequency analysis obtained using Figure 5. Flow evolution at the bottom of the bridge deck model (Fr s = 0.26 and h ∗ = 1.4). Streamlines calculated from velocity fields averaged on temporal window of 0.4 s, 50% overlapping. the lift component of the experimental database of Malavasi & Guadagnini (2003), showed in Figure 6: the frequency analysis of the lift force component on the bridge deck highlights a dominant frequency (~ = 0.6 Hz) that accords with the developing of separation bubble depicted in Figure 5. The higher dominant

Figure 5. Continued 0.00 0.01 0.02 0.03 0.04 0.05 0.06 0.07 0.08 0.01 0.1 1 10 Freq.[Hz] A m p l . [N] Figure 6. Frequency analysis of the lift force on the bridge deck for h ∗ = 1.4. Experimental database of Malavasi & Guadagnini (2003). frequency (~ = 1.0 Hz) accords with the frequency of the vortex shedding downstream the obstacle. The situation on the upper side of the bridge seems to support the high frequency value, indeed, the presence of the free surface favors the shear layer reattachment and inhibits the bubble formation, so the permanent separation occurs on the down-stream corner only. The distortion of the flow and the absence of the upper side separation bubble are highlighted by the mean flow field obtained by the time average of several velocity fields acquired with different fields of view. Figures 7, 8 show the streamlines of the 2D mean velocity field around the obstacle at Fr s = 0.26 and h ∗ = 1.4 and h ∗ = 1 respectively. These results give new information for the phenomenon knowledge, which up to now was based only on the mean force coefficients behavior (Figs 3a, b). It is well known that the separation bubble generates a low-pressure area on the corresponding side of

the obstacle. In symmetrical condition (Fig. 2), the mean separation bubbles at the opposite sides of the obstacle have the same dimension and the resulting lift force is zero (C L = 0). In the asymmetrical case depicted in Figure 7 (h ∗ = 1.4, Fr s = 0.26), the presence of only one significant separation bubble at the lower side of the bridge deck induces a resulting negative lift force (C L =-2.5). As h ∗ decreases from 1.4 to 1, the dimension of the mean bubble increases and as a consequence the module of lift increases too. When h ∗ = 1 the bubble reaches its maximum dimension (Fig. 8) and the lift coefficient (Fig. 3b) reaches its minimum value (C L =-9.1). In literature some comments on the relationship between the C D and, the mean dimensionless thickness and position of the vortex of the wake are available for unbounded conditions (Igarashi & Mayumi 2001, Bearman & Trueman 1972). Nevertheless our

experiments (Figs 7, 8) seem to provide not enough

information about the behavior of the C D with h * .

More experimental evidences are necessary to under

stand the trend of figure 3a that, in the range here

considered, presents a not-monotonic behavior.

5 CONCLUSIONS

The problem of submerged river bridges has been the

object of the present study. A kinematic investiga

tion has been conducted on a rectangular bridge deck

model. The flow structure around the model has been

studied in order to understand some dynamic behaviors

highlighted by force analysis in previous works. Time

evolutions of 2D flow fields and mean flow fields have

been experimentally obtained by applying a PIV tech

nique expressly developed. It has been successfully

tested on a hydraulic model of relative large dimen

M. Gög˘üs¸

Hydraulics Lab., Civil Engineering Dept., Middle East Technical University, Eskis¸ehiryolu, Ankara, Turkey

ABSTRACT: Estimation of the depth of scour at bridge foundations is a problem that has perplexed designers for many years. In this study, an investigation on the reduction of scour around bridge abutments using rectangular collars was carried out for clear-water flow over uniform sediment particles. The primary cause of local scour around a bridge abutment is the presence of vortex flow called the principal vortex. The growth of vortex can be arrested by forming a rigid surface around the abutment with a collar plate. The primary objective of this study is to determine the scour reduction of collars of different sizes at different elevations for abutments. Experimental results showed that a collar plate placed on the abutment at the bed level reduces the maximum scour depth by 45% in comparison to an unprotected abutment. However, in the eventuality of lowering or rising the collar with reference to the sand bed, its efficiency depends on the abutment’s width and length.

1 INTRODUCTION

Scour of a streambed at bridge piers and abutments during flood events has resulted in more bridge failures than all other causes in recent history. For exam ple, all major bridge failures that occurred in New

Zealand during the period 1960-1984 showed that, 29 were attributed to abutment scour of the 108 failures recorded (Melville, 1992). Unfortunately, because of the failure experiences, abutment scour has been the subject of intense research during the last decades. However despite a lot of research on this topic, abut ment scour is still a problem of engineering concern and the mechanisms that govern the interaction of the approach flow with the foundation structure, the river bed and the scour are still not entirely understood (Kandasamy and Melville, 1998).

Because the maximum scour depth is insufficient to describe the problem of bridge failures caused by scouring, the protection methods of bridge structures have been searched.

Traditional engineering methods applied to local scour problems are not very sophisticated. There are three basic approaches of providing protection to the bridge foundation: (a) to place the bridge foundations of structures deeply, (b) to enhance the ability of the bed material to resist erosion, (c) to reduce the power of the eroding agents, which is normally achieved by placing an extended base plate or collar at or around the bed level or providing an array of piles in front of the bridge foundations (Chiew, 1992; Singh et al., 1995). The primary objective of the present study is to investigate the scour reduction of collars with different sizes and at

different elevations around bridge abutments. 2 LITERATURE REVIEW A literature review shows that placing a collar (thin plate) around a bridge pier can reduce the depth of scour. Chiew (1992) conducted experiments in a 0.30 m wide and 8 m long channel having a cohesionless, uniform sand of a median particle size of 0.33 mm. Chiew used a single cylindrical pier of 32 mm-diameter and investigated the effect of a slot, a collar and a combination of both on bridge pier scour. A combination of collar and slot can be an appropriate alternative solution to riprap protection in tackling scour problems at bridge piers. Kumar et al. (1997) used a 1-m wide, 30 m long flume having a longitudunal slope of 7.73× 10 −4 and uniform sediments of median diameters 0.78 mm, 1.18 mm and 1.54 mm as bed material. The scour reduction efficacy of slots of two different lengths provided along the height of the pier with a constant width of 0.25D was studied, where D is the diameter of

the pier. They also developed a predictive equation for

scour reduction by the use of collars of different ele

vations at or above the bed level. For the experiments

on collar efficiency, five collar sizes (1.5D, 2D, 2.5D,

3D, and 4D) were used.They presented an equation for

predicting the scour depth with collars and concluded

that larger diameter collars at or close to the bed were

more effective.

Singh et al. (2001) investigated arresting the growth

of the vortex on rigid surface as a collar plate or by

confining it within an enclosure like a sleeve skirt

ing around the pier. Uniform sediment with d 50 =

0.285 mm was employed in a 12-m long, 0.6-m wide

channel. Model piers of diameters 25 mm and 62 mm

were used. The best location was at 0.1D below the

average bed level where a collar plate of a diameter

twice of the pier gave a performance potential of 91%.

In addition, a collar plate equal to twice the diameter of the pier was able to reduce scour by 68% when placed at the bed.

This review demostrates that most of the works toward the understanding of scour evolution were conducted on bridge piers. Therefore, the primary objective of the present study is to determine the scour reduction efficacy of collars of different sizes and shapes, placed at different elevations of abutments.

3 DIMENSIONAL ANALYSES

For clear-water approach flow conditions, the equilib rium scour depth, (d se) c , at an abutment with a collar is a function of:

where, L a = the lateral dimension of the abut ment, B a = abutment width, B c = collar width, Z c = elevation of the collar with respect to the sand level, T c = collar thickness, U=mean approach flow veloc ity, y= approach flow depth, S= slope of the chan nel, g= gravitational acceleration, ρ s = the density of the sediment, ρ= the density of the fluid, μ= dynamic viscosity of fluid, d 50 =median particle grain size, σ g = (d 84 /d 16) 0.5 = geometric standard deviation of sediment size distribution, t= scouring time, and B= channel width.

Buchingham’s π theorem gives the dimensionless

terms: Considering that the experiments are conducted with one sediment size, constant bed slope, channel width, collar thickness, abutment length, duration of the experiment, and discharge, one can simplify Equation (2) as the reduction in the scour depth around the bridge abutments as compared to case without collar, d se , is or 4 EXPERIMENTAL PROCEDURE Experiments were conducted under clear water conditions, U * /U *c < 1, where U * is the shear velocity of the approach flow and U *c is the value of U * at the threshold.A rectangular channel with transparent walls, 30 m long and 1.5 m wide was filled with erodable uniform sediment. The general view of the channel is shown in Figure 1. The flume flow was supplied from a water tank by a pump and measured by a sharp-crested rectangular weir. The depth of flow and the bed profile measurements were conducted by a point gage with a vernier scale to the nearest 0.1 mm. The mobile bed was made of uniform sand having a median diameter of d 50 = 1.48 mm and a distribution ratio of σ g = 1.28. The depth and length of the sand layer in the working reach were 0.50 m and 10 m, respectively. Figure 2 shows a definition sketch with a typical view of a collar-abutment arrangement used in this study. The abutments used were always rectangular in plan, having widths of B a = 0.025 m, 0.05 m and 0.10 m and lengths are kept constant at L a = 0.25 m. According to Oliveto & Hager (2002) and initial findings of this study, the effect of the streamwise abutment length is small and may be dropped. The scour hole was obtained by performing a 6hours continuous run under clear-water conditions and both maximum scour depth and scour formation at the abutment site were investigated. Four different collar widths B c = 0.025 m, 0.050 m, 0.075 m and 0.10 m were used for all abutment types. As the efficiency of the collar is also a function of Rectangular weir Screen Abutment Control gate Flow direction Sand bed Recession section 10 m 30 m

arrangement.

its vertical location on the abutment, different collar

widths were placed at different elevations on the abut

ments; such as at the bed level, 0.025 m and 0.050 m

above the bed level. 5 SCOUR MECHANISM Local scour around a solid abutment results from the down flow at the upstream face of the abutment and the subsequent development of a horseshoe vortex at its base. Hence, one way of reducing scour is to weaken and possibly prevent the formation of the downflow and the horseshoe vortex. A collar at any level above the bed divides the flow into two regions; i.e. above and below the collar. For the region above the collar, it acts as an obstacle against the downflow in which the downflow looses its strength an impingement at the bed. For the region below the collar, the downflow and the horseshoe vortex are reduced. However, the efficacy of a collar depends on its size and the location on the abutment with respect to the bed. 6 ANALYSES OF RESULTS In this study, in order to obtain the maximum reduction in scour depth, various collar and abutment widths were investigated systematically. Figure 3 shows the effect of the various sizes of collar plates on maximum scour depth around abutments. From this figure, it is clearly seen that the maximum reduction in scour depth is observed while the location of the collar plate approaches to the sand bed level (Z c /y→ 0) for a given abutment width B a and collar width B c . Among the tested abutment-collar arrangements, the one having B a = 10 cm and B c = 0 cm for Z c /y= 0 yielded the maximum reduction of 45% in scour depth. Figure 4 shows the efficiency of the collar for the abutments and for the piers together. In this figure, the abutment data was obtained for B a = 10 cm and the pier data were obtained from the previous studies of Tanaka andYano, 0.00 0.05 0.10 0.15 0.20 0.25 0.30 0.35 0.40 0.45 0.50 0 0.1 0.2 0 .3 0.4 0.5 0.6 Z c /y % r e d u c t i o n , (d s e (d s e) c) / d s e Ba=10cm, Bc=2.5cm Ba=10cm, Bc=10cm Ba=5cm, Bc=7.5cm Ba=2.5cm, Bc=5cm Ba=10cm, Bc=5cm Ba=5cm, Bc=2.5cm Ba=5cm, Bc=10cm Ba=2.5cm, Bc=7.5cm Ba=10cm, Bc=7.5cm Ba=5cm, Bc=5cm Ba=2.5cm, Bc=2.5cm Ba=2.5cm, Bc=10cm

Ettema, and Chiew (Chiew, 1992). The size of the col

lar with respect to the pier size in circular bridge piers is

generally expressed with the ratio W/D (where W is the

diameter of the collar and D is the diameter of the pier). In order to compare the pier data with the abutment data, dimensionless term B a /B c , was replaced with (2B c +B a)/B a or simply with B t /B a . If one assumes that W/D ratio for circular piers is equivalent to the

Table 1. Optimization of collar shape Parameters of flow and abutment Q=50l/s, L a =25cm, B a =10cm, B c =10cm, Z c =0 Plan views of collar shapes (Flow direction) full (a) (b) (c) (d) Maximum scour depth, d se , (cm) 18.3 18.3 18.3 19.9 23.2

value of B t /B a , the trend lines of constant W/D and

B t /B a are in agreement. From an extrapolation to be

made in Figure 4 it can be concluded that if B t /B a > 3,

reduction of maximum scour depth is higher than 45%

(B a = 10 cm).

Table 1 summarizes the experiments, which were

conducted to investigate the most economical shape

of collars to be used on abutments. Since the max

imum scour reduction was observed when the col

lar was placed at sand bed level, the experiments

related with full or partial collar forms were conducted

only for Z c /y= 0. For this reason the abutment of

L a = 25 cm and B a = 10 cm was selected since it gave

the maximum reduction in the scour depth.

In addition to full-collar experiments, those partial collars given inTable1 were tested under the same flow conditions, at bed level Z c = 0. Results of the exper iments showed that partial-collars of shapes (a) and (b) cause a maximum erosion depth of d se = 18.3 cm as the full-collar, whereas collar shapes (c) and (d) result in higher scour depths of 19.9 cm and 23.2 cm, respectively.

Therefore, the partial-collar shape (b) can be con sidered the optimum form from an economical point of view.

7 CONCLUSIONS

A collar prevents the sediment particles from erosion by downflow. Efficacy of a collar plate to prevent scour is a function of its size and its vertical location on the abutment.As the size of collar plate increases the scour depth decreases.

Collar plates of sizes B c = 0.25B a , B c = 0.5B a , B c = 0.75B a , and B c =B a , for an abutment width of B a = 0.10 m reduce maximum scour depth about by 10%, 17%, 30% and 45%, respectively, at the bed level of unprotected abutment.

The reduction in the scour depth of the abutment of B a = 0.10 m is increased from 20% to 45% by changing the location of the collar on the abutment from 0.5y to bed level. The effect of the collar on the scour depth around the pier and abutment is similar for clear-water conditions

and uniform sediment sizes. Instead of full-collars, (b) type of partial collars given in Table 1 can be used to provide maximum reduction in scour depth from economical point of view . Numerical and experimental investigation of local scour downstream of a sill

C. Adduce, G. Sciortino & M. Morganti

Dipartimento di Scienze dell'Ingegneria Civile, Università degli Studi di Roma "RomaTRE", Roma

ABSTRACT: This paper presents the results of a laboratory and a numerical study investigating the local scour downstream of a sill followed by a rigid apron. Nine experiments were run in clear water scour conditions, as varying the discharge. A mathematical model simulating the local scour downstream of the sill and using both the experimental velocity fields and the physical and mechanical properties of the sand was developed. The mathematical structure of the model consisted of a second order partial differential parabolic equation whose unknown is the shape of the mobile bed. The numerical integration of this nonlinear equation, with suitable boundary conditions, indicated agreement with the measured scour profiles at the equilibrium condition. Upon comparing the experimental and the numerical data, a similar temporal evolution of the maximum scour depth was observed.

1 INTRODUCTION

Local scour downstream of hydraulic structures is a relevant problem, given its significant practical value. Scour can endanger the stability of structures and cause the risk of failure, if the foundations are not designed taking into account the maximum scour depth.

The study of the local scour process is a complex problem, given the numerous variables related to both the heterogeneity of the eroded soil and the turbulent flow, producing the erosive. Many studies investigated this problem, trying to give a better understanding of this complex phenomena.

Local scour due to a two-dimensional wall jet was investigated by Farhoudi & Smith (1985), who stud ied the geometrical similarities of the scour profiles in time. Kurniawan et al. (2001) showed the flow pattern of an eroding jet, caused by the flow passing under a gate. Chatterjee et al. (1994) investigated scouring pro cesses downstream a submerged horizontal jet, giving empirical relations for the time to reach the equilibrium stage, location of maximum scour depth and peak of the dune. Ghafar et al. (1995) and Habib et al. (1994) studied local scour caused by hydraulic jumps formed over a rigid apron downstream of a sluice gate with LDA. Karim &Ali (2000) tested a CFD model in order to predict the flow field in local scour holes. Dey & Westrich (2003) and Mazurek et al. (2003) investigated local scour of a cohesive soil produced by submerged horizontal jets. Rajaratnam (1980) studied the erosion due to circular wall jets. Hogg et al. (1997) modelled the erosion caused by a planar turbulent jet, comparing numerical results with the laboratory experiments by Rajaratnam (1981). Mossa (1998) and Gaudio & Marion (2003)

investigated the temporal evolution of local scour profiles downstream of a grade control structure, Lenzi et al. (2002) studied the scouring process due to the presence of different bed sills. Sills are used to prevent excessive channel-bed degradation, but the erosive action of the flowing water causes downstream local scour, which can endanger the stability of the structure and cause the risk of a failure. The present paper uses both laboratory and numerical experiments, a local scour downstream of a sill followed by a rigid apron in clear water scour conditions. Nine laboratory experiments were run, varying the discharge in order to investigate the influence of this parameter on the development of the scour hole. A numerical model, simulating the temporal evolution of the scour profile downstream of the sill, was developed. The model, uses the equation of continuity for the local solid discharge, the experimental data about the spatial development of the eroding wall jet and the physical and mechanical properties of the sand. The analysis of the forces acting on the sand particles was performed taking into account the angle of repose of the sand, the instantaneous shape of the mobile bed and a model for the shear stress following an approach similar to that proposed by Hogg et al. (1997). The

mathematical model consisted of a second order par

tial differential parabolic equation whose unknown is

the shape of the mobile bed. Numerical integration of

this nonlinear equation, with suitable boundary con

ditions, namely absence of solid discharge both at the

inflow and at the end of the mobile bed agrees with

the measured scour profiles. A similar temporal evo

lution of the maximum scour depth was also observed

by comparing the experimental and numerical data.

The paper is organized as follows: the experimental

apparatus is described in section 2, the mathematical

model and its numerical integration are presented in

sections 3 and 4, respectively.The comparison between

the laboratory measured and numerical simulated both scoured profiles and time development of the maximum scour depth are discussed in section 5. The conclusions of the work are presented in section 6.

2 EXPERIMENTAL SET UP

The experiments were conducted at the hydraulic laboratory of “RomaTre” University, in a 17 m long, 1 m high and 0.8 m wide tilting flume of a rectangular cross section. Scouring tests were carried out in a 0.3 m high, 0.8 m wide and L= 3 m long sediment recess section, positioned 7 m downstream of the inlet of the flume and created raising artificially the flume bed. A uniformly graded sand of mean diameter d 50 = 0.72 mm and d 90 = 0.96 mm, a density ρ s = 2650 kg/m 3 , was used to fill the sediment recess section, in order to have a mobile bed. The same sand was glued both to the upstream and downstream fixed-bed sections, to produce a bed of homogeneous roughness. All tests were conducted under clear water scour conditions.

A sill of height D p = 0.15 m, followed by a L p = 0.5 m long rigid apron, was positioned upstream of the test section, as shown in figure 1. A control gate, positioned at the end of the flume, was used to vary the tailwater conditions.

The water level in the flume is measured using a

capacitive point gage of accuracy±0.10 mm, mounted on a carriage which moved along the flume. The water discharge at the inlet, controlled by an inlet valve, was measured with an electromagnetic flowmeter.

Before starting the experiments, the level of the mobile sand bed, positioned in the sediment trap, was set to the same height as the fixed bed. To avoid undesirable scour of the sediment bed, the con trol gate was completely closed and the flume was slowly filled with water pumped from the laboratory water reservoir. The water discharge was then slowly increased and set to the desired experimental value, to avoid any movement of the sand bed. The exper iments started when the tailwater depth was set to the desired experimental value, by opening the control gate. The water discharge was maintained constant for the entire duration of the experiment. The evolution of the scour hole was recorded using a CCD camera connected to a digital videocassette recorder. A detailed study of the temporal evolution of the scour hole was possible using image analysis techniques. At the end of an experiment, when the scouring process had reached an equilibrium state, velocity measurements were performed by an ultrasonic velocity profiler (Signal-Processing DOP2000). Measurements of the bed profile were made in 5 different longitudinal sections of the flume, using a point gage of accuracy ±0.10 mm. These 5 longitudinal profiles were called R, CR, CC, CL and L and are positioned at a distance from the right wall of the flume of 0 cm (measure on the right wall), 20 cm, 40 cm, 60 cm, 80 cm (measure on the left wall), respectively as shown in figure 2. The parameters water discharge (Q), water depth over the sill (h s), water depth downstream of the sill (h 0) and maximum scour depth (D smax), are

Figure 3. Sketch of the velocity profiles downstream of sill

for a rigid bottom (dashed lines).

properties of the sand.The analysis of the forces acting

on sand particles is performed taking into account the

angle of repose of the sand, the instantaneous shape

of the mobile bed and the shear stress obtained with

the hypothesis of a wall jet, since this was the case

observed experimentally. During the local scouring

process the wall jet like profile changes (Hoffmans

& Verheij 1997) (figure 3) and the shear stress related

to it has been a subject of recent investigations (Dey

& Westrich 2003). It is supposed that during the scour

process the bed shear stress varies with a Gaussian like

characteristics (Hogg et al. 1997).

The condition of transport, for an horizontal bottom,

can be written as:

where

p e is the weight of a grain, τ idr is the hydrodynamic bed

shear stress, τ cr = const · (γ s − γ) · d 50 (Shields 1936),

γ s = ρ s g, g being the acceleration of gravity, γ = ρg,

ρ being the water density and ϕ is the angle of repose

of a grain. In the following the value of const= 0.047.

If the bottom is not flat and it is described by an

equation z= z(x,t), the transport conditions have to

be modified, to account for the effect of the bottom

slope. In the following description n f and τ f are the

unit vectors, orthogonal and tangent to the bottom,

respectively, with n f · k< 0, where k is an upward unit
Figure 4. Definition sketch of the unit vectors τ f and n f
. vector parallel to the z axis, i is the unit vector
parallel to the x axis and τ f has the same direction of
the mean flow (figure 4). Hence z x is the space derivative
of z(x,t). In this case τ cr is given by Considering
equation (1) where τ cr is the critical stress for a flat
bottom. The stress acting on a grain is obtained by adding
the hydrodynamic bed shear stress and stress due to the
gravity, τ g as Or The condition of incipient motion is

or

Equation (10) reduces to equation (1) for z x → 0,

i.e. a horizontal bottom.

In order to model the volumetric solid discharge Q s

at the bottom, it is reasonable to suppose, from (10), a

functional relation as

If we suppose that the velocity of the solid particles is

locally parallel to the bottom, the continuity equation

for the solid material can be written as:

or

Hence by using (11) the following equation holds

where the prime ′ denotes the derivative with respect to

the variable ψ. The equation is non-linear and it has a

parabolic structure.

The hydrodynamic bed shear stress, at a distance δ

from the wall, caused by a turbulent 2D wall jet can

be modelled using (Schlichting 1979)

where α= 0.0283 is a numerical coefficient, U m is the

maximum velocity of the jet and ν is the kinematic vis

cosity of the fluid. In order to estimate the transport

action at the moving bottom, δ is chosen as the distance

at which the Nikuradse number is N i = δu ∗ /ν ~ = 10, as it

occurs in the viscous sublayer. Further we assume that

the friction velocity, u ∗ , is given by U m √ g/χ, valid for a turbulent rough and uniform flow and where χ= 2.49 √ g log (13.3Rf/d 50). In the previous relation d 50 is the mean sand diameter, R is the hydraulic radius and f is the shape factor of the flume cross section. Given the above assumptions it follows that δ/ν = N i /u ∗ =N i χ/(U m √ g), hence with the following maximum velocity decaying law (Hogg et al. 1997, Schlichting 1979) for m ~ = 0.5 is where C 1 is a constant, M= ∫ h 0 z u 2 dz, h 0 is the undisturbed water depth over the mobile bed, and u is the local velocity component along the longitudinal direction of the flume. Assuming h+ z= h 0 , as experimentally detected, where h is the instantaneous water depth, and using the approximation M ~ = q 2 /(h 0 − z), where q is the discharge for unit width, equation (16) where β= (αC 2 1) becomes This equation reasonably approximate the bed shear stress at a certain distance from the initial profile of the jet (for x= 0 it is singular) for the case of a fixed bottom. During the local scouring process the wall-jet like profile changes and the shear stress related to it has been object of recent investigations (Dey & Westrich 2003). Similarly to Hogg et al. (1997), we assume that the shear stress evolves like a law obtained multiplying equation (19) by a Gaussian decay G(x, z) (Hogg et al. 1997). It follows: In conclusion the Meyer-Peter and Muller transport formula is used for the solid transport,

using as independent variable ψ (instead of τ − τ cr for a flat bed), given by

including the no transport condition η(ψ), which is

defined by the Heaviside function

The potential law expressed by (21) is a continu

ous function together with its derivatives, because the

exponent (3/2)> 1.

4 NUMERICAL INTEGRATION OF THE MODEL

Numerical integration of the mathematical model

was performed adopting a Mac-Cormack-like scheme,

applied to the conservative form of equation (14),

constituted by equation (13). Two difference opera

tors, denoted respectively by B and F, backward and

forward, were defined as

where

x=L/M is the spatial step of integration, M is the

number of interval of discretization and ∆t is the

temporal step of integration. The following predictor

corrector numerical scheme is defined according to

the following integration scheme

where C and P denote the corrector and predictor step,

respectively.

This algorithm is completely defined assigning suit

able boundary conditions at x= 0 and x=L. These

boundary conditions are the clear water scour condi

tion at the inlet of the mobile bed and the absence of

solid transport at the end of it. Using equation (10) the condition of absence of solid transport at the end of the mobile bed can be written as where τ eff = τ cr −τ g and λ is a parameter of the model, whose value has to be suitably chosen. The condition of clear water scour at the inlet of the mobile bed can be discretized as here z n+1 1 is a known value, because it is calculated in an internal grid point, so that (30) is an equation in which the only unknown is z n+1 0 , which can be numerically solved for the assigned λ 0 values. The condition of absence of solid transport at the end of the mobile bed can be discretized as Equation (31) is numerically solved as equation (30), to find the unknown z n+1 M . 5 RESULTS AND DISCUSSION In figures 5 and 6 the laboratory measured scour profiles in 5 different longitudinal sections are presented, Figure 5. Scour profiles measured in different longitudinal sections for test 6. Figure 6. Scour profiles measured in different longitudinal sections for test 9.

Figure 7a-f. Numerical (line) and laboratory measured

(dots) scour profile for test 4, test 5, test 6, test 7, test 8

and test 9, respectively.

for tests 6 and 9 respectively. All the longitudinal pro

file measurements are made at the equilibrium scour

condition.

Following the reference system of figure 2, the five

longitudinal profiles are called R, CR, CC, CL, L,

corresponding to distances from the right wall of the

flume, along the y axis, of 0 cm, 20 cm, 40 cm, 60 cm Figure 8. Time evolution of the dimensionless numerical (line) and laboratory measured (dots) maximum scour depths for test 4. and 80 cm (left wall) respectively. The eroded bed is always symmetrical respect to the center line of the flume (figures 5 and 6), while it is also quasi-2D for large discharges (figure 6). In figures 7a-f the comparison between the measured laboratory bed profiles (dots) and the numerical profiles (lines) is presented. All the bed profile measurements refers to the centre of the flume at the equilibrium scour condition. Six different tests are

simulated: test 4 (figure 7a), test 5 (figure 7b), test 6 (figure 7c), test 7 (figure 7d), test 8 (figure 7e), test 9 (figure 7f). A good agreement between the predicted scour hole and the measured profiles for all the simulated tests. It is to be noted that the mathematical model, as a consequence of the boundary conditions, predicts at any instant a bed profile in which the volume of the scoured bed is strictly equal to the volume of the dune. When the model simulates the dune profile downstream of the scour hole some differences arise. For large discharges (tests 7–9) the dune profiles predicted by the model are similar to the measured, while when the discharges are smaller (tests 4–6), the dunes predicted by the model are always longer than those measured. This behaviour can be explained both by the characteristics of the model described above and because the bottom profile are observed to be quasi 2D when the discharges are large (tests 7–9), while it is symmetrical respect to the center line of the flume but no more quasi 2D for smaller discharges (tests 4–6). Bed profiles measurements in five different longitudinal sections of the flume were made, to study these different behaviours. All the tests performed show that the scour holes are always quasi 2D, while the dunes could be quasi 2D or symmetrical respect to the flume centreline, depending on the discharge value. As the discharge increases, the scour profile becomes more and more 2D. The maximum scour depth and lengths increase with increasing discharges (see figures 7a–b). For smaller discharges a small dune, with a sharp dune

Figure 9. Time evolution of the dimensionless numerical

(line) and laboratory measured (dots) maximum scour depths

for test 8.

crest, follows the scoured hole. Increasing the dis

charge the dune crest becomes flatter and longer. For

very large discharges some small dunes are observed

forming on the dune top.

In figures 8 and 9 the comparison of the tempo

ral evolution of the experimental (squares) maximum

scour depth and the numerical is presented. Both the

experimental and numerical instantaneous maximum scour depth (Ds) are divided by the maximum scour depth at the end of the run (Dsmax).

The numerical model agrees with the measured time development of the maximum scoured depth. Figure 8 and 9 refer to runs 4 and 8 respectively.

6 CONCLUSIONS

Laboratory and numerical model were presented to study local scour downstream of a sill, followed by a rigid apron in clear water scour conditions. A one-dimensional numerical model, simulating the evo lution of the scour hole was developed. Agreement between the measured scour profiles at the equilibrium state and the predictions is observed, together with the temporal evolution of the maximum scour depth. From the bed profiles measured in five different longitudinal sections of the flume, it is possible to observe that the larger the discharge is, the more 2D the scour profile is, the better the performances of the numerical model are. A possible future development of this study is the improvement of the numerical model, starting from experimental measurements of the shear stress inside the scour hole and coupling the continuity equation of solid discharge with the equation of continuity and momentum.

ABSTRACT: The present study investigates local scour downstream of a sill followed by a rigid apron, due

to a wall jet and a surface jet, related to the development over the apron of a hydraulic jump and an undular

hydraulic jump, respectively. Eight laboratory experiments were run, for variable discharge and downstream

water depth. A transition jump, which changes intermittently between a hydraulic jump and an undular hydraulic

jump, was observed. The different characteristics of the scouring process due to different kinds of jumps are

presented, together with the velocity fields inside the scour hole, due to both the surface jet and the wall jet.

A stability analysis of the undular hydraulic jumps shows their intermittent behaviour. Agreement between the

mathematical model and the laboratory results was found.

1 INTRODUCTION

Sills are used to prevent excessive channel-bed degra

dation, but the erosive action of the flowing water

causes downstream local scour endangering the sta

bility of the structure itself and causing the risk of

failure. Mossa (1998) and Gaudio & Marion (2003)

investigated the temporal evolution of local scour downstream of a grade control structure, whereas Lenzi et al. (2002) studied the scouring process due to the presence of different bed sills.

The water flowing over a sill creates different kinds of jet, related to different hydraulic conditions, such as a wall jet, if a hydraulic jump forms downstream of the sill, or a surface jet for an undular hydraulic jump. Recent investigations considered local scour down stream of jets created by water flowing downstream of different hydraulic structures (sills, gates, spillways). Farhoudi & Smith (1985) investigated local scour due to a two-dimensional wall jet, along with geometrical similarities of the scour profiles in time. Kurniawan et al. (2001) showed the flow pattern of an eroding jet, caused by the flow passing under a gate. Chat terjee et al. (1994) investigated the scouring process downstream of a submerged horizontal jet, with empir ical relations for the time to reach the equilibrium state, the location of maximum scour depth and the peak of the dune. Mossa et al. (1995) and Habib et al. (1994) studied a local scour caused by hydraulic jumps formed over a rigid apron downstream of a sluice gate, making velocity measurements with LDA. Dey & Westrich (2003) and Mazurek et al. (2003) investigated local scour of a cohesive soil produced by submerged

horizontal jets. Many of these studies deal with wall jets or hydraulic jumps created downstream of hydraulic structure; for undular hydraulic jump, the local scour evolution can be very different, related to the development of a different kind of velocity field. An undular hydraulic jump develops in open channel flow when the upstream Froude number is 1 < Fr u < 1.7 (Chow 1959). Chanson & Montes (1995) investigated experimentally the undular hydraulic jump, indicating both 5 different types and the formation of lateral shock waves for Fr u > 1.2. Montes & Chanson (1998) measured the velocity field in an undular hydraulic jump, showing its tridimensionality and developed a mathematical model in order to simulate the velocity, pressure and energy distribution in the jump. Ohtsu et al. (1997, 2001) found that the formation of the jump depended not only on the inflow Froude number but also on the boundarylayer development. They showed photographs of the free water surface related to different types of undular hydraulic jumps. Bukreev (2001) studied undular hydraulic jumps in open channel flow over a sill and showed a transition condition between the free surface jet (undular hydraulic jump) and the submerged jet (hydraulic jump). Other recent investigations focused on the determination of the analytical free surface profile in presence of a steady undular hydraulic jump (Grillhofer & Schneider 2003, Steinruck et al. 2003). All these numerical and laboratory studies investigated the undular hydraulic jump, over a rigid flat bottom.

The present study investigates with laboratory

experiments local scour due to both submerged and

surface jets, i.e. due to hydraulic jumps and undu

lar hydraulic jumps, respectively. Eight tests were run

changing both the water discharge and the downstream

water depth, in order to develop both undular hydraulic

jumps and hydraulic jumps over the apron.A transition

jump, which intermittently changes between an undu

lar hydraulic jump and a hydraulic jump, was observed.

The velocity fields, measured in the scour hole with an

ultrasonic velocity profiler, both in case of an undular

hydraulic jump and a hydraulic jump, are presented.

A mathematical model, following Montes & Chanson (1998) approach accounting for the scour, was applied to study the stability of the undular hydraulic jump.

The paper is organized as follows: the experimental apparatus is described in section 2, the laboratory mea sured velocity profiles are presented in section 3, the stability analysis of the undular hydraulic jump with a mobile bed is described in section 4. The conclusions of the work are presented in section 5.

2 EXPERIMENTAL SET-UP

The laboratory experiments were conducted, at the hydraulic laboratory of “RomaTre” University, in a 17 m long, 1 m high and 0.8 m wide tilting flume of rectangular cross section. Scouring tests were car ried out in a 0.3 m high, 0.8 m wide and L= 3 m long sediment recess section, positioned 7 m down stream of the flume inlet and by raising artificially the flume bed. An uniformly graded sand characterized by d 50 = 0.72 mm, d 90 = 0.96 mm and a density p s = 2650 kg/m 3 , was used to have a mobile bed. The same sand was glued both to the upstream and downstream fixed-bed sections, to produce a bed of homogeneous roughness. All the tests were conducted in clear water scour conditions.

A sill of height D p = 0.15 m followed by a rigid apron of length L p = 0.5 m was positioned upstream of the test section, as shown in Figure 1. A control gate, positioned at the end of the flume, was used to change the downstream water depth.The water level in the flume was measured using a capacitive point gage of accuracy ±0.10 mm, mounted on a carriage which moves along the flume.The water discharge at the inlet was controlled by an inlet valve and measured by an electromagnetic flowmeter.

Before starting the experiments, the level of the mobile sand bed, positioned in the sediment trap, was set to the same height of the fixed bed. In order to avoid the undesirable scour of the sediment bed, the con trol gate was completely closed and the flume slowly filled with the water pumped from the laboratory water reservoir by an auxiliary pumping device. The water discharge was then slowly increased, starting from zero, and set to the desired experimental value, paying attention to avoid any movement of the sand bed. The experiment started when the downstream water depth was set to the desired experimental value by opening the control gate. The water discharge was maintained constant for the entire duration of the experiment. The evolution of the scour hole was recorded using a CCD camera connected to a digital video-cassette recorder. At the end of the experiment, when the scouring process was assumed to have reached an equilibrium state, velocity measurements are performed by an ultrasonic velocity profiler (Signal-Processing DOP2000). The UVP (Ultrasonic Velocity Profiler) is

Figure 1. Definition sketch for model tests.

constituted by a piezoelectric probe, which works both as emitter and receiver of a signal consisting of ultrasonic pulses travelling across the fluid and backscattered by the targets, i.e. small air bubbles or particles, moving with the flow. For a detailed description of the UVP technique, see Takeda (1995, 1999). The size of the measurement volume depends on the characteristics of the probe (emitting frequency and diameter) and increases far from the probe, due to the lateral spreading of the pressure wave. During the present experiments probes with an emitting frequency of 2 MHz and a diameter of 14 mm were used, for a divergence angle equal to 1.83 ∘ . The UVP allows a quasi-instantaneous measurement of the velocity in different volumes (gates), positioned along the axis of the probe. The distance between the center of these gates used for the experiments is 3.52 mm. The longitudinal size used for the sampling volume is 2.96 mm, while its lateral size depends on the distance from the transducer. Three probes with the same emitting frequency were used (Longo et al. 2001), for the measurement of the profiles of the horizontal and the vertical velocity components.Velocity profiles of both the horizontal and the vertical component are measured in different points along the centreline of the flume. The experimental parameters water discharge (Q), water depth over the sill (h s), water depth downstream of the sill (h d) and maximum scour depth (z max), are presented in Table 1. 3 EXPERIMENTAL RESULTS Eight laboratory experiments were run to investigate local scour due to water jets. The discharge and the

downstream water depth were varied. Three different kinds of water jets were observed: Wall jet, Surface jet and Transition jet, related to the development of a hydraulic jump, an undular hydraulic jump and a tran sition jump respectively. The transition jet is defined as a jet which changes intermittently between a surface jet and a wall jet, related to the intermittently change of an undular hydraulic jump into a hydraulic jump, respectively. Both the velocity field and the scour hole development related to the different kinds of jet are different.

3.1 Qualitative results

A different behaviour, both concerning the develop ment of the scour hole and the measured velocity field, is observed for the different kinds of hydraulic jump. When a hydraulic jump forms over the rigid apron downstream of the sill, a wall jet with a reverse flow close to the water surface is observed (tests H1 and H2). The scour process develops very fast during the first minutes of the run and becomes slower and slower with time advance. The sand is moved downstream by the wall jet and a dune is formed. The scour hole increases both in depth and length together with the dune, which continues its downstream movement and increases in length and height. At the end of the test

the scour hole and the dune were quasi-2D.

When an undular hydraulic jump forms over the rigid apron downstream of the sill, a surface jet with a reverse flow close to the bottom was observed (tests U1, U2 and U3). The sand, positioned close to the rigid apron, was moved upstream over the apron, creating a small dune, which moved towards the sill. The sand which was far from the apron slowly moved down stream by the flow.At the end of the test it was possible to observe the presence of two dunes: a first which covers all the apron and part of the sill and a sec ond positioned downstream over the mobile bed. The dune over the apron is not 2D, together with the scour hole and the dune downstream, which are symmetrical respect to an axis passing through the centreline of the flume. In tests T1, T2 and T3 a transition jump was observed: a jump which changes in time between a hydraulic jump and an undular hydraulic jump. In these tests the velocity field continues to change in time showing both the presence of a wall jet and a surface jet. When a surface jet was present the sand is partly moved upstream over the apron and partly moved downstream over the mobile bed, as for tests U1, U2 and U3.The sand moving upstream formed a dune over the rigid apron, which increased height and length. Suddenly the undular hydraulic jump developed into a hydraulic jump, with a wall jet velocity distribution, pushing fast the sand present over the apron downstream. The sand created a new dune, which moves over the eroded bed and partly fills the scour hole. The undular hydraulic jump and the hydraulic jump can be present over the apron simultaneously in different horizontal sections of the flume. So it is possible to observe that the sand over the apron at the same time, but in different horizontal sections, is partly moved downstream and partly upstream. The scour hole at the end of the test is 3D, because of the

presence of a intermittently and 3D flow field. 3.2 Measured velocity fields The velocity field was measured by an ultrasonic velocity profiler (Signal-Processing DOP2000); the bed and the free surface profiles were both measured along the centreline of the flume. They are shown in Figures 2 and 3 for tests H1 and U1, respectively. The horizontal and vertical distances were made dimensionless by h s , the water depth over the sill. Due to the instrument configuration, data can not be obtained in regions closer to 5 cm from the water surface. Figure 2 shows the velocity field inside the scour hole for test H1. Ten velocity profiles, positioned at x=-5, 5, 15, 25, 35, 45, 55, 65, 75 and 85 cm, respectively, following the reference system shown in Figure 1, were measured. The first profile at x=-5 cm shows a wall jet like vertical velocity distribution, or a hydraulic jump, over the apron downstream of the sill. It is possible to observe a reverse flow at the top of the first measured profile. The wall jet like vertical velocity distribution develops into free-jet like pattern downstream of the apron, with a mobile bed, as shown by the velocity profiles positioned at x= 5 cm and x= 15 cm. The top reverse flow is not present in these velocity profiles, for x= 5 cm the velocity assumes very small values both at the top and at the bottom of the vertical profile. For x= 15 cm a small positive horizontal component is present at the top of the velocity profile, while at the bottom the velocity is close to zero. A small negative horizontal velocity component, close to the bottom, is present for x= 25 cm, x= 35 cm and x= 45 cm. From x= 55 cm to x= 85 cm, a positive horizontal velocity component both close to the

Figure 2. Velocity field for test H1.

Figure 3. Velocity field for test U1.

top and to the bottom of these velocity profiles was

observed.

Figure 3 shows the velocity field inside the scour

hole of test U1. Fifteen velocity profiles, positioned at

x=-5, 5, 15, 25, 35, 45, 55, 65, 75, 85, 95, 105, 115,

125 and 135 cm, respectively, were measured follow

ing the reference system shown in Figure 1. In this

test an undular hydraulic jump developed over the rigid apron, so a surface jet is present. No reverse flow close the water surface was observed. All the measured profiles show a large positive horizontal velocity component at the top of the flow. A small reverse flow close to the bottom can be observed at x= 5 cm, x= 15 cm, x= 25 cm and x= 35 cm. The horizontal velocity component close to the bottom downstream of x= 45 cm is first small, then increases in the downstream direction.

4 MATHEMATICAL SIMULATION

4.1 Stability analysis of undular hydraulic jump on a mobile bed

The stability analysis consists of the unsteady motion equations considered in the streamline centred s-n Figure 4. Definition sketch for the mathematical model. system of reference (Rouse 1938). As a fundamental hypothesis, we assume that the modulus of the velocity vector does not depend on time, while the direction of the velocity does. Such a hypothesis makes sense for steady flow, in which the unsteadiness is due to perturbations of an order of magnitude smaller than that typical for the flow characteristics (discharge, downstream water depth). The quantities required for the description of the phenomenon are defined in Figure 4. Let V be the velocity vector, defined as V= V (s, n) e s (s, t), being V the modulus, e s the unit vector tangent to the instantaneous streamline, s the coordinate on it and n the coordinate along the direction normal to the instantaneous streamline at s= 0. The equations of motion are: where the term ∂e s /∂t accounts for the dependence of the direction of V on the time and R is the radius of curvature of the instantaneous streamline. The direction of the term ∂e s /∂t is parallel to e n : that is why it appears in (2). It is important to note that terms accounting for tangential stress have been neglected. Such a hypothesis is to be considered reasonable only far from boundary layers, i.e. far from the bed and

the free surface. As a consequence, equation (1) gives the Bernoulli equation Inserting equation (3) in (2), the following equation for the determination of V is obtained which is the same obtained by Montes & Chanson (1998), but the term accounting for the unsteadiness of

the perturbations imposed to the base flow. Of course,

for such equation is useful, it is necessary to express all

the unknown quantities (e.g. R, ∂e s /∂t, e s) appearing in

the coefficients. Adopting the geometrical hypothesis

of Montes & Chanson (1998), it is possible to express

such quantities in terms of the bottom and free surface

profiles and their derivatives with respect to x, t.

Here we assume that the bottom profile does not

depend on time, while the free surface profile does.

Such an assumption makes sense, because it is evident

from the experiments that, in condition of quasi

equilibrium scour, the order of magnitude of the time

scale of the evolution of the free surface is much

smaller of the corresponding time scale of the bottom

profile.

If we assume that ∂V/∂n=-cos(θ)∂V/∂z, θ being

the angle formed by the tangent to the instantaneous

streamline with the horizontal axis, and if we introduce

the non dimensional variable η, defined as:

equation (4) becomes, written in a compact way

in which the coefficients A, B, C are defined as

where:

The influence of the unsteadiness due to the pertur

bations is considered by coefficient C, while A and B

account for the curvature effects both concerned with

the free surface and the bed.

The solution of equation (6) is the sum of the

homogeneous solution and of the particular solution, which can be expressed as a power series whose coefficients are defined by means of a recurrence relation obtained substituting the particular solution in equation (6) and equating terms with the same power of η. The constant c om is determined by imposing that (V p + V om) η=1 =V fs , V fs being the velocity on the free-surface, and then expressingV fs through the mean velocity U, defined as: After some calculations, it is possible to obtain the analytical expression of the horizontal and vertical velocity components as well as the pressure as Expressions (14), (15) and (16) depend on z b (x), h(x,t), U(x,t), H(x,t)= z b (x)+h(x,t) as well as on an undetermined coefficient a 0 . An analytical determination of this latter is possible, but is rather complicated. In this work such a coefficient is left undetermined and calibrated on the experimental results. Moreover, it is assumed that z b (x) is given by interpolations of experimental measurements. At last evolution equations for h(x,t),U(x,t) can be obtained by considering integral forms of the continuity and momentum equation (Montes & Chanson 1998)

where λ, and# are, respectively, the friction factor and

the hydraulic radius, defined in the usual way for open

channel flow with a mobile bed (Marchi & Rubatta

1980, Garde & Ranga Raju 1977). Equations (17) and

(18) are the classic Saint Venant equations for free

surface flows, in which curvature effects connected

to the free surface and bottom profiles have been

accounted. For the last step is to assume the unknown

functions h(x,t) and U(x,t) as the sum of a base flow and

an unsteady perturbation with a known dependency on time:

It is supposed that the perturbations are small quantities with respect to the quantities of the base flow, at least at the early stage. Then, substituting expressions (19) and (20) in equations (17) and (18), it is possible to discard nonlinear terms with respect to the perturbations. Imposing that the expressions (19) and (20) satisfy equations (17) and (18), two different differential systems are obtained. The first can be used to determine the base solution h 0 (x), U 0 (x), while the second, known the base solution, is useful to determine the evolution of the perturbations flow, characterised by h 1 (x), U 1 (x).The parameter γ , which can be considered as an eigenvalue of the linear and homogeneous perturbation equations, gives information on the stability of the base solution: if the real part of γ is positive, perturbations imposed on the base solution will tend to destroy the base solution and then this latter is considered unstable. On the contrary, if the real part of γ is negative, perturbations imposed on the base solution will tend to decrease with time and the base solution is considered stable. Of course, such conclusions are considered valid in the framework of a linear stability analysis: i.e. they are valid in the early stage

of the perturbations.

4.2 Computational considerations and analysis

The differential equations for the determination of the base flow and the perturbations are omitted for the sake of simplicity. However it is important to observe that it is difficult to obtain the solution of the differential equations for the base flow h 0 (x), U 0 (x), due to their strongly nonlinear nature. On the other hand, the aim of this work is to investigate the stability of a given exper imental condition, which represents the base flow: so the base flow is assumed known, interpolating experi mental results. More precisely, the free surface profile H 0 (x) = h 0 (x)+z b (x) and the bottom profile z b (x) are measured along the x direction, in correspondence of the centreline of the experimental channel, while the mean velocity U 0 (x) is obtained as Q being the discharge, considered constant with respect to time. Interpolating expressions for H 0 (x), z b (x) adopted in this work are the following where l 0 and η are respectively the measured wavelength and amplitude of the free surface undulations, defined respectively as the distance between the first two crests of the free surface and half the distance between first crest and first throat. L s and z max are the measured wavelength and the maximum scour depth. z b0 is the scour depth in correspondence of the end of the apron, i.e. at x= 0. The measured wavelength of the bottom is defined as the wavelength with which the sine expressions (23) and (24) best fit the scour profile. For the sake of simplicity, no decaying phenomena were considered for the free surface undulations. Six experimental configuration were considered, whose characteristics are shown in Table 2. Where Fr d is the Froude number, defined with the characteristics of the flow downstream, far from the undular hydraulic jump, where the motion has become uniform again. The stability of the experimental configurations can be investigated by solving the linear differential equations for the perturbation flow h 1 (x), U 1 (x). Such Table 2. Experimental configurations. Run Fr d l 0 [m] η[m] L s [m] Stability T1 0.15 0.12 0.0045 1.5 Unstable T2 0.17

0.15 0.003 2.4 Unstable T3 0.18 0.18 0.002 3.0 Unstable U1
0.14 0.35 0.003 3.0 Stable U2 0.15 0.25 0.004 3.8 Stable U3
0.16 0.35 0.0035 4.0 Stable

differential equations, though linear, have coefficients depending on x and an approximate procedure is adopted in order to solve them. Such a procedure consists in assuming a Fourier series development of the perturbation flow, in which the fundamental wavelength of the perturbation flow coincides with the wavelength of the free surface undulations, and in substituting it in the perturbation equations. Imposing a suitable solvability condition, an algebraic equation, whose order depends on the number of modes adopted in the Fourier expansion, is obtained for γ . The real part of this latter gives indications on the stability of the base flow.

Results are shown in the stability diagrams presented in Figure 5 and Figure 6, in which the horizontal axis represents the wavelengths of the undular hydraulic jump, the vertical axis the Froude number, defined with the downstream characteristics of the flow. In Figure 5 the lines (black, grey and dashed lines refer to the experimental conditions in Table 1 by T1, T2 and T3 respectively) separate the unstable from the stable region: the stability region is on the right of the lines. The three unstable experimental configu

rations are represented in the diagram by a square, a

circle and a triangle and are referred to T1, T2 and T3

respectively.

In Figure 6 the lines (black, grey and dashed lines,

which refer to the experimental conditions indicated

Figure 5. Stability diagrams for tests T1, T2, T3.

Figure 6. Stability diagrams for tests U1, U2, U3. in Table 1 by U1, U2 and U3 respectively) separate the unstable from the stable region: the stability region is on the right of the lines. The three unstable experimental configurations are represented in the diagram by a square, a circle and a triangle and are referred to U1, U2 and U3 respectively. The horizontal lines limit the area over which it is physically possible to have a hydraulic jump for the experimental conditions considered: i.e. they are obtained imposing that the upstream Froude number is less than for the considered discharges. The stability diagram is divided into three regions: the stable region on the right, the unstable region on the left and the no hydraulic jump region in the lower part. As a general remark, we observe that undular hydraulic jumps of small wavelength tend to become unstable and then evolve to different forms of hydraulic jumps. At last we observe that the theoretical predictions confirm the experimental observations. CONCLUSIONS The qualitative description of local scour development, due to three different kinds of jets, a wall jet (hydraulic jump), a surface jet (undular hydraulic jump) and a transition jet (transition between hydraulic and undular hydraulic jump), is presented. The scour hole is observed to be quasi 2D if a hydraulic jump develops over the apron. If the local scour is caused by an undular hydraulic jump or a transition jump, it is 3D. The profiles of the vertical and horizontal velocity component, measured in the scour hole, by an ultrasonic velocity profiler, both in case of a hydraulic jump and an undular hydraulic jump are presented. The stability analysis of the undular hydraulic jump, performed starting from the unsteady momentum equations, written in the s, n coordinate system, permits to characterise the time evolution of the flow, assumed as the superposition of a base and a perturbation flow. In particular, the stability of the flow is expressed by a coefficient γ which can be considered as the eigenvalue of the perturbation equations. His real part gives information of the stability of the considered

experimental conditions. Comparisons between analytical and experimental results are satisfactory. ABSTRACT: An experimental study was used to understand flow structure at water intake.To find the optimum

angle at water intake, the separation zone was compared for five deflection angles from 45 to 90-degrees. The

experimental tests were carried out in an experimental flume with rectangular cross section. The velocity of the

flow inside each intake was measured in 727 points of fluid in a fine grid. The points of velocity measurements

include 243 points at three horizontal layers and 486 points in 6 cross sections. Two components of flow velocity

were measured using an electromagnetic disk type velocity

meter (PE-30 Type, DELFT). Five types of water intake with 45, 56, 69, 79 and 90-degree were installed at one side of a straight canal. To compare the separation in five types of water intakes, the size of the separation zones inside the lateral was measured at similar flow condition. The water intake with minimum separation was defined as the optimum angle for installation of water intake. It was found that the optimum angle is 55-degree at water intake.

1 INTRODUCTION

The streamlines of the flow at a straight open channel are approximately parallel to the flow direction. When a water intake with an angle is installed at one side of the canal, the streamlines of the flow deflect toward the intake. At this flow condition, a separation zone is produced at one side in the lateral canal. The flow structure at open-channel junction was studied by many researchers; for example, Taylor (1944), Law and Reynolds (1966), Hager (1984), Hsu et al (1998) and Grace and Priest (1958).Taylor (1944) considered the flow depth at upstream and downstream of a canal junction as a parameter of flow condition and produced a theoretical development. Most previous studies were carried out in junction where flow in two channels combines together and flow separation occurs in the main channel. But, at water intake flow diverts from the main channel and flow separation

occurs in the lateral. In a study by Neary and Odgaard (1993), the vertical secondary current at water intake with 90-degree diversion was investigated. To study the secondary current, they considered the velocity distribution and separation zone at the bed and water surface of 90-degree diversion. However, little study was carried out to understand the flow structure inside the water intakes with angles different from the 90degree. In this study, to find the optimum angle, a comprehensive experimental test was carried out in the laboratory and separation size was measured at water intake with five different angles. 2 EXPERIMENTAL SETUP The experiments were carried out in a non recirculating experimental flume with a lateral. The experimental model was built in hydraulic laboratory of Shiraz University, Shiraz, Iran. Five water intakes were installed at one side of the main channel. The water intakes were installed with 45, 57, 67, 89 and 90-degree to the main channel. The main channel consists of a rectangular cross section with base width of 0.50 m, height 0.40 m and 15.80 m length. The longitudinal slope of the flume was set to 0.003. In order to visualize the flow structure at water intake, one side wall of the flume at the front of water intake was built of glass. The first water intakes were installed at a distance of 6.40 m from the inlet. The lateral diversion channel consists of 0.25 m width, 0.40 m height and zero slope. The Flow separation at 45 to 90-degree water intakes 2 main canal and the lateral were built of smooth concrete. The flow of the intakes passed downstream through a 7.63 m lateral canal. The flow rate at the end of main and lateral canals was measured using two pre calibrated right-angle V-notches. To make streamlines parallel to the main canal direction, a series of flow straightener were used at the inlet of the main chan nel. A schematic diagram of the experimental model is shown in figure 1.

The experimental tests were performed at flow rate equal to 16 liter per second. The depth of flow for all tests was a constant depth (16 cm) using downstream gates. The velocities of the flow in two components were measured using an electromagnetic velocity meter (PE-30 Model, Ellipsoid type, DELFT). The velocity measurement was done at three layers in depth of flow at water intakes. The velocity in the horizontal layers was measured at a regular grid. The grid size for the velocity measurement in horizontal layers was 25 mm in width and 50 mm in the length of the intake. To find the size of separation zone in depth, the velocity of the flow was measured at three depths as: 3 cm from the bed, 6 cm from the bed and 12 cm from the bed. Additionally, a fine measurement was carried out at cross sections of 10, 20, 30, 40, 50 and 60 cm from the inlet of water intakes.The depth increment for velocity measurement in vertical was selected in 2 mm incre ment. The vertical measurement at cross sections was selected at a grid size of 2 mm by 2.5 mm. Due to the size of electromagnetic velocity meter probe, it was

measure the velocity very close to the bed and water surface. The experiments were performed at different flow conditions and they are listed in table 1. 3 RESULTS AND DISCUSSION To find a relationship between deflection angle of water intake and separation size, the velocity of the flow at two components were measured.The velocities were measured in time for duration of 40 seconds with sampling rate of 0.1 Hz. Therefore, a total number of 400 velocity data at each point of flow was recorded in the computer. The time-averaged velocity in the flow direction (U) and in transverse direction (V), at each point were calculated using the following equations: where, u i and v i are instantaneous velocities in the flow direction and transverse direction, respectively, and n is the number of sampling. Figures 2 to 15 show the velocity vector and particle trace plots at the depths of 3, 6 and 12 cm from the bed. They are plotted for five different angles. The most feature of the plots is the observation of the separation zone along the water intake. The separation zones are very clear at the upstream or downstream portion of the water intake. The width and length of the separation zone were derived from the plots. The particle trace plots show the location of the separation zone and deflected streamlines toward the intake. It can be seen that in the separation zone the streamlines are deflected from the wall at upstream of water intake. The size of the separation zone is small near the bed, while it is large near the surface. Neary and Odgaard (1993) pointed out that this occurs because of high velocity near the water surface. Due to the difference in velocity particularly where streamlines are very close, a momentum transfer occurs between the streamlines and produces a series of eddies. The eddies will move downstream of the intake. The eddies dissipate energy along the intake.

Figure 6b. Streamlines for 90-degree water intake at 6 cm

from the bed.

The large separation size will cause higher momentum

transfer between streamlines and therefore large eddies

will form. At this condition a large amount of energy

will dissipate along the intake. This will cause less

flow rate inside the intake. To minimize the separation

zone, and producing less energy dissipation, design of

intake with minimum separation size is necessary and

it is the major focus of this study.

Figures 2 to 6 show that how the size of separation varies for different angle and at similar flow condition. Point A at figures 2a, 2b and 2c indicate upstream of the 45-degree water intake and point B in the same figures indicates downstream of the 45-degree water intake.Also the letters C, E, G and I indicate upstream, whereas, the letters D, F, H and J in figures 3 to 6, indi cate downstream of 56, 67, 79 and 90-degree at water intakes, respectively. At 90-degree water intake, the separation zone is mostly occurred at the upstream of water intake, while at 45-degree water intake it occurs at the downstream portion. The size of separation is very large at 90-degree angle and it grows to the half of the width of the water intake. Therefore, as the deflection angle decreases from 90 to 45 degrees, the 3 size of separation changes at upstream and down stream of water intake. At 79-degree water intake the size of separation decreases at upstream and a small separation starts to grow at downstream when com pares to 90-degree water intake. Again at the angle of 67-degree, the formation of separation occurred both at upstream and downstream of the intake. At intake with the angle 56-degree, there is minimum separation zone was produced at upstream and downstream portions. As previously mentioned, at intake with the angle of 45-degree, the separation zone is relatively large at downstream, while at the same time, the separation zone is small at upstream. It means that

Figure 6c. Streamlines for 90-degree water intake at 12 cm from the bed. Figure 6d. Velocity vectors for 90-degree water intake at 12 cm from the bed.

location of the separation zone moves from upstream to downstream when compared the separation zone in 90 and 45-degree intake. The width and the length of the separation at upstream and downstream were measured for the angles of 45, 56, 67, 89 and 90-degree and they are plotted separately for upstream and downstream locations. The length of the separation is plotted in figure 7 for upstream and downstream, while the width of the separation for upstream and downstream are plotted in figure 8. The intersection of the best-fit equations represents the optimum angle of the water intake. From the above figures, the minimum separation zone was found to occur at 55-degree water intake both at the upstream and downstream. Therefore, the optimum angle for the water intake was found to be 55-degree. A statistical analysis of the data is shown that there is a relation between the angle of water intake and the size of separation. The following relations were found

Study on structure-induced flow and turbulence considering

bed morphology

S. Giri, Y. Shimizu & B. Surajate

Hokkaido University, Japan

ABSTRACT: The study reported herein was conducted in a

meandering like laboratory flume in order to

determine near-bed flow and turbulent characteristics around river training structures with and without scour

hole/deposition. Observation was performed near a couple of spurs placed in different part of the bend simultane

ously. The purpose of this study is to evaluate near-bed three dimensional flow field, the turbulent stresses and the

turbulent kinetic energy distribution around spurs with rough rigid bed as well as with developed bed morphology

under similar flow condition. This study has revealed the distinctive characteristics of flow & turbulence quanti

tatively before and after the development of structure-induced bed morphology. Likewise, distinction in flow and

turbulence near spurs placed in different part of the bend simultaneously was also investigated. Furthermore, a

simple flow visualization technique was implemented to observe the generation and migration of vortices from

the tip of the structure. A preliminary attempt was made to simulate the flow and vorticity field in near-spur

region using 2D numerical model and validated with experiment on flow with spurs for rigid bed case as well.

1 INTRODUCTION

The prediction of structure-induced flow and morphol

ogy is of great significance from practical engineer

ing point of view. Taking this into consideration,

various physical and numerical studies (Shimizu &

Nishimoto, 1993) were performed in the past and still

being carried out. However, quantitative determina

tion of flow and turbulent characteristics considering

structure-induced bed evolution has not received due consideration. To our knowledge, very few have been done in this connection (Melville & Raudkivi, 1977; Graf & Istiarto, 2002). Of most the past studies were carried out on the flow pattern near spur for rigid & smooth bed. Some studies were conducted to ana lyze the flow around structure using theory of three dimensional turbulent boundary layers (Rajaratnam & Nwachukwu, 1983; Ferdous & Rajaratnam, 2000) as well as to evaluate the exchange process between spur region and transit flow (Uijttewaal, 2001; Chen & Ikeda, 1997). Study on structure-induced mean flow pattern throughout the bend reach was performed by authors (Giri et al, 2003) that was verified with a numerical model in which flow characteristics in shear layer region was simulated using subgrid scale model (Surajate & Shimizu, 2003; Uittenbogaard, 2001).

It is to be emphasized that the flow field near spur-like structures is completely three-dimensional.

It becomes more complicated while consider the bed morphology. Consequently, it is thought to be of importance to determine the turbulent characteristics, viz. turbulent stresses & energy distribution in the vicinity & nearby region before and after the development of scour-holes and deposition so as to assess the distinction in the flow and turbulence before and after the development of river bed morphology. On the other hand, it is necessary to assess, simultaneously, the flow and turbulence near spurs placed in different part of bend in order to quantify their interaction as well as allocation effect. This study has made a basic attempt to determine the three-dimensional

flow field and turbulence induced by spurs and bed morphology. The objective of this study is to achieve an initial insight into the flow and turbulent structure with and without considering bed morphology near spurs placed in different bends. Such kind of studies may be of use to understand the physical mechanism associated with structure-induced bed evolution and mixing process before and after the development of bed morphology assessing simultaneously the effect of change of the bend direction. A three-dimensional ADV was used to measure the instaneous flow field. A preliminary numerical study was performed using 2D CIP numerical technique. The case of rigid bed experiment on flow with spurs was used to validate this numerical model. Velocity distribution throughout the bend reach was reproduced numerically and

compared with experimental results. Similarly, vor

tices shedding from the tip of spurs were also simulated

using this model.

An attempt was made to visualize the migration of

small eddies generated from the tip of the spurs using

simple experimental technique.

2 EXPERIMENTAL SET UP

This experiment was carried out in a laboratory flume

of Applied Hydrology Laboratory of Hokkaido Uni

versity. The flume was 28 m long and 1 m wide with

a meandering reach of 7.7 m wave length having 3

consecutive bends of 40 ∘ , 80 ∘ & 40 ∘ arc angles respec

tively. Detail can be found in Giri et al. (2003). The

experimental condition has been adopted according to

the characteristics of Plane Rivers with mild slope and

sub-critical flow. Experiment was performed for clear

water condition. The channel bed was filled up with

uniform sand having median grain size of 1.2 mm. A

couple of non-submerged spurs were used (h= 15 cm)

with the length, namely 1/4 of channel width. Spur 1

& spur 2 were placed in 35 ∘ of arc angle in bend 1 and

60 ∘ of arc angle in bend 2 (Fig.1). In order to make the

Figure 2. Temporal development of scour-holes. Table 1. Test condition. Approach flow depth, h (cm) 10.5 Froude number, Fr 0.18 Flow Reynolds number, Re 19530 Average velocity, U 0 (cm/sec) 18.6 Sediment diameter, d 50 (mm) 1.20 Flow intensity, U t /U 0* 0.5 Shear velocity, U * (cm/sec) 1.14 near spur region rigid, the cement powder was used that enables the sand particles to be interlinked. A clear water experiment was conducted with 60 hrs of run when scour and deposition was seen to have attained quazi-equilibrium condition so as to perform study for the case with developed bed topography. The temporal development of scour-holes has been depicted in Figure 2. Quazi-equilibrium bed topography for this experimental case can be found in Giri & Shimizu (2004). Measurement was performed using a 3D Acoustic Doppler Velocimeter with the frequency of 25 Hz (25 samples/sec) for more than 1 min at each measurement points. Measurement was concentrated on near bed region (about 60% of average flow depth). More than 1500 data points were measured throughout the bend reach. More detail measurements were conducted around both spurs. Raw data were processed and filtered using spike removal algorithm developed by Wahl (2000, 2003). Data processing has included calculation of average velocities, turbulent intensities, Reynolds stresses in all three directions, and aggregated measures of data quality. It is to be noted that some data with low correlation & SNR were removed. See Table 1 for the test condition. Flow visualization was performed using highresolution digital video camera. The shadow of eddies was captured throwing the light from halogen lamp to the channel surface in the dark conducting experiment in the night. The migration of small eddies (their shadow) were visible quite clearly. 3

DATA ANALYSIS AND DISCUSSION Shear velocity was calculated using method described in Giri & Shimizu (2003). 3.1 Calculation of turbulent characteristics The turbulent characteristics (normal stresses, Reynolds stresses & turbulent kinetic energy) were computed using root-mean-square (RMS) of the turbulent velocity fluctuations as well as covariances for all three velocity combinations. The RMS of turbulence denotes the standard deviation of the samples taken by ADV and equal to the normal stress for respective velocity component, e.g. for downstream velocity component: where V ′ X – downstream velocity fluctuation; n – number of sample. Similarly, the transverse and vertical component of normal stresses can be expressed.

For the analysis of Reynolds stresses, the covari

ance is used that denotes the correlation between two

variables and can be expressed as:

V ′ x V ′ z and V ′ y V ′ z can be expressed in similar way.

The turbulent kinetic energy can be defined as:

3.2 Flow and turbulent analysis

The mean flow and turbulent analysis was performed

throughout the bend reach of channel for a hori

zontal layer at 40% of the depth from the channel

bed. This level is taken as the location where veloc

ity magnitude is equal to its depth-average value for

uniform flow (Graf, 1998). It was observed that in

this layer longitudinal and transverse velocity pro

files are not much varied for both cases. However, -0.5 0 0.5 1 1.5 2 0 0.2 0.4 0.6 0.8 1 -0.5 0 0.5 1 1.5 2 0 0.2 0.4 0.6 0.8 1

Figure 4. Typical examples of flow deflection and down

flow velocity distribution near spur. in shear layer region, the mixing length for the case with scour-deposition was found to be greater (Fig. 3) apparently due to the effect of deposition in shear layer region. Similarly, with the scour case the flow deflection is greater in upstream-stagnated region but lower in region away from the tip of spurs. The downflow in this layer is found to be significantly greater for scour-deposition case (Fig. 4). Variation of normal and Reynolds stresses as well as kinetic energy in longitudinal direction along the spurs tip in both bends has been depicted in Figure 5 and 6 respectively. It can be seen that normal stresses in all three direction, dominant component of Reynolds stress and turbulent kinetic energy amplify in the vicinity of spur. Turbulent level seems slightly higher near spur 1 region than near spur 2. Similarly, turbulent characteristics are found to be larger in this layer for rigid bed case. Spatial distribution of normalized turbulent intensities, Reynolds stresses and kinetic energy over vertical sections located in front of spurs, along spurs and behind them has been depicted in form of contour plots for 40% of width and about 50%–60% of depth (Fig. 7). Plots have been presented for both cases and bends (Figs 9–13). Some selected sections (5 cm in 0 2 4 0 50 100 150 0 2 4 0 50 100 150 0 2 4 0 50 100 150 V ' X V ' Z -1 1 3 5 0 50 100 150 U ∗ V ' X V ' X U ∗ V ' Y V ' Y U ∗ V ' Z V ' Z Spur1 region Spur2 region U 2 ∗ Figure 5. front of spurs, 5 cm behind spurs and along the spurs for both bends) with dominant components have only been illustrated within the scope of this paper.

The nature of normal & Reynolds stresses distribu tion in near spur region appears to be rather chaotic that was observed by Graf and Istiarto (2002) as well. As it is to be expected, the turbulent characteristics were seen to amplify in the vicinity, particularly in shear layer. In other word, normal and Reynolds stresses were found with high magnitudes behind the spur rather than in front of it. Furthermore, the turbulent stresses appear to be slightly higher near spur 1 region; however in second bend near spur 2 turbulent charac teristics were found to possess splash characteristics with chaotic behavior. This evidence indicates the complicated flow structure due to the bend and influ ence of spur placed in preceding bend that generates the small eddies (see 3.3) and in turn produces effect on flow pattern in successive bend. Nonetheless, the dis tinction in turbulent characteristics near spurs placed in two different bends is thought to be still not clear and

thus subject to further investigation. Turbulent charac

teristics in layers upper than scour-hole were found to

damp after the development of scour-hole.

The flow & turbulence inside the scour is seen to

be complicated with some splash behavior beneath the

spur. However they possess very local & splashy char

acter that eventually may not have significant impact
Figure 9. Contour plotting of Normal stress √ V ′ x V ′ x /U∗. Remarks: Scale has been distorted. Color level alters case by case.

on near bed sediment entrainment (except for some

sort of sediment motion inside the scour-hole).

It is obvious that the turbulent kinetic energy

has similar characteristic. In the vicinity and shear

layer, the turbulent kinetic energy appears to pos

sess higher amplitude and becomes uniform in the

same region after the development of scour. How

ever, it appears inside the scour hole. Besides, in

the dead region in front of and behind spurs, all

components of normal stresses & kinetic energy are

uniform having low turbulence. It becomes ampli

fied in the vicinity and shear layer, apparently due to

the generation of turbulent agents like vortices in this region.

3.3 Flow visualization

An attempt was made to visualize the generation of vortices from the tips of the spurs and their migration towards downstream region. Under the light of halogen lamp in the dark, the shadow of these small eddies (Fig. 8) and their migration speed are visible very well. The migration speed of these eddies was observed to be near to average velocity. This observation verifies the prior study (Chen and Ikeda, 1997). Vortices generated from the tip of spur 1 are seen to be migrating towards second bend where spur 2 located and even accumulated in dead region in front of spur 2. Likewise, some of them accumulated in recirculation region near the reattachment point before having diffused. Furthermore, these vortices are more random in case of movable bed (with scour and deposition). Such kind of vortices possesses high turbulent energy and is responsible for scouring & mixing process in downstream.

4 NUMERICAL MODEL

A preliminary attempt was made to calculate average flow (streamwise and transverse velocities) along the channel for the case with rough rigid bed using a sim

ple two dimensional numerical model. Following basic

equations were used: where x and y= co-orthogonal coordinates; t= time; u and v= depth-averaged velocity components in x and y directions respectively; h= depth; H =water surface elevation; g= gravitational acceleration; and C d = bed friction coefficient. No sub grid model was used for turbulence as no significant effect of the subgrid model for such a small scale simulation was found. Simple eddy viscosity concept was used as follows: where, k =Karman constant; u * = shear velocity; A=weight coefficient. Shear velocity was calculated using following expression: Several value of weight coefficient A was used to evaluate the effect of viscosity in high turbulent region. Not so significant effect was found within the values of 0.1 to 1. 4.1 Numerical algorithm Navier-stokes equations are transformed into nonconservation form and calculated splitting them into non-advection and pure advection phase. Nonadvection phase was calculated using CIP (Cubicinterpolated Pseudo-particle) numerical method (Shimizu, 2002; Yabe and Ishikawa, 1990), e.g.:
Non-advection phase 1: Non advection phase 2: Advection phase: Equations (5), (6) & (7) were transformed to general coordinate system and came to the following Y/B=0.1

Figure 14. Streamwise and transverse velocity profiles in

different longitudinal sections along the channel. boundary fitted continuity and momentum equations (see Shimizu & Surajate, 2003 for more detail): where ξ and η= spatial coordinates and τ = time; D ξ and D η =momentum diffusion term in ξ and η directions (Shimizu & Itakura, 1991). Furthermore, the vortices in the plane normal to vertical axis (z) are calculated using following wellknown equations: The average flow-field and the time depended vortices shedding have been successfully simulated using this model. Moreover, the results of the calculation has been depicted quantitatively for average flow property and compared with experimental data. The streamwise and transverse velocity components along the channel are compared and depicted in Figure 14. Likewise, streamwise and transverse velocity profile along shear layer is depicted in Figure 15 that shows agreeable result. Figure 16 shows velocity profiles and contour plotting of the simulation results. Similarly, vorticity field was simulated using this numerical model which has qualitatively shown realistic result. Typical examples of simulation result of vorticity field near spurs for some selected time steps are depicted in Figure 17. Quantitative comparison with experimental results should be made for the further verification of model. It can be said that this simple two dimensional numerical model has been satisfactorily able to simulate the mean flow field of such a complicated case. 35 deg

Figure 15. Streamwise and transverse velocity profiles

along shear layer. Figure 16. Average velocity field: plotting of simulation result. Figure 17. Vorticity field: plotting of simulation results for some selected time steps. It is obvious that there may still lack in this model and space to bring about an improvement which is in progress. Furthermore, 3D calculation is supposed to be performed so as to improve the results and possibility of the model that enables three dimensional flow structures as well as turbulent characteristics to be simulated properly. 5 CONCLUSION The turbulent characteristics were found to be very chaotic and high near both spurs. They were seen to have most pronounced in shear layer region rather than in

upstream part of the spurs and much chaotic in case of developed morphology, apparently due to the deposition in the wake region. The turbulent intensities, Reynolds stresses and turbulent kinetic energy are considerably higher in near spur region for the rigid bed case. After the development of scour, these characteristics become uniform and even collapsed in upper layer. Inside the scour-hole, turbulent level was seen to be slightly higher, particularly beneath the spur tip; however it seems to possess splash characteristic that does not appear to have significant impact. Besides, turbulent level seems to be higher near spur 1 region rather than near spur 2. Nevertheless, this phenomenon does not seem to be clear enough for any conclusion to

be made and is thought to depend on flow condition as

well. The turbulent kinetic energy is much stronger in

shear layer region and in the scour-hole near the maxi

mum depth, whereas it was found to be low & uniform

over the depth in dead regions in front of and behind

the spurs.

A simple two dimensional numerical model has

been developed using a novel numerical technique

referred to as CIP. The mean flow field for the case of

rigid bed as well as vorticity field was simulated using

the model satisfactorily with realistic results. In order

to simulate 3D flow field and turbulent characteristics

in the vicinity of spurs, 3D extension of this model is

required to be performed, which is in progress.

It appears to be possible to visualize shedding

of turbulent structures like vortices and their migra

tion pattern simply capturing the shadow of these

structures. Such visualization seems to be simple to

evaluate the shedding of the vortices and their migra
tion towards downstream and can be used to validate
numerical simulation as well. Moreover, behavior of
such turbulent structures is of importance, since they
are responsible for sediment entrainment as well as for
mixing process.

Such kind of studies is of significance to add to
knowledge on the assessment of the role of turbulence
in sediment entrainment and mixing process before
and after the bed evolution. Similarly, additional work
and more thorough analysis may provide a key to relate
the turbulence characteristics with structure-induced
sediment entrainment and deposition as well as their
temporal evolution. On the other hand, the simultane
ous effect of the river training structures on the flow
and turbulence and, in turn, on the channel bed and
mixing process considering channel plan form is also
subject of practical and academic interest.

This experimental data may be of use to further
elaboration of numerical model on turbulence around
spurs.

Observations concerning erosion in model of a mobile river bed

L. Ciaravino

Department of Hydraulic and Environmental Engineering “G. Ippolito”, Naples, Italy

ABSTRACT: This paper reports an analysis of the experimental results regarding localized scour on a mobile bed, caused by a stream with a three-dimensional hydrodynamic pattern. This pattern is affected by the geometry of the cross sections of stream flow and by a marked asymmetry in the supply. The experimental installation is represented by a physical model reproducing a stilling basin and a downstream section of a mobile river bed. The experimental data highlight the influence exerted by the diameter of the granular material, used to reproduce the mobile bed, on scour geometry. The particular and complex hydrodynamic phenomenon causing scour and the obtained results suggested an interesting working hypothesis for the subsequent experimental activities.

1 INTRODUCTION

There are a number of important issues regarding river dynamics, such as the determination of general solid transport and river modelling, but localized scour in mobile river beds is certainly a major concern.

Scour may be induced by particular geometries of the river bed but also and above all by man-made structures.

By interacting with the water flow, these structures

modify the stream flow pattern and may lead to crit

ical values of velocity V c and shear stress τ c being

exceeded along the bed and/or the banks, thus setting

the eroded material in motion. (Shield, 1936; Einstein,

1942; Kalinske, 1947).

Generally, the structure may give rise to limited

local turbulence, such that the mean kinematic char

acteristics of the whole cross section of river bed

concerned remain practically unaffected (in this case

the structure is normally defined as an obstruction), or

it may have a more general impact on the river section

(in which case it is referred to as a constriction).

With reference to the most common structures, an

interesting practical problem lies in the determination

of localized scour caused by a stream flow which, with

considerable kinetic energy, leaves the layer covering

the river bed with rigid material before returning to the

uncovered, and hence submitted to erosion, bed.

In general, these localized scour phenomena are

studied through simplified (mainly two-dimensional)

experimental installations and numerical models with

permanent flows (the overall river geometry likewise

is permanent) and with no solid material in suspen

in general). However, in practical cases this phenomenon
may present not negligible three-dimensional
characteristics and, therefore, the inadequacy of numerical

models often means that the phenomenon has to be studied by means of a specific physical model. The present paper analyses the results of an investigation previously carried out on a physical model, one of whose aims was to study scour downstream of a stilling basin. These results are essentially qualitative and, despite their specific nature, provide considerations that can be held to be of general interest. 2 CONSIDERATIONS REGARDING PHYSICAL MODELS OF MOBILE RIVER BEDS Studies on physical models are based on the theory of similarity between a prototype (original river work) and a model (in reduced scale). The scale S is defined as the ratio between the single model quantity (indicated by the subscript m) and the corresponding prototype quantity (indicated by the subscript p). Generally speaking, in order to define the mechanical similarity between the prototype and the model, it is necessary to define the relationship between three fundamental dimensional quantities, such as length, time and force (Montuori, 1997). Studying physical models of free surface flows encounters an intrinsic limitation in the actual choice of scale relationships between the quantities in question, caused by the fact that the prototype phenomena and the modelled phenomena are subjected to the same

acceleration of gravity g and that, in any case, water is

used as the experimental fluid.

In this case (stream flows governed by gravity),

when the effects of viscosity, elasticity, surface ten

sion and cavitation are negligible then Froude’s law

of similarity is held to be valid and hence the Froude

number:

is the same for model and prototype (where V is the

mean velocity and h is the water depth) that is:

that provides the scale:

From which, as is well known, being S L the length

scale, it can be derived:

that is velocity scale;

that is flow rate scale;

that is time scale.

The above mentioned conditions are sufficient to solve the problem of mechanical similarity when both in prototype and in model the conditions are of fully developed turbulence.

When a model is studied in which a mobile river bed has to be reproduced, it is necessary to identify further criteria (Pezzoli, 1979; Calomino et al., 1997). In particular, with regard to a study of localized scour in model, the main criterion consists of set ting the condition that the densimetric particle Froude number Fr d is constant (even in critical conditions of incipient sedimentary motion), therefore it can be written:

in which γ W and γ S are the specific weights of water and solid grains of diameter d, respectively, and where R and J are the hydraulic radius and the hydraulic gra dient, which is generally made equal to the slope i of river bed.

Therefore, the corresponding scale will be: where Fr dm and Fr dp are model and prototype densimetric particle Froude number respectively. Consequently, the reduction scale of the solid grain diameters will be: where γ Sp and γ Sm are the specific weights of solid grains in prototype and in model respectively. If solid material of the same type as that found in the prototype is used in the model, although smaller than in the prototype according to the length scale, very often a grain size is obtained so small that

grains remain in suspension during the experimental tests. The drawbacks related to the reduction scale of the solid mobile material could be overcome by adopting a distorted model. In this case, if we use S h to indicate the height scale, which is different from the planimetric length scale S L , and D=S h /S L to indicate the distortion ratio, and once again assuming the densimetric particle Froude number to be constant, it can be written: Therefore, if a scale S d is wanted to give solid grains that are lighter and greater in size, a height scale S h has to be imposed smaller than the planimetric length scale S L . However, the latter hypothesis could upset the Froude hydraulic similarity as the reduction in the S h scale generally results in a reduction in the Reynolds number, thus making it fall to values that are incompatible with fully developed turbulent flow conditions. However, the complicated definition of the parameters characterising the solid mobile material from the real river bed, which are necessary for more accurate modelling (grain-size curve, cohesion and homogeneity of mobile river bed material) may introduce a certain randomness in the results obtained with the experimental tests. For this reason, in technical modelling practice there is a tendency to work on the simplest models which comply with Froude's similarity rather than on distorted models. Froude type models yield excellent results as regards quantities related to the hydraulic characteristics of the considered flow being studied and, by using suitable methodologies, important although only qualitative results can be obtained for defining erosion phenomena. A modelling technique that is still held to be valid in determining both scour and granular material to be adopted, is the one suggested by Scimemi (1939), also studied by Veronese (1937) and later adopted by Ghetti & Zanovello (1954) as well. This technique starts from the considerations made by Schoklitsch (1935) and confirmed by Veronese,

which state that under identical conditions the local

ized scour site increases as the characteristic diameter

d of the mobile material decreases until it assumes

a value close to 5 mm, below which value the scour

remains constant. Therefore, Scimemi suggests exper

imenting on a model with decreasing grain sizes until

the scour is determined by extrapolation with respect

to the material of diameter d= 0.

Ghetti (1954), also adopts this technique and claims that, with all other conditions remaining the same and varying the grain size, the scour is geometrically sim ilar; a model can therefore be used to measure the velocity field for comparisons with the critical veloc ity of the prototype material in order to obtain, with a certain degree of approximation, the actual size of the eroded area in the prototype.

3 ANALYSIS OF THE MODEL AND THE EXPERIMENTAL RESULTS

In the light of the considerations made in the previ ous sections, the present study analyses experimental scour measurements that had previously been taken using a mechanically similar model complying with Froude's law and reproducing a stilling basin and a brief downstream section of a mobile river bed.

In actual fact the above mentioned model is part of a more complex model that was intended to clarify the hydraulic working of a structure comprising the stilling basin and the outlet devices (two spillways from which water is directed in one open channel and two bottom sluices from which water is directed in two free flow tunnels).

However it was necessary to check the working of the stilling basin in order to reduce the scour in

the downstream mobile river bed to tolerable limits

(Ciaravino & Ciaravino, 2003).

It should be noted that the hydraulic operation

of the basin was characterised by a marked three

dimensional effect which affected the geometry and

the entity of the scour in the reproduced mobile bed.

This three-dimensional effect is caused by the asym

metry with which the flows from the outlet works are

directed into the basin under the various conditions.

The model was built in reduced geometric scale

S L = 1/50 from which the scale of reduction for

the other hydraulic quantities can be derived, under

the hypotheses made and as it was pointed out in the

previous section.

The mobile river bed downstream from the still

ing basin was reproduced by using a natural granular

material of two different sizes d:

- sand graded with a 4× 4 mm mesh riddle;

- gravel graded using a 10× 10 mm mesh riddle (and

which does not pass through the riddle mentioned

in the previous point). That is to say, two sizes were chosen that essentially fall into the two fields (d< 5 mm and d> 5 mm) identified by Schoklitsch and by Veronese. The structures reproduced in the model are shown in diagram form in Figures 1 to 4. These figures also report the results of the mobile bed scour measurements in some of the different operating conditions that were analysed. In actual fact, several batteries of tests were conducted, each time modifying the stilling basin geometry in order to

determine which one resulted in a reduction of scour. It should be pointed out that, in order to allow conclusions to be drawn from the analysis of the experimental results, the various test batteries are equivalent. That is to say that it is possible to draw the same general conclusion from all the test batteries conducted with the various geometrical configurations. Therefore the figures report the results of the tests carried out on a particular basin geometry with two different flow rates. Mobile river bed 0.501.00 0 1.000.50 m 2.00 m 0.50 1.00 1.50 0 Stilling basin Supply channel Free flow tunnels Figure 1. Experimental tests in mobile river bed reproduced with gravel. 0.50

1.00

Figure 2. Experimental tests in mobile river bed reproduced

with sand. Flow rate in model: Q m = 0.017 mc/s.

In particular, tests are reported with the maximum

flow rate of the stilling basin, equal in the model to

Q m = 0.064 mc/s, and with an intermediate flow rate

of Q m = 0.017 mc/s.

Tests have been repeated both with a mobile bed

reproduced using sand and with one reproduced using

gravel.

In order to take into account the evolution over time

of the scour and hydrodynamic phenomena and so as

to obtain practically stable scour depths even when the

mobile bed was reproduced with sand, every single test

had a duration of 1.5 hours.

In the figures the scour is measured in millimetres

starting from a reference value 0.00 equal to the bed

height in the terminal section of the stilling basin.

Starting from this 0.00 reference value, the figures

also indicate the scours with positive values and solid

material deposits with negative values.

Figure 1 and Figure 2 report experimental scour

measurements produced by the model flow rate Mobile river bed Stilling basin Supply channel Free flow tunnels 1.00 0.500.50 0 m 1.00 2.00 m 1.50 0 0.50 1.00 Figure 3. Experimental tests in mobile river bed reproduced with gravel. Flow rate in model: Q m = 0.064 mc/s. Q m = 0.017 mc/s when the mobile bed is reproduced with gravel or sand, respectively. The maximum scours with this flow rate are 10 mm and 55 mm in the two cases. Figure 3 and Figure 4 report the experimental measurements of scour produced by the model flow rate Q m = 0.064 mc/s when, once again the mobile bed is reproduced with gravel or sand, respectively. The maximum scours with this flow rate are, in the two cases, 55 mm and 145 mm. As a first conclusion, we can say that the experimental measurements confirm the increase in scour depth as the granular material diameter decreases in the investigated field (Scimemi, 1937; Chia-Chun Wu et al., 2002). Moreover it can be noticed that, for both model flow rates, a considerable difference in the resulting scour geometry can be observed, with other conditions remaining the same, when the bed is reproduced with sand and when it is reproduced with gravel. Mobile river bed Stilling basin Supply channel Free flow tunnels 1.00 0.500.50 0 m 1.00 2.00 m

1.50 0

0.50

1.00

Figure 4. Experimental tests in mobile river bed reproduced

with sand. Flow rate in model: Q m = 0.064 mc/s.

In the case of the gravel bed (Fig. 1 and Fig. 3) the

scour assumes an axially symmetrical pattern with an appreciable reduction along the sides and downstream, with a somewhat uniform and considerably flattened transverse conformation and with a depositing area that may also reach the axial area downstream, for the higher flow rate.

As a matter of fact the ratio between the longitudinal dimension (parallel to the axis) and the transverse dimension (orthogonal to the axis) of the level curves measured experimentally, is less than 1 and in the area of greatest depth, for the higher flow rate, it assumes a value of about 0.12.

For these tests with gravel as the mobile bed material, the ratio between maximum scour and the flow rate (variable between 0.60 and 0.86) also assumes a value of lower than 1.
